It is clear that the slope of each line of the estimate is given by (see figure below):

$$\frac{\Delta S_t}{\Delta t} \tag{15.3.1538}$$

and for the last estimate, more specific, we will have:

$$\frac{\Delta S_t}{\Delta t}=\frac{S_t-S_{t-1}}{t-(t-1)}=\frac{S_t-S_{t-1}}{1}=S_t-S_{t-1} \tag{15.3.1539}$$

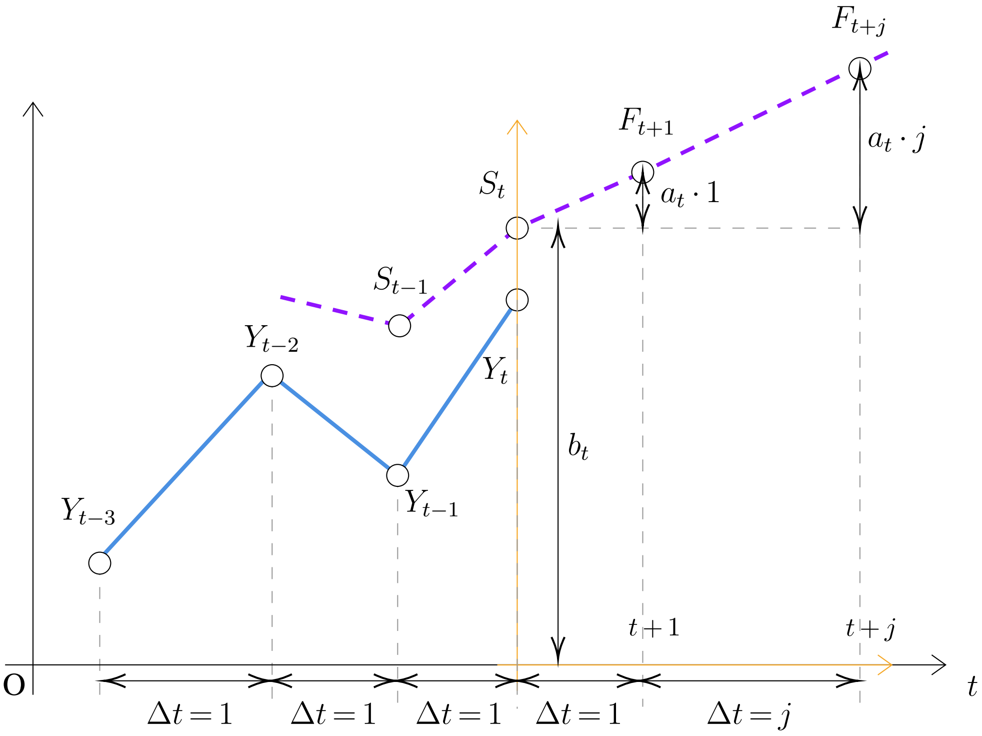

Figure 15.240: Idea diagram of the building blocs of Holt's model

and the idea is to make an exponential smoothing of the slope of all straight lines whose slope is calculated in the same manner, that is (compared to the expression of simple exponential smoothing)

$$a_t = \beta \frac{\Delta S_t}{\Delta t} + (1-\beta)a_{t-1} = \beta(S_t - S_{t-1}) + (1-\beta)a_{t-1} \qquad (15.3.1540)$$

The latter expression is just the estimated slope at time t.

Now, for the intercept, we see in the figure that $b_t = S_t$. Therefore, it comes at first as:

$$a_t = \beta \frac{\Delta S_t}{\Delta t} + (1-\beta)a_{t-1} = \beta(b_t - b_{t-1}) + (1-\beta)a_{t-1} \qquad (15.3.1541)$$

The relation:

$$a_t = \beta(b_t - b_{t-1}) + (1-\beta)a_{t-1} \qquad (15.3.1542)$$

is known as the "trend update equation", as it updates the trend estimate of the current time step based on the difference between previous level estimates. One may notice it is very akin to the original "level update equation" L_t in simple exponential smoothing.

Similarly to the level update equation, the trend update equation also takes its own parameter, β. The beta is the trend equation's own smoothing constant, and is therefore more or less analogous to the α smoothing constant seen earlier in simple exponential smoothing.

Once this fact seen, we choose a model where the intercept is an exponential smoothing of all intercepts with his own smoothing constant such as:

$$b_t = S_t = \alpha Y_t + (1-\alpha)(S_{t-1} + a_{t-1}) = \alpha Y_t + (1-\alpha)(b_{t-1} + a_{t-1}) \qquad (15.3.1543)$$

What may seem sometimes confusing here is the last parenthesis. In fact, technically, we should rather write:

$$(S_{t-1}+a_{t-1}\Delta t)=(b_{t-1}+a_{t-1}\Delta t) \tag{15.3.1544}$$

but as the Δt is always equal to 1, we omit to write it. So the last parenthesis represents the estimated at a one previous time unit to which we add the increase of one time unit of the estimated of slope as estimated at the same time t.

The expression:

$$S_t=\alpha Y_t+(1-\alpha)(b_{t-1}+a_{t-1}) \tag{15.3.1545}$$

is somewhat unfortunately named in practice the "estimated level series at period t".

In the end, we work with these three relations:

$$\boxed{\begin{aligned}F_{t+j}&=a_t j+b_t\\ a_t&=\beta(b_t-b_{t-1})+(1-\beta)a_{t-1}\\ b_t&=\alpha Y_t+(1-\alpha)(b_{t-1}+a_{t-1})\end{aligned}} \tag{15.3.1546}$$

To start the forecast with this model, we need an estimate of the settings S_0 and a_0. The first forecast values will be greatly affected by these estimates. The practitioner should also always check what his software uses for a method of determination for these settings to specify it in his reports.

✍**Example:**

Let us consider the following list and model settings area in Microsoft® Excel® 14.0.6123 that contains the observed data in column `B`, and the model in columns `C` through `E` for which we will detail the formulas just after:

	A	B	C	D	E	F	G	H	I	J	K
3	**Period**	Y_t	a_t	b_t	F_t		**Relative absolute Error**	**Absolute Error**		α:

27	24	266	6.70	256.61	248.52		0.07	17.48			
28	25				**263.30**	$j=1$					
29	26				**270.00**	$j=2$					
30	27				**276.69**	$j=3$					
31	28				**283.39**	$j=4$					
32	29				**290.08**	$j=5$					
33	30				**296.78**	$j=6$					

Figure 15.243: **Final values and projections of Holt's model with Microsoft® Excel® 14.0.6123**

Which gives graphically (and also in comparison with the single and double smoothing):

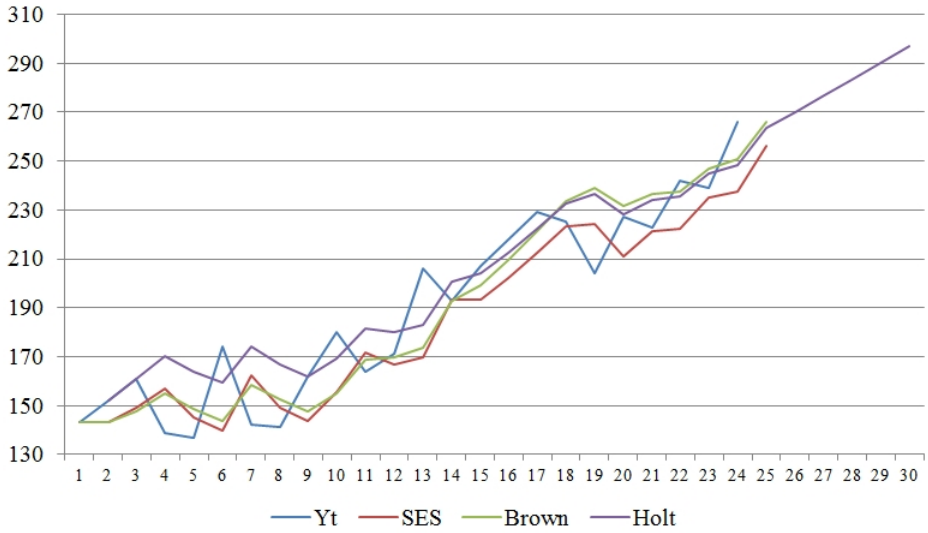

Figure 15.244: **Full Holt's model plot with Microsoft® Excel® 14.0.6123**

Holt's smoothing has a MAPE of 7.49% while the Brown model has for recall a MAPE of 7.45% (this comparison is a form of "backtesting"). However the advantage of Holt's model relatively to previous models is that we can make projections on more than one period.

It is of course interesting to compare the projections to 6 months between the additive method of Holt and Brown's smoothing:

Month	Brown's DSES	Holt's additive DSES
25	261.50	263.30
26	268.19	270.00
27	264.55	276.69
28	280.53	283.39
29	238.20	290.08
30	311.19	296.78

Table 15.60: **Comparison between Holt's and Brown's DSES**

So we see that Holt's model almost always have forecasting values greater than the Brown model.

It is the job of the practitioner to judge these values and compare them to past observations and also to future one...

15.3.13.3.3.4 Holt's and Winter Triple Exponential Smoothing with 3 Parameters (Multiplicative Method)

We will discuss now another technique which construction is also as empirical as the previous model and also strongly inspired from that latter and who is named "Holt's and Winter Triple Exponential Smoothing with 3 Parameters (Multiplicative Method)". I never found a rigorous proof of this model. It is therefore probably more mathematical engineering that pure mathematics strictly speaking, but as it is a classic in statistical softwares, we will focus on it a little bit.

Peter Winters (Charles C. Holt's student) has based it's work in the years 11960 (holocene calendar) on the method of his teacher to define a model that takes into account the seasonal component. The idea is to use three smoothing equations: one for the level of demand (without seasonality), one for the trend and one for seasonality.

Remark

There are two methods Winter's method according to that seasonality is additive or multiplicative. We present here only the multiplicative model because it is the one most commonly used. And we can not present all the existing models as they are all empirical and there are probably hundreds of them!

Let N be the number of periods in each seasonal cycle (cycle assumed to be constant!). Three exponential smoothing equations are used in each period to update the estimates of series (the part without seasonality), seasonal factors and trend. These equations have different smoothing constants traditionally denoted α, β and γ:

1. The first equation is defined quite naturally by:

   $$b_t = \alpha \frac{Y_t}{C_{t-N}} + (1-\alpha)(b_{t-1} + a_{t-1}) \qquad (15.3.1547)$$

   where Y_t is then the current level of the series without the seasonality effect (then we speak sometimes of "adjusted series") thanks to the appropriate seasonal factor C_{t-N} (otherwise we fall back on the Holt's method when $C_{t-N} = 1$).

2. The second equation is naturally defined by:

   $$a_t = \beta(b_t - b_{t-1}) + (1-\beta)a_{t-1} \qquad (15.3.1548)$$

   where we see again the slope of the trend identical to Holt's model.

3. The third equation is completely new, this does not prevent that it is quite intuitive and is given by:

   $$C_t = \gamma \frac{Y_t}{b_t} + (1-\gamma)C_{t-N} \qquad (15.3.1549)$$

   and finally the forecast is seasonlized again (it is the form of the forecast that makes that we speak of "multiplicative model"):

   $$F_{t+j} = (a_t j + b_t)C_{t+j-N} \qquad (15.3.1550)$$

> This equation assumes that $j < N$. If $N < j < 2N$, the appropriate seasonal factor. If equation, the equation would be C_{t+j-2N}. If $2N < j < 3N$, the appropriate seasonal would be C_{t+j-3N} and so on.

So in the end, we have the system:

$$\boxed{\begin{aligned} F_{t+j} &= (a_t j + b_t)C_{t+j-N} \\ a_t &= \beta(b_t - b_{t-1}) + (1-\beta)a_{t-1} \\ b_t &= \alpha\frac{Y_t}{C_{t-N}} + (1-\alpha)(b_{t-1} + a_{t-1}) \\ C_t &= \gamma\frac{Y_t}{b_t} + (1-\gamma)C_{t-N} \end{aligned}} \tag{15.3.1551}$$

Also sometimes denoted:

$$\begin{aligned} \hat{Y}_{t+j} &= (jT_t + L_t)S_{t+j-N} \\ T_t &= \beta(L_t - L_{t-1}) + (1-\beta)T_{t-1} \\ L_t &= \alpha\frac{Y_t}{S_{t-N}} + (1-\alpha)(L_{t-1} + T_{t-1}) \\ S_t &= \gamma\frac{Y_t}{L_t} + (1-\gamma)S_{t-N} \end{aligned} \tag{15.3.1552}$$

where the first relation is often denoted in practice as following too:

$$F_{t+k} = [L_t + kT_t]\, S_{t+k-M} \tag{15.3.1553}$$

We can find also the following variation of the previous model in some books:

$$\begin{aligned} \hat{Y}_{t+j} &= (jT_t + L_t)S_{t+j-N} \\ T_t &= \beta(L_t - L_{t-1}) + (1-\beta)T_{t-1} \\ L_t &= \alpha\frac{Y_t}{S_{t-N}} + (1-\alpha)(L_{t-1} + T_{t-1}) \\ S_t &= \gamma\frac{Y_t}{T_t + L_t} + (1-\gamma)S_{t-N} \end{aligned} \tag{15.3.1554}$$

Inspired by the additive Holt's model, the Holt & Winter additive model is given by:

$$\boxed{\begin{aligned} \hat{Y}_{t+j} &= jT_t + L_t + S_{t+j-N} \\ T_t &= \beta(L_t - L_{t-1}) + (1-\beta)T_{t-1} \\ L_t &= \alpha(Y_t - S_{t-1}) + (1-\alpha)(L_{t-1} + T_{t-1}) \\ S_t &= \gamma(Y_t - L_t) + (1-\gamma)S_{t-N} \end{aligned}} \tag{15.3.1555}$$

where the first relation is often denoted in practice as following too:

$$F_{t+k} = L_t + kT_t + S_{t+k-M} \tag{15.3.1556}$$

The difference between the multiplicative and additives methods is in the nature of the seasonal component. The additive method is preferred when the variation of seasonal component is almost constant through the series. Seasonal component is expressed in absolute terms and sum up to zero. While multiplicative is used when seasonal variations changes proportionally to the level of the series.

Additive

$$\boxed{F_{t+k} = L_t + kT_t + S_{t+k-M}}$$

Multiplicative

$$\boxed{F_{t+k} = (L_t + kT_t)S_{t+k-M}}$$

It is important to notice that each of the time series components do not need to exhibit the same behaviour. For instance, the multiplicative seasonality formula does — obviously — have multiplicative seasonality, however the trend portion is additive:

Multiplicative Seasonality

$$\boxed{F_{t+k} = \underbrace{(L_t + kT_t)}_{\text{the trend is additive}}S_{t+k-M}}$$

This independence allows the mixing and matching of different behaviours to model many different types of time series:

A: additive T: Trend M: Multiplicative S: Seasonality

ATAS

$$\boxed{F_{t+k} = (L_t + kT_t) + S_{t+k-M}}$$

ATMS

$$\boxed{F_{t+k} = (L_t + kT_t)S_{t+k-M}}$$

ATAS

$$\boxed{F_{t+k} = L_t T_t^k + S_{t+k-M}}$$

MTMS

$$\boxed{F_{t+k} = L_t T_t^k S_{t+k-M}}$$

It's also interesting to compare side by side the update equations for each type of seasonality as we can see below:

Multiplicative

$$\boxed{L_t = \alpha \frac{y_t}{S_{t-M}} + (1-\alpha)(L_{t-1} + T_{t-1})}$$

Additive

$$\boxed{L_t = \alpha(y_t - S_{t-M}) + (1-\alpha)(L_{t-1} + T_{t-1})}$$

We can see the specific deseasonalization effect here:

Multiplicative

$$L_t = \alpha\frac{y_t}{S_{t-M}} + (1-\alpha)(L_{t-1}+T_{t-1})$$

Additive

$$L_t = \alpha(y_t - S_{t-M}) + (1-\alpha)(L_{t-1}+T_{t-1})$$

We see above that in order to remove the seasonal component, we must know what type of time series seasonality we are attempting to model, and do the inverse. This translates into either dividing or subtracting the seasonal component for multiplicative and additive time series seasonality, respectively.

To start the forecast with the multiplicative model, we also need to estimated the initial parameters. Again, first forecasted values will be greatly affected by these estimates. The practitioner should as always check that what method its software for the determination of the parameters to specify it in his reports.

✍**Example:**

Let us consider the following list in Microsoft® Excel® 14.0.6123 that contains the observed data in column `D` and the model in the columns `E` to `H` which we will detail the formulas just after (here we have the N of our above system that is then equal to zero). Notice that we have 6 years with each 4 quarters (so there will be verbatim 4 seasonal factors that are the first 4 rows of column `G`):

	A	B	C	D	E	F	G	H	I	J	K	L	M	N

29			26					**270.85**			
30			27					**292.96**			
31			28					**258.17**			
32			29					**265.60**			
33			30					**265.60**			

Figure 15.249: Holt & Winter's final values, forecasts and errors with Microsoft® Excel® 14.0.6123

Graphically this gives if we compare all four models:

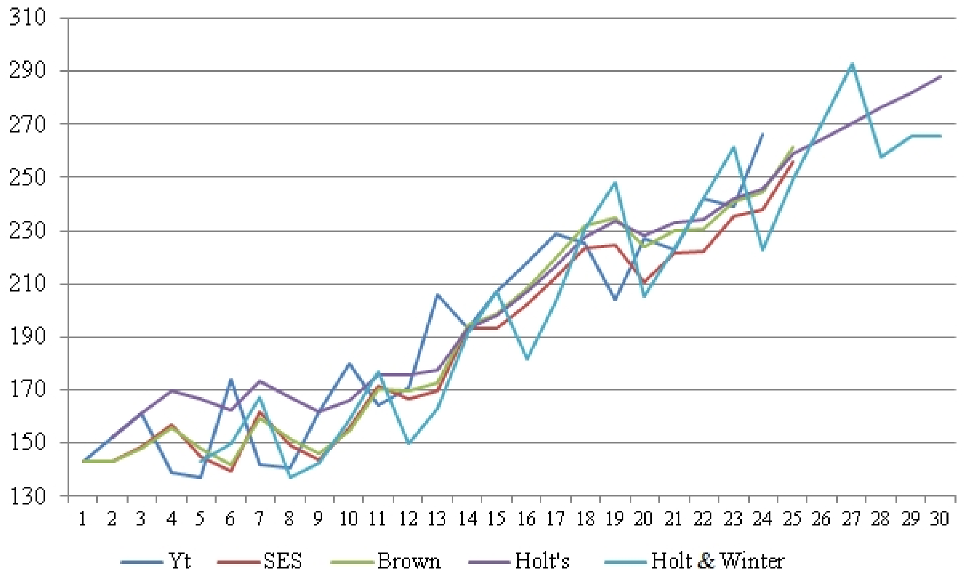

Figure 15.250: **Holt & Winter's full plot and comparison with other models in Microsoft® Excel® 14.0.6123**

Holt's smoothing therefore had a MAPE of 7.49% and the Brown's one a MAPE of 7.45%. The Holt & Winter's seasonal smoothing has a MAPE of 9.61%, that is to say the fitting is worst than the other models. However the advantage of Holt & Winter's model is than we can make projections over more than one period AND with cycles as we can see on the chart above.

It is of course interesting to compare the 6 months forecast values between the Brown's, Holt's additive and Holt & Winter's model:

Month	Brown's DSES	Holt's DSES additive	Holt & Winter's multiplicative
25	261.50	263.30	249.42
26	268.19	270.00	270.85
27	264.55	276.69	292.96
28	280.53	283.39	258.17
29	238.20	290.08	265.60
30	311.19	296.78	265.60

Table 15.61: **Comparison between Holt's and Brown's DSES + Holt & Winter's multiplicative TSES**

So we see again that depending on the chosen technique, the differences are relatively important.

The reader should not forget that there is also an additive Holt & Winter's model. Furthermore we have seen once that there is also a "Holt & Winter's multiple model" that is not the same as the "Holt & Winter's multiplicative model"!

Caution! "Traditional" exponential smoothing models like simple exponential smoothing, Holt-Winter double exponential smoothing, Brown's double exponential smoothing Peter Winters' triple exponential smoothing are heuristic models and do not have an underlying statistical theory! Hence they don't have a maximum likelihood estimator. However, seminal work published in the *Journal of the American Statistical Association* by Ord, Koehler & Snyder in 11997 (holocene calendar) provided a statistical basis for exponential smoothing using a state space framework and provided a maximum likelihood estimation procedure under Gaussian assumption. The *Forecasting with Exponential Smoothing* ([269]) extends the original work into all the forms of exponential smoothing.

15.3.13.3.3.5 ETS (Error, Trend, Seasonality) Models

We have previously see a series of methods for time series prediction named "exponential smoothing". But this is only a basic overview of the most common academics undergraduate models.

If we include statistical errors (noise) the models that we have seen before, that include already a "trend" term and "seasonality" term, have a complementary term named the "error".

Such models, named "ETS models" (that are simply a generalized framework of exponential smoothing models), are summarized into the following notation:

$$\text{ETS}(\cdot,\cdot,\cdot) \tag{15.3.1557}$$

where each dot can respectively be denoted:

- N: For "None" (that means there can be no trend, or no error, or no seasonality)
- A: For "Additive" (that means there can be additive trend, or additive error, or additive seasonality)
- M: For "Multiplicative" (that means there can be multiplicative trend, or multiplicative error, or multiplicative seasonality)
- A_d: For "Additive damped" (that means there can be additive damped trend)
- M_d: For "Multiplicative damped" (that means there can be multiplicative damped trend)

As ETS models have three parameters, which is written:

$$\boxed{\text{ETS}\left(\{A,M\},\{N,A,M,A_d,M_d\},\{N,A,M\}\right)} \tag{15.3.1558}$$

hence a total of $2\cdot 5\cdot 3=30$ models!!!

✍**Examples:**

E1. The notation ETS(A,A,A) means that we have an exponential smoothing model with additive error terms, additive trend, additive seasonality (used in Microsoft® Excel® since 2013 and Microsoft Power BI since 2017).

$$\begin{aligned}y_t &= \ell_{t-1}+b_{t-1}+s_{t-m}+\varepsilon_t\\ \ell_t &= \ell_{t-1}+b_{t-1}+\alpha\varepsilon_t\\ b_t &= b_{t-1}+\beta\varepsilon_t\\ s_t &= s_{t-m}+\gamma\varepsilon_t\end{aligned}\tag{15.3.1559}$$

We can see very clearly above what do Microsoft® Excel® or Microsoft Power BI when they ask the user an input for the value of *Seasonality* (corresponding to m in the relation above)! If your time-step t is the month for example, it means how far back in the past (m months) the algorithm must go to add (because the model is additive) a given constant. At least this is how it work in the year 12023 (holocene calendar).

E2. The notation ETS(A,A,N) means that we have an exponential smoothing model with additive error terms, additive trend, but no seasonality (used in Microsoft® Excel® since 2013 and Microsoft Power BI since 2017).

$$\begin{aligned}y_t &= \ell_{t-1}+\varepsilon_t\\ \ell_t &= \ell_{t-1}+\alpha\varepsilon_t\end{aligned}\tag{15.3.1560}$$

E3. And relatively to previous seen models, we have for example that:

- simple exponential smoothing (or SES) method is $\{N,N\}$, i.e. non-additive neither non-multiplicative trend or seasonality
- Holt's linear method is $\{A,N\}$ additive trend without seasonality
- Holt-Winters' additive method is $\{A,A\}$, i.e. additive trend and additive seasonality
- Holt-Winters' multiplicative method is $\{A,M\}$, i.e. additive trend and multiplicative seasonality

All 30 models (some authors merge together the "additive damped" and "multiplicative damped" and speak therefore of 24 models instead of 30) are summarized in this both amazing double entry tables in an non-recursive formulation:

ADDITIVE ERROR MODELS

Figure 15.251: **Classification of ETS$(\cdot,\cdot,\cdot)$ models (source: [270])**

The general formulation of all thirty models above involves a state vector $\vec{x}_t = (\ell_t, b_t, s_t, s_{t-1}, \ldots, s_{t-m+1})'$ and state space equations of the form:

$$\begin{aligned} y_t &= w\left(\vec{x}_{t-1}\right) + r\left(\vec{x}_{t-1}\right)\varepsilon_t \\ \vec{x}_t &= f\left(\vec{x}_{t-1}\right) + g\left(\vec{x}_{t-1}\right)\varepsilon_t \end{aligned} \quad (15.3.1561)$$

✍**Example:**

To give a specific example, consider the ETS(M,A_d,M) model:

$$\begin{aligned}
y_t &= (\ell_{t-1}+\phi b_{t-1})\, s_{t-m}\,(1+\varepsilon_t)\\
\ell_t &= (\ell_{t-1}+\phi b_{t-1})\,(1+\alpha\varepsilon_t)\\
b_t &= \phi b_{t-1}+\beta\,(\ell_{t-1}+\phi b_{t-1})\,\varepsilon_t\\
s_t &= s_{t-m}\,(1+\gamma\varepsilon_t)
\end{aligned}$$

with $m=4$. Then:

$$\vec{x}_t=\begin{pmatrix}\ell_t\\ b_t\\ s_t\\ s_{t-1}\\ s_{t-2}\\ s_{t-3}\end{pmatrix},\ \vec{x}_{t-1}=\begin{pmatrix}\ell_{t-1}\\ b_{t-1}\\ s_{t-1}\\ s_{t-2}\\ s_{t-3}\\ s_{t-4}\end{pmatrix}$$

Therefore we put:

$$\begin{aligned}
w\,(\vec{x}_{t-1}) &= (\ell_{t-1}+\phi b_{t-1})\, s_{t-4}\\
r\,(\vec{x}_{t-1}) &= (\ell_{t-1}+\phi b_{t-1})\, s_{t-4}
\end{aligned}$$

Hence:

$$\begin{aligned}
y_t &= w\,(\vec{x}_{t-1})+r\,(\vec{x}_{t-1})\,\varepsilon_t=(\ell_{t-1}+\phi b_{t-1})\, s_{t-4}+(\ell_{t-1}+\phi b_{t-1})\, s_{t-4}\varepsilon_t\\
&= (\ell_{t-1}+\phi b_{t-1})\, s_{t-m}\,(1+\varepsilon_t)
\end{aligned}$$

and:

$$\begin{aligned}
\vec{x}_t=\begin{pmatrix}\ell_t\\ b_t\\ s_t\\ s_{t-1}\\ s_{t-2}\\ s_{t-3}\end{pmatrix} &= f\,(\vec{x}_{t-1})+g\,(\vec{x}_{t-1})\,\varepsilon_t=\begin{pmatrix}\ell_{t-1}+\phi b_{t-1}\\ \phi b_{t-1}\\ s_{t-4}\\ s_{t-1}\\ s_{t-2}\\ s_{t-3}\end{pmatrix}+\begin{pmatrix}\alpha\,(\ell_{t-1}+\phi b_{t-1})\\ \beta\,(\ell_{t-1}+\phi b_{t-1})\\ \gamma s_{t-4}\\ 0\\ 0\\ 0\end{pmatrix}\varepsilon_t\\
&= \begin{pmatrix}\ell_{t-1}+\phi b_{t-1}+\alpha\,(\ell_{t-1}+\phi b_{t-1})\,\varepsilon_t\\ \phi b_{t-1}+\beta\,(\ell_{t-1}+\phi b_{t-1})\,\varepsilon_t\\ s_{t-4}+\gamma s_{t-4}\varepsilon_t\\ s_{t-1}\\ s_{t-2}\\ s_{t-3}\end{pmatrix}=\begin{pmatrix}(\ell_{t-1}+\phi b_{t-1})\,(1+\alpha\varepsilon_t)\\ \phi b_{t-1}+\beta\,(\ell_{t-1}+\phi b_{t-1})\,\varepsilon_t\\ s_{t-4}(1+\gamma\varepsilon_t)\\ s_{t-1}\\ s_{t-2}\\ s_{t-3}\end{pmatrix}
\end{aligned}$$

According to the specialists in the field, it seems that from the thirty models above, only the fifteen visible in the table below are numerically stable:

Class 1			
ANN	$Y_t = \ell_{t-1} + \varepsilon_t$ $\ell_t = \ell_{t-1} + \alpha\varepsilon_t$	ANA	$Y_t = \ell_{t-1} + s_{t-m} + \varepsilon_t$ $\ell_t = \ell_{t-1} + \alpha\varepsilon_t$ $s_t = s_{t-m} + \gamma\varepsilon_t.$
AAN	$Y_t = \ell_{t-1} + b_{t-1} + \varepsilon_t$ $\ell_t = \ell_{t-1} + b_{t-1} + \alpha\varepsilon_t$ $b_t = b_{t-1} + \alpha\beta\varepsilon_t$	AAA	$Y_t = \ell_{t-1} + b_{t-1} + s_{t-m} + \varepsilon_t$ $\ell_t = \ell_{t-1} + b_{t-1} + \alpha\varepsilon_t$ $b_t = b_{t-1} + \alpha\beta\varepsilon_t$ $s_t = s_{t-m} + \gamma\varepsilon_t.$

Class 3			
MNM	$Y_t = \ell_{t-1}s_{t-m}(1 + \varepsilon_t)$ $\ell_t = \ell_{t-1}(1 + \alpha\varepsilon_t)$ $s_t = s_{t-m}(1 + \gamma\varepsilon_t)$		
MAM	$Y_t = (\ell_{t-1} + b_{t-1})s_{t-m}(1 + \varepsilon_t)$ $\ell_t = (\ell_{t-1} + b_{t-1})(1 + \alpha\varepsilon_t)$ $b_t = b_{t-1} + \alpha\beta(\ell_{t-1} + b_{t-1})\varepsilon_t$ $s_t = s_{t-m}(1 + \gamma\varepsilon_t).$		
MDM	$Y_t = (\ell_{t-1} + b_{t-1})s_{t-m}(1 + \varepsilon_t)$ $\ell_t = (\ell_{t-1} + b_{t-1})(1 + \alpha\varepsilon_t)$ $b_t = \phi b_{t-1} + \alpha\beta(\ell_{t-1} + b_{t-1})\varepsilon_t$ $s_t = s_{t-m}(1 + \gamma\varepsilon_t).$		

Figure 15.252: **Another simplified typical classification of ETS models**

Obviously not all of the 15 numerically stable models are appropriate for all data. The multiplicative error models are not well defined if there are zeros in the data. Similarly, we don't consider the additive error models with multiplicative trend or multiplicative seasonality if any observations are zero. Further, if the data are not quarterly or monthly (and do not have some other obvious seasonal period), then we do not consider any of the seasonal methods.

A very nice paper that compare all these models and that we strongly recommend the reader to take a look at is *A state framework for automatic forecasting using exponential smoothing* ([272]).

The content of the thirty models presented in the above tables can be expressed in a different way using the recursive formulation (we have already seen in details how to go from a non-recursive to a recursive formulation in the four previous models: Simple Exponential Smoothing, Double Exponential Smoothing with one parameter, Holt's Double Exponential Smoothing with two parameters, Holt's and Winter Triple Exponential Smoothing with three parameters):

Trend	Seasonal		
	N	A	M
N	$\ell_t = \alpha y_t + (1-\alpha)\ell_{t-1}$ $\hat{y}_{t+h\|t} = \ell_t$	$\ell_t = \alpha(y_t - s_{t-m}) + (1-\alpha)\ell_{t-1}$ $s_t = \gamma(y_t - \ell_{t-1}) + (1-\gamma)s_{t-m}$ $\hat{y}_{t+h\|t} = \ell_t + s_{t-m+h_m^+}$	$\ell_t = \alpha(y_t / s_{t-m}) + (1-\alpha)\ell_{t-1}$ $s_t = \gamma(y_t / \ell_{t-1}) + (1-\gamma)s_{t-m}$ $\hat{y}_{t+h\|t} = \ell_t s_{t-m+h_m^+}$

$\mathrm{M_d}$	$\ell_t = \alpha y_t + (1-\alpha)\ell_{t-1}b_{t-1}^{\phi}$ $b_t = \beta^*(\ell_t / \ell_{t-1}) + (1-\beta^*)b_{t-1}^{\phi}$ $\hat{y}_{t+h\|t} = \ell_t b_t^{\phi_h}$	$\ell_t = \alpha(y_t - s_{t-m}) + (1-\alpha)\ell_{t-1}b_{t-1}^{\phi}$ $b_t = \beta^*(\ell_t / \ell_{t-1}) + (1-\beta^*)b_{t-1}^{\phi}$ $s_t = \gamma(y_t - \ell_{t-1}b_{t-1}^{\phi}) + (1-\gamma)s_{t-m}$ $\hat{y}_{t+h\|t} = \ell_t b_t^{\phi_h} + s_{t-m+h_m^+}$	$\ell_t = \alpha(y_t / s_{t-m}) + (1-\alpha)\ell_{t-1}b_{t-1}^{\phi}$ $b_t = \beta^*(\ell_t / \ell_{t-1}) + (1-\beta^*)b_{t-1}^{\phi}$ $s_t = \gamma(y_t / (\ell_{t-1}b_{t-1}^{\phi})) + (1-\gamma)s_{t-m}$ $\hat{y}_{t+h\|t} = \ell_t b_t^{\phi_h} s_{t-m+h_m^+}$

In each case, ℓ_t denotes the series level at time t, b_t denotes the slope at time t, s_t denotes the seasonal component of the series at time t, and m denotes the number of seasons in a year; α, β^*, γ and ϕ are constants, $\phi_h = \phi + \phi^2 + \cdots + \phi^h$ and $h_m^+ = \lfloor (h-1) \bmod m \rfloor + 1$.

Figure 15.253: **Classification of ETS models with recursive formulation (source: [269])**

Remark

"Intermittent demand" (ID) (also known as "sporadic demand") comes about when a product experiences several periods of zero demand. Often in these situations when the demand that occurs is small and sometimes highly variable in size models like those seen previously and also recurrent neural networks perform very poorly! Actually a common used model for such situations is named the "Croston's method" that we will not introduce in details in this textbook as it is too empirical in the point of view of the redactor of this section.

It's possible to derive (but actually out of the scope of this textbook), the forecast mean and standard deviation of the 15 models given in the table above (for the details and proofs see [273]).

The summary of the corresponding forecast mean and variance are given by the tables below but it is important to notice that estimates for σ^2 are not done in the same manner for all three classes in the previous table. The estimate for σ^2 would be:

$$\hat{\sigma}^2=\sum_{t=1}^{n}\hat{\varepsilon}_t^2/n \tag{15.3.1562}$$

where:

$$\hat{\varepsilon}_t=\begin{cases} Y_t-\hat{Y}_t & \text{for Class 1}\\ \left(Y_t-\hat{Y}_t\right)/\hat{Y}_t & \text{for Classes 2 and 3}\end{cases} \tag{15.3.1563}$$

So now that this is given here are the h-period-ahead forecast means and variances:

	Mean	**Variance**
Class 1	μ_h	$v_1=\sigma^2$ and $v_h=\sigma^2\left(1+\sum_{j=1}^{h-1}c_j^2\right)$
Class 2	μ_h	$v_h=(1+\sigma^2)\,\theta_h-\mu_h^2$ where $\theta_1=\mu_1^2$ and $\theta_h=\mu_h^2+\sigma^2\sum_{j=1}^{h-1}c_j^2\theta_{h-j}$
Class 3	μ_h	$v_h=s_{n-m+h}^2\left[\theta_h\,(1+\sigma^2)\,(1+\gamma^2\sigma^2)^k-\tilde{\mu}_h^2\right]$ where $\theta_1=\tilde{\mu}_1^2,\theta_h=\tilde{\mu}_h^2+\sigma^2\sum_{j=1}^{h-1}c_j^2\theta_{h-j}$ and $k=\lfloor(h-1)/m\rfloor$.

with:

	μ_h	$\tilde{\mu}_h$	c_j
Class 1/Class 2			
ANN/MNN	ℓ_n		α
AAN/MAN	ℓ_n+hb_n		$\alpha(1+j\beta)$
ADN/MDN	$\ell_n+\phi_{h-1}b_n$		$\alpha\,(1+\phi_{j-1}\beta)$
ANA/MNA	$\ell_n+s_{n-m+1+(h-1)^*}$		$\alpha+\gamma d_{j,m}$
AAA/MAA	$\ell_n+hb_n+s_{n-m+1+(h-1)^*}$		$\alpha(1+j\beta)+\gamma d_{j,m}$
ADA/MDA	$\ell_n+\phi_{h-1}b_n+s_{n-m+1+(h-1)^*}$		$\alpha\,(1+\phi_{j-1}\beta)+\gamma d_{j,m}$
Class 3			
MNM	$\ell_n s_{n-m+1+(h-1)^*}$	ℓ_n	α
MAM	$(\ell_n+hb_n)\,s_{n-m+1+(h-1)^*}$	ℓ_n+hb_n	$\alpha(1+j\beta)$
MDM	$(\ell_n+\phi_{h-1}b_n)\,s_{n-m+1+(h-1)^*}$	$\ell_n+\phi_{h-1}b_n$	$\alpha\,(1+\phi_{j-1}\beta)$

For more details on exponential smoothing models and their forecasting with strongly recommend to the reader the 360 pages textbook *Forecasting with Exponential Smoothing* ([269]).

15.3.13.3.4 Logistic Model

It always happens in corporations that in the analysis of a product or service over a given period of time that the quantities of sales of the latter increase, then go through an inflection point (second derivative equal to zero as seen at page 1454) and then go towards an asymptote to decrease again later with a more or less similar characteristic.

The logistic model adapted to simulate such behaviour as part of the field of time series analysis (and that must not be confused with the logistic regression as seen in the section of Numerical Methods at page 6449) is defined as:

$$\boxed{Y_t=\frac{\hat{Y}_{\max}}{1+br^t}} \tag{15.3.1564}$$

The logistic model is inspired from many models that we find in physics and $\hat{Y}_{\max}$ is the estimated saturation threshold (horizontal asymptote) which can be approximated (with a tolerance interval) by an audit of the market.

Remark

We often speak about 3M (Mathematics Method for Management) or even sometimes "scientific management" to describe the set of mathematical tools applied to management (there exists also a training curriculum on the subject of fifty days...). Some people also use the abbreviation "SciProM" for "Scientific Project Management). A common English term that became fashionable in Europe to describe this area of application is also the "Decisioneering" referring to the fact that these are tools decision support for engineers.

It must be known that in such a market dynamics this model is obviously much better than that used by the Exponential smoothing[40] option included in the Microsoft® Excel® 14.0.6123 Analysis Toolpack (obviously as we have seen it mathematically previously, they absolutely do not work on the same principles). A simple comparative observation of the results is enough to realize it.

The parameters b and r are two parameters of the model such as:

$$b>0 \qquad 0<r\leq 1 \tag{15.3.1565}$$

and the inflection point is always giving the cumulated 50% of saturation value $\hat{Y}_{\max}$. The result is then a S-curve of the following type (we will see where it comes from further below):

---

[40] i.e. simple exponential smoothing

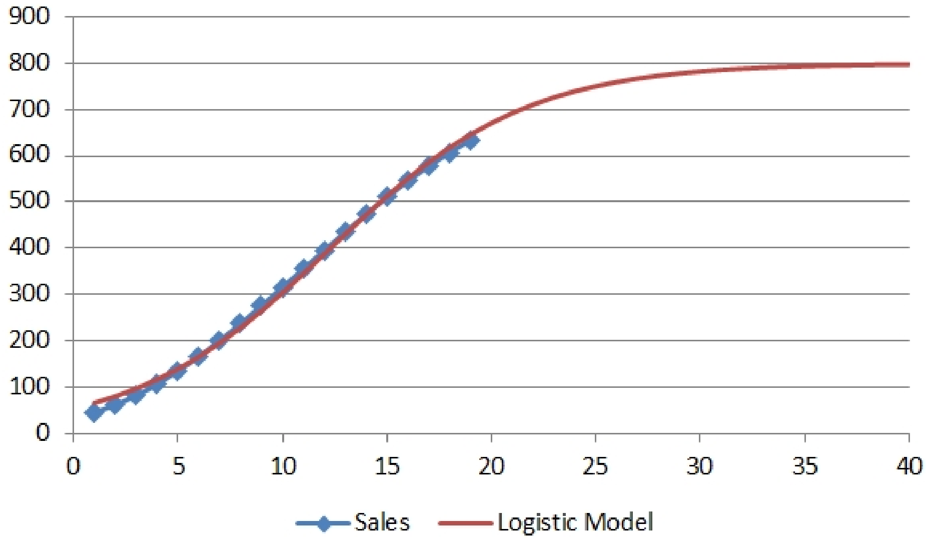

Figure 15.254: **Logistic S-curve characteristics with Microsoft® Excel® 14.0.6123**

where in blue has been represented the actual data of a product and in red the associated estimated theoretical model with its forecast and asymptotic value.

To determine the equation of the logistic model, we can directly use the solver of some softwares. But they may need to have the initial data close to the theoretical value. We will first show how these starting values can be determined with an example.

Let us consider the following first 24 rows in Microsoft® Excel® 11.8346 (the sales are in units of hundreds of thousands):

	A	B
1	Weeks	Sales
2	1	44.7
3	2	61
4	3	81.3
5	4	105.8
6	5	134
7	6	165.6
8	7	200.1
9	8	236.9
10	9	275.4
11	10	315
12	11	355.2
13	12	395.2
14	13	434.8
15	14	473.3
16	15	510.1
17	16	544.9
18	17	577.3
19	18	607
20	19	633.9
21	20	
22	21	
23	22	
24	23	

Figure 15.255: Logisttic initial values in Microsoft® Excel® 14.0.6123

and the associated graph:

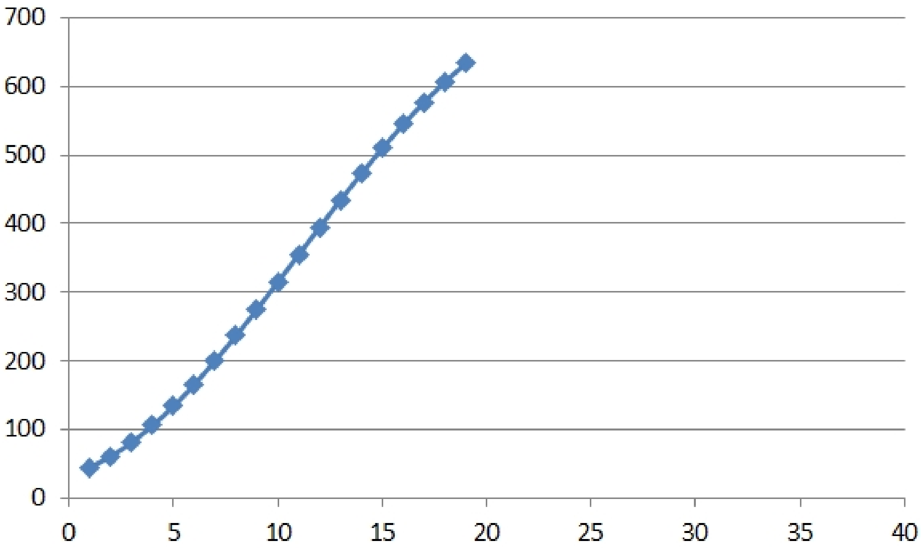

Figure 15.256: Logistic initial values plot with Microsoft® Excel® 14.0.6123

which could be considered as linear (locally) following the time at which begins the descriptive analysis of the sales.

To determine the theoretical model, we will linearise the logistic equation using a hypothetical threshold (market sales targets) of $\hat{Y}_{\max}=800$.

So:

$$Y_t=\frac{\hat{Y}_{\max}}{1+br^t}\Rightarrow 1+br^t=\frac{\hat{Y}_{\max}}{Y_t}\Rightarrow br^t=\frac{\hat{Y}_{\max}}{Y_t}-1\Rightarrow \ln\left(\frac{\hat{Y}_{\max}}{Y_t}-1\right)=\ln(b)+t\ln(r) \tag{15.3.1566}$$

That is to say we have the new following variable to explain:

$$Y_t'=\ln\left(\frac{\hat{Y}_{\max}}{Y_t}-1\right)=\ln\left(\frac{800}{Y_t}-1\right) \tag{15.3.1567}$$

And for which we will write the corresponding linear model:

$$Y_t'=a_1t+a_0+\varepsilon_t \tag{15.3.1568}$$

with therefore:

$$a_1=\ln(r)\Rightarrow r=e^{a_1} \tag{15.3.1569}$$

$$a_0=\ln(b)\Rightarrow b=e^{a_0} \tag{15.3.1570}$$

Finally injecting in the initial expression we get:

$$Y_t=\frac{\hat{Y}_{\max}}{1+br^t}=\frac{\hat{Y}_{\max}}{1+e^{a_0}e^{a_1t}}=\frac{\hat{Y}_{\max}}{1+e^{a_1t+a_0}} \tag{15.3.1571}$$

So we see here that we fall back typically on an expression similar to that of the Logistic regression as seen in the section of Numerical Methods at page 6449.

In our example the linear regression (see section Numerical Methods page 6348) gives:

$$Y'_t=a_1t+a_0+\varepsilon_t=-0.224t+2.7908 \tag{15.3.1572}$$

That is:

$$r=e^{a_1}=e^{-0.224}\cong 0.7988 \qquad b=e^{a_0}=e^{2.7908}\cong 16.293 \tag{15.3.1573}$$

Then we have immediately:

$$Y_t\cong\frac{800}{1+16.294\cdot 0.7988^t} \tag{15.3.1574}$$

That gives graphically:

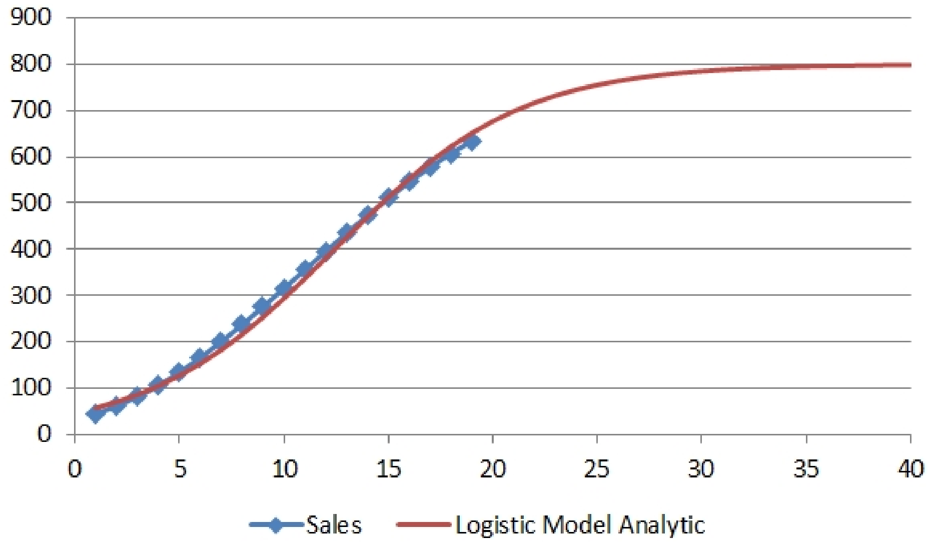

Figure 15.257: **Logistic initial values and analytical forecast plot with Microsoft® Excel® 14.0.6123**

with this analytical approach, we have a sum of squared error (SSE) between the real values and the model equal to:

$$\text{SSE} \cong 3528 \tag{15.3.1575}$$

Now let us enter that data into Microsoft® Excel® 14.0.6123 as follows:

	A	B	C	D	E	F	G	H

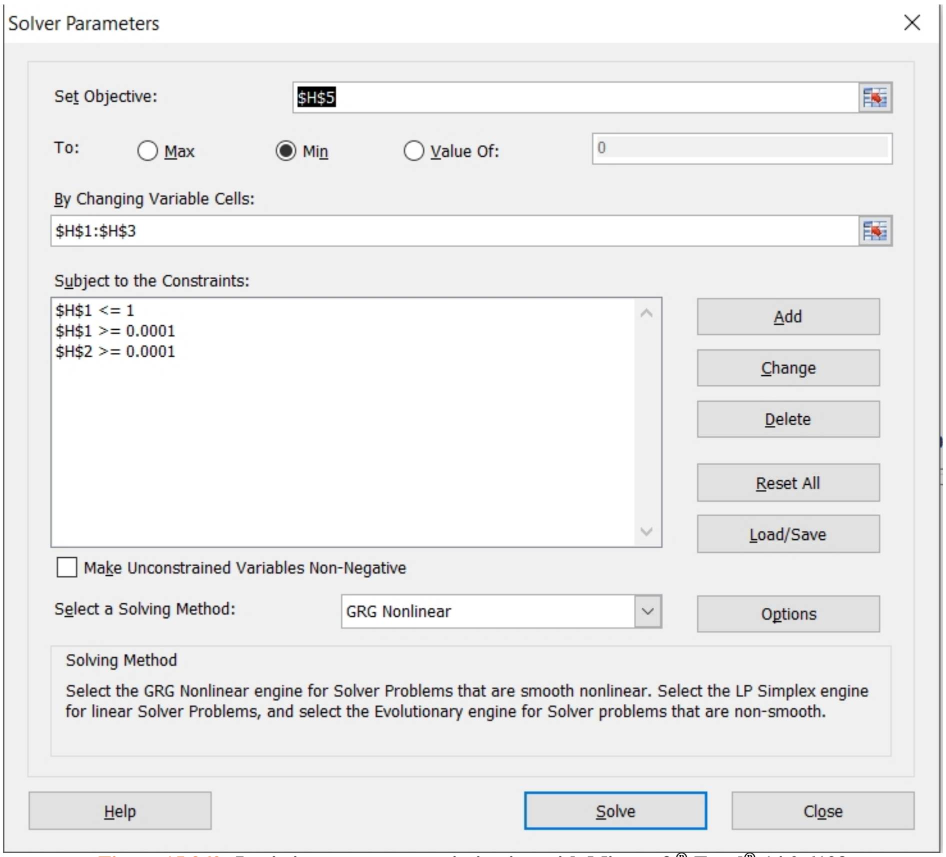
Figure 15.259: Logistic initial values and analytical/solver forecast explicit formulas with Microsoft® Excel® 14.0.6123

If we run the Microsoft® Excel® 14.0.6123 Solver with the following parameters (we have put 0.0001 as lowest value since the solver does not offer a strict order relation):



Solver Parameters

Set Objective: $H$5

To: ○ Max ● Min ○ Value Of: 0

By Changing Variable Cells:
$H$1:$H$3

Subject to the Constraints:
$H$1 <= 1
$H$1 >= 0.0001
$H$2 >= 0.0001

☐ Make Unconstrained Variables Non-Negative

Select a Solving Method: GRG Nonlinear

Solving Method

Select the GRG Nonlinear engine for Solver Problems that are smooth nonlinear. Select the LP Simplex engine for linear Solver Problems, and select the Evolutionary engine for Solver problems that are non-smooth.

Figure 15.260: **Logistic parameters optimization with Microsoft® Excel® 14.0.6123**

Which gives:

	G	H
1	***r***	0.784903832
2	***b***	14.77346738
3	$\mathbf{Y}_{\mathbf{max}}$	717.9904265
4		
5	SSE:	698.8948932

Figure 15.261: **Optimized logistic parameters with Microsoft® Excel® 14.0.6123**

Therefore:

$$\hat{Y}_t \cong \frac{717.99}{1+14.773\cdot 0.78490^t} \tag{15.3.1576}$$

with:

$$\text{SSE} \cong 698 \tag{15.3.1577}$$

What is quite good with the solver approach is that we get $\hat{Y}_{\text{max}}$ and this is a very important information for trendy product type for marketing and business analysts!!!

As we can see with the solver approach the SSE is quite much lower than the method using linear regression method. Indeed, let us see the following list:

	A	B	C	D

Figure 15.262: **Logistic Analytical vs Solver values with Microsoft® Excel® 14.0.6123**

Which gives visually:

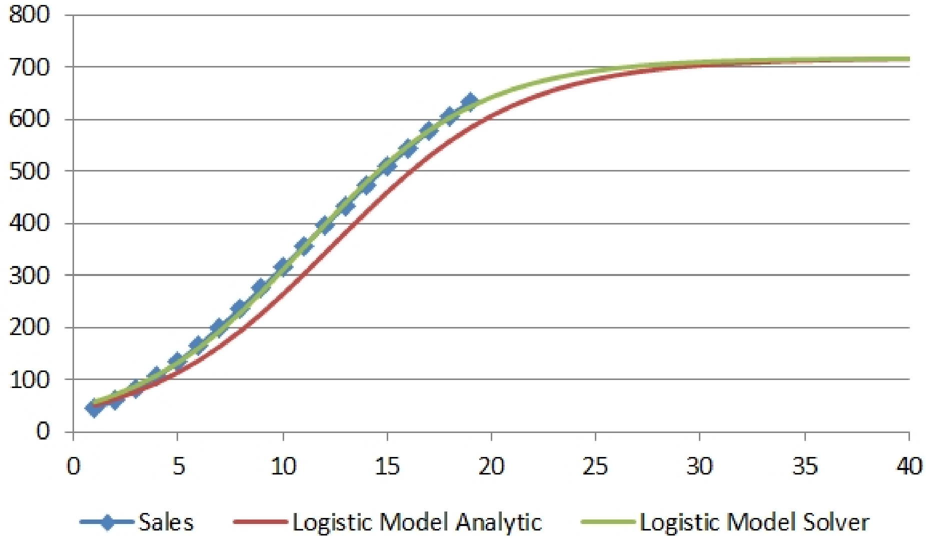

Figure 15.263: **Logistic Analytical vs Solver plot with Microsoft® Excel® 14.0.6123**

We see clearly that using the solver (numerical model) is better than the analytical model given indirectly by the linear regression.

To end this part on deterministic forecasting models, remember that they must be monitored regularly to ensure that the model and parameters used are still appropriate. As the reader may have guessed, a forecasting model must not have bias. The sum of the errors must be near zero, with sometimes overestimated and underestimated values. When a model tends to always overestimate (or underestimate), the latter has a bias and it must be revised (to monitor this we can use the control charts techniques as studied in the section of Industrial Engineering at page 8934).

It is also necessary for the conclusion to remember that there is sometimes a significant difference between the observed values (actual values) and the observed that would really occur if the supply (offer) was infinite. Indeed, observed sales do not take into account missed sales because lack of stock in one or many of the thousands of subsidiaries that have your company, and therefore the possible option that a customer went buy at competitor product. Thus, sales observed are most of times a "minimum" because of missed opportunities!

Remark

Let us indicate that it is trivially possible to make the difference of all subsequent points in time of a time series and then to make a histogram to determine the probability distribution of changes, allowing to make statistical inference with all necessary precautions (analysis that should always be done in practice!).

15.3.13.4 Autoregressive Models

In statistics and signal processing, an autoregressive (AR) model is a representation of a type of random process; as such, it describes certain time-varying processes in nature, economics, etc. The autoregressive model specifies that the output variable depends linearly on its own previous values and on a stochastic term (an imperfectly predictable term); thus the model is in the form of a stochastic difference equation.

Together with the moving-average (MA) model, it is a special case and key component of the more general ARMA and ARIMA models of time series (see further below), which have a more complicated stochastic structure; it is also a special case of the vector autoregressive model (VAR) as we will see further below, which consists of a system of more than one stochastic difference equation.

In the study of a time series, it is natural to think that the series value at time t may depend in part on the values taken on the previous dates such that:

$$X_t = f(X_{t-1}, X_{t-2}, \ldots) \tag{15.3.1578}$$

which of course is for now a limited approach to only discrete univariate series (we will study multivariate series further below) and for which the sampling frequencies constant (at the opposite of what is done in some areas of financial transactions).

Autoregressive models have become such common that they are now integrated in Microsoft® Excel® 2016 (in fact Microsoft® Excel® implement an additive ETS model but as we will see later, ETS additive models are equivalent to ARIMA models):

Figure 15.265: **Microsoft® Excel® 2016 forecast native tool demo**

Before focusing on AR models remember that we saw in the section Probabilities (see page 537) that when we focus only a dependency at time $t-1$, then we speak of "Markov chain", or more rigorously of "order 1 Markov chain" and... let us open a small parenthesis on the interest of Markov chains (recall oriented for the finance field)...

Let us consider that we have sampled stock prices at a fixed frequency (eg daily or hourly ... whatever!). It is then very easy to calculate the proportion of increases (A) versus that of Decreases (D) of the values of interest. Thus, taking into account the whole set of history, we will typically have a table of the following type (values derived from the S&P 500 indices between 11947 and 12007 according to holocene calendar):

Proportion Increases (A)	**Proportion Decreases** (D)	**Total**
0.474	0.526	1

Table 15.62: **Proportion of A/D variations on a history set**

But this is not quite useful excepted perhaps to run a hypothesis test on the both proportions... If we complicate a little bit the analysis by asking us how many times we have two successive increases (AA), two successive decreases (DD) or alternating events (DA) and (AD) throughout history this doubles the work and could give us a typical table of the following type:

$X_i =$	(A)	(B)	**Total**
$X_{i-1} = (D)$	0.519	0.481	1
$X_{i-1} = (A)$	0.4.33	0.567	1

Table 15.63: **Proportion of A/D variations relatively to previous period**

So the above values can obviously be seen as conditional probabilities:

$$P(X_i|X_{i-1}) \tag{15.3.1579}$$

And if now we do an analysis not only on the previous period but the last two, it means that we calculate the proportions of the sequences (DDD), (DDA), (DAD), (DAA), (ADD), (ADA), (AAD), (AAA) and it doubles the number of calculations:

		$X_i = 0$		
X_{i-1}	X_{i-1}	(A)	(D)	**Total**
(D)	(D)	0.501	0.499	1
(D)	(A)	0.412	0.588	1
(A)	(D)	0.539	0.461	1
(A)	(A)	0.449	0.551	1

Table 15.64: **Proportion of A/D variations relatively to 2 previous periods**

The above values must obviously be seen as conditional probabilities:

$$P(X_i|X_{i-1},X_{i-2}) \tag{15.3.1580}$$

We see that each time we add an additional period to the analysis, we double the number of calculations. Thus, taking the last 20 periods, this leads us to nearly 1 million conditional probabilities (proportions)!!! So we understand then the interest to restrict ourselves to a small number of previous values or a single value as do the Markov chains.

Coming back to our example, we have then that the probability that the next 4 days the sequence is $(ADAA)$ will be without simplifying assumption:

$$\begin{aligned}P(AADA)=&P(X_1=A)\cdot P(X_2=A|X_1=A)\cdot P(X_3=D|X_2=A,X_1=A)\\&\cdot P(X_4=A|X_3=D,X_2=A,X_1=A)\end{aligned} \qquad (15.3.1581)$$

but will be reduced in the hypothesis of a Markov chain (that is to say a dependency only with the previous period) to:

$$\begin{aligned}P(AADA)=&P(X_1=A)P(X_2=A|X_1=A)P(X_3=D|X_2=A)P(X_4=A|X_3=D)\\&=0.526\cdot 0.567\cdot 0.433\cdot 0.481\cong 0.062=6.2\%\end{aligned} \qquad (15.3.1582)$$

Whether the approach of total conditional probabilities or the simplified Markov chain approach is the best is a broad debate and should be treated case by case. The hypothesis of random walk (implicitly: the Markov model) is defended by a majority of economists ... but this hypothesis obviously also a number of opponents.

It is therefore not usually necessary to take into account all the past values of series or only the last event and we often limit ourselves to p values:

$$X_t=f(X_{t-1},X_{t-2},\ldots,X_{t-p})+\varepsilon_t \qquad (15.3.1583)$$

where ε_t is a white noise $\mathcal{N}(0,\sigma)$ or Wiener process sometimes denoted WN. More rigorously, and for reasons of application of statistical techniques, the white noise is defined such that:

$$\begin{aligned}&\text{E}(\varepsilon_t)=0\\&\text{E}(\varepsilon_t^2)=\text{V}(\varepsilon_t)=\sigma^2\\&\text{E}(\varepsilon_t\varepsilon_\tau)=\text{cov}(\varepsilon_t,\varepsilon_\tau)=0\quad\forall t\neq\tau\end{aligned} \qquad (15.3.1584)$$

The first equality is obvious. The third one is required a constraint. The second has not been proved in the section Statistics. So let us prove this now!

So remember that in the section Statistics we have proved the Huygens relation (see section Statistics page 593):

$$\text{V}(X)=\text{E}(X^2)-(\text{E}(X))^2 \qquad (15.3.1585)$$

Solving for the needed quantity gives:

$$\text{E}(X^2)=\text{V}(X)+(\text{E}(X))^2 \qquad (15.3.1586)$$

But four our case $\text{E}(X)=0$, therefore:

$$\text{E}(X^2)=\text{V}(X)=\sigma^2 \qquad (15.3.1587)$$

Hence:

$$\text{E}(\varepsilon_t^2)=\sigma^2 \qquad (15.3.1588)$$

The only difference relatively to the standard Brownian motion is that as we will see further below, there is the presence here of an inertia factor traditionally denoted α in the simple cases, that strongly influences the dynamics of the process such as:

$$X_t=\alpha X_{t-1}+\varepsilon_t \qquad (15.3.1589)$$

Indeed, as it is very easy to do in Microsoft® Excel® in accordance with the procedure indicated in our study of Wiener process earlier in this section.

Here are various plots of the time series according to some values of the inertia factor:

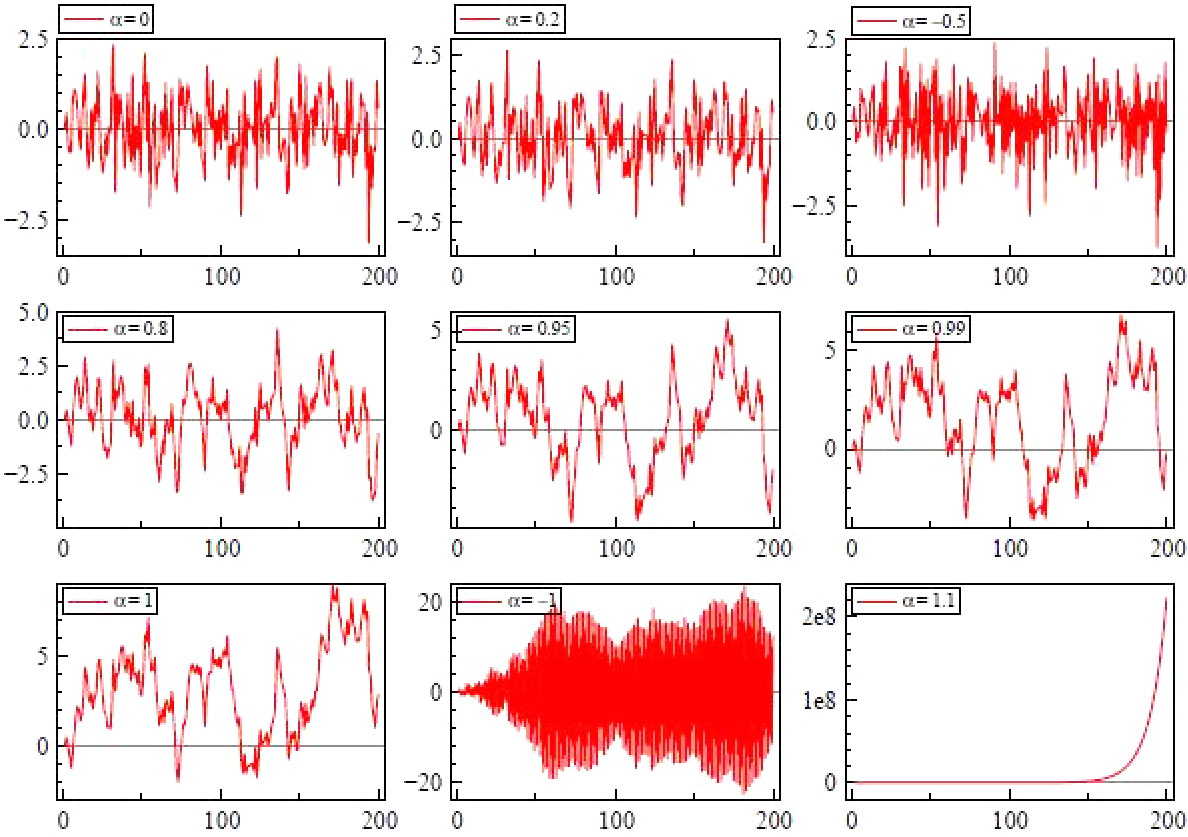

Figure 15.266: **Autoregressive process of order** 1

If we consider X_t as a specific random variable (with a given density function) that we would denote by X and X_{t-h} as another specific random variable (with a given density function) that we would denote by Y, then nothing prevents us being known the density functions of each of these variables to compute their covariance denoted most of times $\gamma_t(h)$ and named "autocovariance function" (ACVF) in the field of times series analysis:

$$\boxed{\gamma_t(h)=c_{X,Y}=\text{cov}(X,Y)=\text{cov}(X_t,X_{t-h})=\text{E}(X_tX_{t-h})-\text{E}(X_t)\text{E}(X_{t-h})} \quad (15.3.1590)$$

Let us see two important properties for the autocovariance:

P1. The first properties is already known to us (from our study of statistics):

$$\gamma_t(0)=\text{V}(X_t) \quad (15.3.1591)$$

P2. If we consider a process such that $\text{E}(X_t)=c^{te}$, then considering without loss of generality $\text{E}(X_t)=0$, we then have:

$$\text{E}(X_{t_1+h}X_{t_1})=\gamma_{t_1}(h) \quad (15.3.1592)$$

for all t_1 and t_1+h contained in the index set. Now let us set $t_0=t_1-h$. Then:

For example, in practice we often know the mean μ of the two random variables at the two different times and also some of the values of their underlying distributions (random issues). So, it becomes easy to calculate their covariance. But this is not really a useful indicator. Nothing prevents us assuming a linear relation to use the linear correlation coefficient:

$$R_{X,Y}=\frac{c_{X,Y}}{\sqrt{\mathrm{V}(X)\mathrm{V}(Y)}}=\frac{c_{X,Y}}{\sqrt{\mathrm{cov}(X,X)\mathrm{cov}(Y,Y)}}=\frac{c_{X,Y}}{\sqrt{c_{X,X}c_{Y,Y}}} \tag{15.3.1593}$$

But that is written traditionally and trivially in the field of time series analysis:

$$\boxed{\rho_t(h)=\frac{\gamma_t(h)}{\sqrt{\gamma_t(0)\gamma_{t-h}(0)}}} \tag{15.3.1594}$$

and is named "autocorrelation coefficient" often abbreviated ACF (AutoCorrelation Function) in statistical softwares.

Remarks

R1. There are different variations of this relation in some statistical softwares. Therefore we get sometimes small numerical differences with respect to the use of the above ACF analysis.

R2. Keep in mind that calculate the average, variance and also by extension the autocorrelation makes sense only for stationary processes! Calculating these statistical indicators for non-stationary processes is generally a huge error.

We prefer to write the above relation in the following explicit form (the covariance is explicit):

$$\rho_{X,Y,t}=\frac{\mathrm{E}\left[(X_t-\mu_{X,t})(Y_t-\mu_{Y,t})\right]}{\sigma_X\sigma_Y} \tag{15.3.1595}$$

The reader should know that when we do the analysis of time series in practice, we often compare a series with itself but with a time lag h. The autocorrelation of order h is then the correlation between the series and itself delayed by h lags.

Thus, as both series are dependent and have the same statistical characteristics, we write in this special case say to be a "second order stationary process" the following relation named the "empirical autocorrelation coefficient":

$$\begin{aligned}\rho(h)=\frac{\mathrm{E}\left[(X_t-\mu_X)(X_{t-h}-\mu_X)\right]}{\sigma_X\sigma_X}=\frac{\gamma_t(h)}{\gamma_t(0)}&=\frac{\dfrac{1}{n-1}\displaystyle\sum_{t=h+1}^{n}(X_t-\mu_X)(X_{t-h}-\mu_X)}{\dfrac{1}{n-1}\displaystyle\sum_{t=h+1}^{n}(X_t-\mu_X)^2}\\&=\frac{\displaystyle\sum_{t=h+1}^{n}(X_t-\mu_X)(X_{t-h}-\mu_X)}{\sigma_X^2}\end{aligned} \tag{15.3.1596}$$

where obviously we must not forget that in practice the mean and the standard deviation are only estimators although this is not explicit in the above definition since the in the field of time series analysis we indicate rarely the estimators with hat symbol as we do in Statistics or Reliability Analysis.

That latter relation is also often written en the following equivalent form:

$$\rho(h)=\frac{\mathrm{c}(X_t,X_{t+h})}{\hat{\mathrm{V}}(X_t)}=\frac{\dfrac{1}{T-1}\displaystyle\sum_{t=1}^{T-h}(X_t-\bar{X})(X_{t+h}-\bar{X})}{\hat{\mathrm{V}}(X_t)} \tag{15.3.1597}$$

Obviously in the case of the analysis of time series where we suspect cyclicality, the largest value ρ for a given h indicates the underlying cyclicality frequency (respectively the periodicity) of the series which can help by for example the choice of the type of moving average (see further below).

Remark

Notice (important case!), that if the averages are zero, the above relation resumes to:

$$\rho(h)=\frac{\mathrm{c}(X_t,X_{t+h})}{\hat{\mathrm{V}}(X_t)}=\frac{\dfrac{1}{T-1}\displaystyle\sum_{t=1}^{T-h}X_tX_{t+h}}{\dfrac{1}{T-1}\displaystyle\sum_{i=1}^{T}X_t^2}=\frac{\displaystyle\sum_{t=1}^{T-h}X_tX_{t+h}}{\displaystyle\sum_{i=1}^{T}X_t^2} \tag{15.3.1598}$$

Definition (#15.3.704): We name "correlogram", the diagram representing the autocorrelation coefficients of order $1,2,3,\ldots,h,\ldots$.

Below are given for example a family of time series:

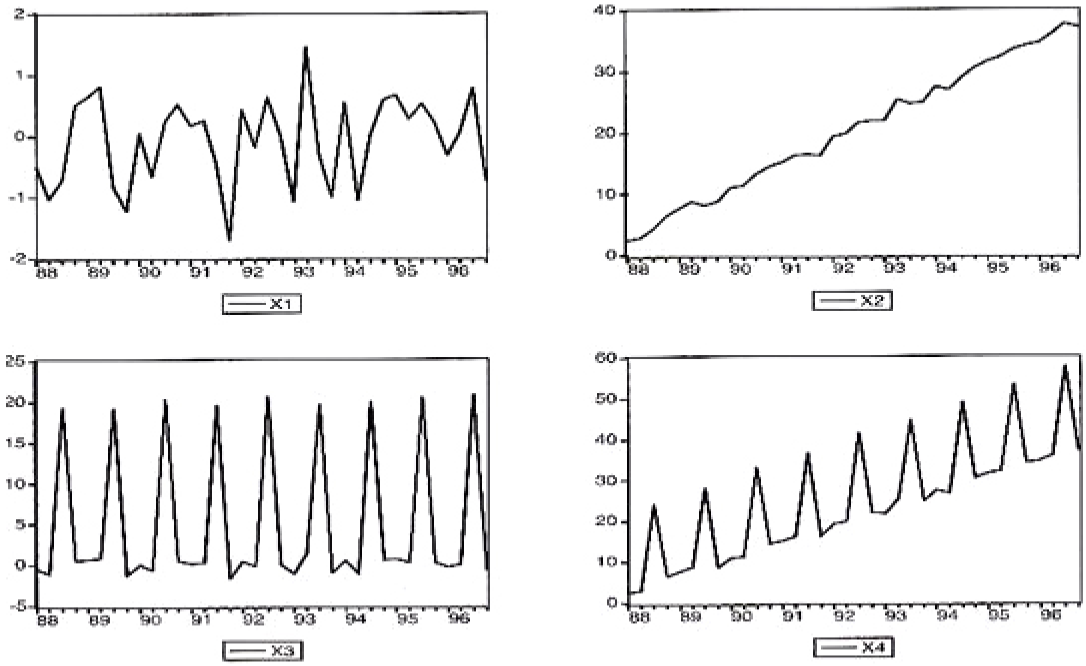

Figure 15.267: Some examples of time series

with their corresponding correlogram for different values of h on the x-axis and the values of ρ on the y-axis[41]:

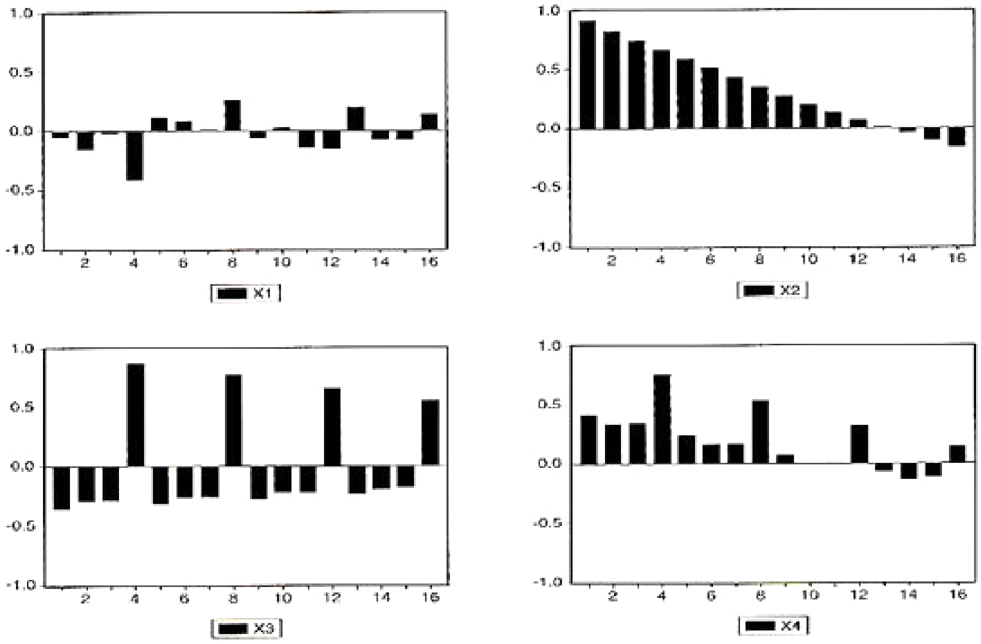

Figure 15.268: **Corresponding AFC correlograms of the time series**

Or here four examples of four non-stationary time series (a "unit-root" time series means that there is a stochastic trend):

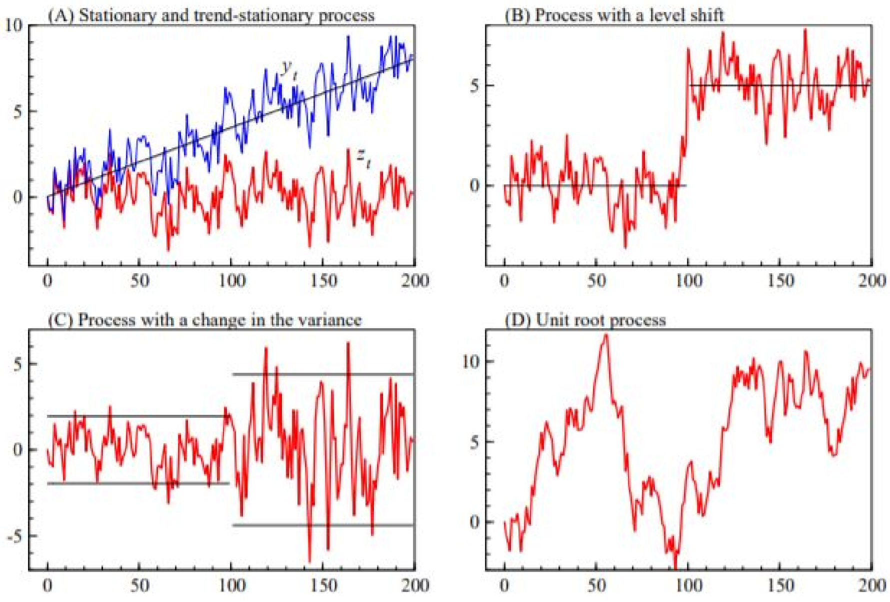

Figure 15.269: **Four non-stationary time series**

✍**Example:**

---

[41] Most softwares don't plot $\rho(0)$ as it is obviously equal to 1...

A random walk is of the form:

$$X_t = \sum_{i=1}^{t} \varepsilon_i \tag{15.3.1599}$$

Note that as $X_t = X_{t-1} + \varepsilon_t$ we then have:

$$\text{cov}\left(X_t, X_{t-1}\right) = \text{cov}\left(X_{t-1} + \varepsilon_t, X_{t-1}\right) = \text{V}\left(X_{t-1}\right) \tag{15.3.1600}$$

Also note that:

$$\sigma_t^2 = \text{V}\left(X_t\right) = t\sigma_\varepsilon^2 \tag{15.3.1601}$$

Consequently:

$$\text{ACF}_{\text{RW}}\left(X_t, X_{t-1}\right) = \frac{\sigma_{t-1}^2}{\sigma_{t-1}\sigma_t} = \frac{\sigma_{t-1}}{\sigma_t} = \sqrt{\frac{t-1}{t}} = \sqrt{1-\frac{1}{t}} \cong 1 - \frac{1}{2t} \tag{15.3.1602}$$

Which is to say we should see a correlation of almost 1 because as soon as t starts to get large, X_t and X_{t-1} are almost exactly the same thing - the relative difference between them tends to be fairly small.

Generalizing we get (using a slightly different notation but also quite common in the literature):

$$\text{ACF}_{\text{RW}}(t,k) = \frac{\text{cov}\left(X_t, X_{t+k}\right)}{\sqrt{\text{V}\left(X_t\right)\text{V}\left(X_{t+k}\right)}} = \frac{t\sigma^2}{\sqrt{t\sigma^2(t+k)\sigma^2}} = \frac{1}{\sqrt{1+k/t}} \tag{15.3.1603}$$

Let us make a practical example of calculation of correlogram with Microsoft® Excel® 14.0.6123 and fictitious data:

✍**Example:**

Consider the following list of data:

	A	B	C	D	E	F
3	Sales	Average		ρ	h	Minitab/R
4	144	159.15		0.269596705	1	0.26959
5	151	159.15		0.712261494	2	0.712261
6	134	159.15		0.142952352	3	0.142952
7	151	159.15		0.563177806	4	0.563178
8	145	159.15		-0.02725071	5	-0.027251
9	145	159.15		…	…	…
10	141	159.15

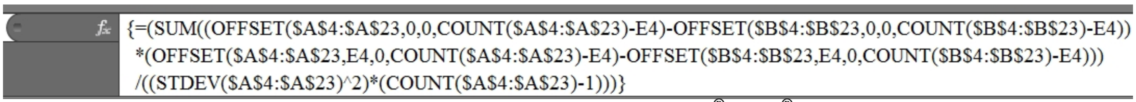
23	169	159.15				

Figure 15.270: Data list for AFC example and comparison with Minitab/R in Microsoft® Excel® 14.0.6123

with the following matrix formula in the cells `D3` and below (sorry I did not found until now an other way to do it...):



```
{=(SUM((OFFSET($A$4:$A$23,0,0,COUNT($A$4:$A$23)-E4)-OFFSET($B$4:$B$23,0,0,COUNT($B$4:$B$23)-E4))
 *(OFFSET($A$4:$A$23,E4,0,COUNT($A$4:$A$23)-E4)-OFFSET($B$4:$B$23,E4,0,COUNT($B$4:$B$23)-E4)))
 /((STDEV($A$4:$A$23)^2)*(COUNT($A$4:$A$23)-1)))}
```

Figure 15.271: Autcorrelation formula in Microsoft® Excel® 14.0.6123

and visually this gives the following correlogram:

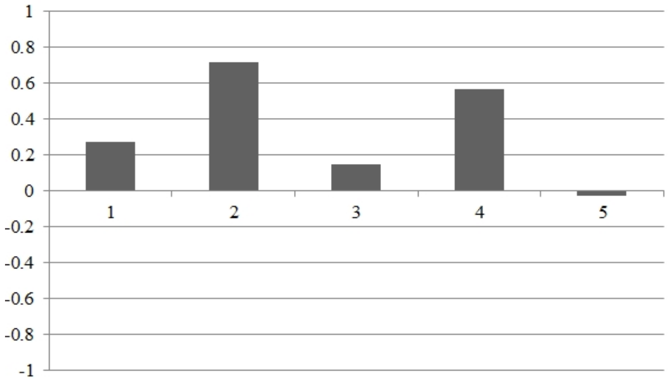


Figure 15.272: AFC Correlogram in Microsoft® Excel® 14.0.6123

Definitions (#15.3.705):

D1. A time series X_t is said to be "strictly stationary" when the probability density function of the collection of the random variables X_t is the same for any t. The strict stationary property restricts the probabilistic properties of any collection of random variables to be invariant to time shifts, which implies that the probabilistic behaviour of each random variable is the same across time.

D2. A time series is said to be "stationary in the weak sense" or just "weak stationary process" or also "second-order or covariance stationary, if the first (mean) and second (variance) moments exist, are finite and constant over time (therefore not time-dependent), that is $\forall i \in 1 \ldots T$:

$$\begin{gathered}\mathrm{E}(X_t)=\mu=c^{te}\\ \mathrm{V}(X_t)=\sigma^2=c^{te}\\ \mathrm{cov}(X_t,X_{t+h})=\gamma(h)\end{gathered} \quad (15.3.1604)$$

The weak stationarity property restricts the mean and variance of the time series to be finite and invariant in time (the first condition of constancy of the mean eliminates any possible trend) and the autocorrelation $\gamma_t(h)$ to be independent of time t but only depending from the lag h. This can be however violated in different ways. Through deterministic trends (trend stationary), level shifts, variance changes, unit roots (i.e. stochastic trends).

If the underlying density function of each X_t is a Normal distribution, then we speak of "Gaussian process".

Second order stationarity is weaker than strict stationarity. Second order stationarity requires that first and second order moments (mean, variance and covariances) are constant throughout time and, hence, do not depend on the time at which the process is observed.

Second order stationarity series are not necessarily strictly stationary because the mean and autocovariance are not, in general, enough to determine the distribution.

D3. If we have N non-stationary time series and that their weighted sum (the sum of the weights w_i being equal as usual to the unit) is such that $\forall i \in 1 \ldots T$:

$$\begin{gathered}\mathrm{E}(\vec{w}_i\circ\vec{X}_i)=\mu=c^{te}\\ \mathrm{V}(\vec{w}_i\circ\vec{X}_i)=\sigma^2=c^{te}\end{gathered} \quad (15.3.1605)$$

gives a weak stationary process, then we say that the time series are "co-integrated". This is useful in finance so that with some non-stationary financial instruments we can produce a portfolio whose time series is weakly stationary (for mathematical processing reasons).

Let us consider an important case in many corporations on some more or less long periods. Given:

$$\bar{X}_t=\frac{1}{T}\sum_{i=1}^{T}X_t \quad (15.3.1606)$$

the time average. If $\bar{X}_t$ converges in probability to μ when $T\rightarrow+\infty$ we say that the process is "ergodic for the average".

15.3.13.4.1 AR(p) Autoregressive processes

Let us introduce the concept of autoregressive process by introducing the special case of an autoregressive process of order 1, denoted by AR(1) and defined by the relation (up to an additive constant):

$$X_t=\varphi X_{t-1}+\varepsilon_t \tag{15.3.1607}$$

It is therefore a Markov chain of order 1 (we can always verify in practice if the resulting model is a posteriori with or without gaussian residues!).

We say that the autoregressive AR(1) is stationary if we have for any time t:

$$\text{E}(X_t)=\mu=c^{te} \qquad \text{V}(X_t)=\sigma_X^2=c^{te} \tag{15.3.1608}$$

More generally, we have:

$$\begin{aligned}\mu&=\text{E}(X_t)=\varphi\text{E}(X_{t-1})+\text{E}(\varepsilon_t)=\text{E}(X_{t-1})=\varphi^t X_0\\ \sigma_X^2&=\text{V}(X_t)=\varphi^2\text{V}(X_{t-1})+\text{V}(\varepsilon_t)=\varphi^2\text{V}(X_{t-1})+\sigma^2=\sum_{i=0}^{t}\varphi^{2i}\sigma^2\end{aligned} \tag{15.3.1609}$$

and therefore the stationary necessarily implies that (remember that the additive constant was put as zero in the above definition, otherwise it changes the conclusions below):

$$\begin{cases}\mu=\varphi\mu\\ \sigma_X^2=\varphi^2\sigma_X^2+\sigma^2\end{cases}\Rightarrow\begin{cases}\mu=0 \text{ or } \varphi=1\\ (1-\varphi^2)\sigma_X^2=\sigma^2\end{cases}\Rightarrow\begin{cases}\mu=0\\ |\varphi|\ll 1\end{cases} \tag{15.3.1610}$$

Then stationary implies the two useful results:

$$\begin{aligned}\text{E}(X_t)&=\varphi\text{E}(X_{t-1})=1\cdot\text{E}(X_{t-1})=\text{E}(X_{t-1})\\ \sigma_X^2&=\frac{\sigma^2}{1-\varphi^2}\end{aligned} \tag{15.3.1611}$$

It is interesting to notice that the variance is independent of the time and therefore it does not diverge. However, we must not necessarily this a positive fact because it is not very consistent in practice that the volatility is constant (homoscedastic process). This is why we will address more complex models whose volatility is time-dependent.

Notice also that for the variance to be always positive (by definition of the variance) we must have $\varphi<1$.

Let's see what the hypothesis of stationarity involves and for this, we'll first need the following equality:

$$\begin{aligned}X_t&=\varphi X_{t-1}+\varepsilon_t=\varphi(\varphi X_{t-2}+\varepsilon_{t-1})+\varepsilon_t=\varphi^2X_{t-2}+\varphi\varepsilon_{t-1}+\varepsilon_t\\ &=\varphi^hX_{t-h}+\sum_{k=0}^{h-1}\varphi^k\varepsilon_{t-k}\end{aligned} \tag{15.3.1612}$$

Therefore:

$$\begin{aligned}\gamma_t(h)&=\text{cov}(X_t,X_{t-h})=\text{E}(X_tX_{t-h})-\text{E}(X_t)\text{E}(X_{t-h})=\text{E}(X_tX_{t-h})\\ &=\text{E}\left(\left(\varphi^hX_{t-h}+\sum_{k=0}^{h-1}\varphi^k\varepsilon_{t-k}\right)X_{t-h}\right)=\text{E}(\varphi^hX_{t-h}^2)=\varphi^h\text{E}(X_{t-h}^2)\end{aligned} \tag{15.3.1613}$$

And let us recall the Huygens relation (see section Statistics page 593):

$$\mathrm{V}(X)=\mathrm{E}(X^2)-\mathrm{E}(X)^2 \tag{15.3.1614}$$

Therefore it comes:

$$\gamma_t(h)=\varphi^h\mathrm{E}(X_{t-h}^2)=\varphi^2\left[\mathrm{V}(X_{t-h})+\mathrm{E}(X_{t-h})^2\right]=\varphi^h\mathrm{V}(X_{t-h})=\varphi^h\sigma_X^2 \tag{15.3.1615}$$

Notice that if you redo the above developments with $-h$ instead of h you will fall back on exactly the same result. Hence for an autoregressive process the autocovariance is an even function:

$$\gamma_t(h)=\gamma_t(-h) \tag{15.3.1616}$$

So the autocorrelation is indeed dependent only of the lag h (not of the exact time limits of the implicit sum) and given by:

$$\rho_t(h)=\frac{\gamma_t(h)}{\sqrt{\gamma_t(0)\gamma_{t-h}(0)}}=\frac{\varphi^h\sigma_X^2}{\sqrt{\varphi^2\sigma_X^2\varphi^0\sigma_X^2}}=\varphi^h \tag{15.3.1617}$$

Since the stationarity implies that $\varphi \ll 1$, the ACF correlograms of AR(p) processes will have a decreasing profile: the process somehow forgets past values.

We also have for an AR(1) stationary process with constant (offset):

$$X_t=\varphi_0+\varphi_1 X_{t-1}+\varepsilon_t \tag{15.3.1618}$$

the following mean:

$$\begin{aligned}\mathrm{E}(X_t)&=\mathrm{E}(c^{te}+\varphi_1X_{t-1}+\varepsilon_t)=c^{te}+\mathrm{E}(\varphi_1X_{t-1})+\mathrm{E}(\varepsilon_t)=c^{te}+\varphi_1\mathrm{E}(X_{t-1})+0\\&=c^{te}+\varphi_1\mathrm{E}(X_{t-1})+0=c^{te}+\varphi_1\mathrm{E}(X_t)\end{aligned} \tag{15.3.1619}$$

Therefore:

$$\mathrm{E}(X_t)=\frac{\varphi_0}{1-\varphi_1} \tag{15.3.1620}$$

So if the constant is equal to zero we fall back well on a mean equal to zero as proved earlier above. The variance will have the same expression as already the one proved earlier above, that is to say:

$$\sigma_X^2=\frac{\sigma^2}{1-\varphi^2} \tag{15.3.1621}$$

since the addition of a constant does not change the variance of the series. So we got above the mean and (unconditional) variance of an AR(1) process.

If $\varphi=1$ then we have the AR(1) process which is written:

$$X_t=X_{t-1}+\varepsilon_t \tag{15.3.1622}$$

and is therefore by construction not stationary anymore. Nonstationary is common in practice and bring to analysis issues. There is therefore a trick to make some stationary some non-stationary series, do manipulations on them and then to make them again nonstationary by the reverse procedure.

Thus, about the AR(1) with $\varphi = 1$, the idea is to use what we name the "integration property" of a time series. Thus, AR(1) is an integrated series of order 1, designated by I(1) because if it differs from a time unit, we get a stationary series given by:

$$X_t - X_{t-1} = \varepsilon_t \qquad (15.3.1623)$$

Which is written with the so named "backshift operator" denoted B:

$$\begin{aligned}&\text{B}y_t = X_{t-1}\\&\text{B}^2 y_t = X_{t-2}\\&(1-\text{B})X_t = \varepsilon_t\end{aligned} \qquad (15.3.1624)$$

And so a series is "integrated of order 2" if it needs to be "differentiate" twice to make it stationary.

We can also introduce the "lag operator" denoted ∇ or also L:

$$\nabla X_t = (1-\text{B})X_t = \varepsilon_t \qquad (15.3.1625)$$

or a generalization of that latter given by:

$$\nabla_d X_t = X_t - X_{t-d} = X_t - \text{B}^d X_t = (1-\text{B}^d)X_t \qquad (15.3.1626)$$

Remark

If $X_t = t_t + Y_t$, applying the first difference operator to X_t, then:

$$\nabla X_t = X_t - X_{t-1} = (t_t - t_{t-1}) + (Y_t - Y_{t-1}) \qquad (15.3.1627)$$

so if t_t is a trend such that $t_t = t_t(\vec{\beta}) = \beta_0 + \beta_1 t$, then $t_t - t_{t-1} = \beta_1$, i.e. ∇ removes a linear trend.

∇^d removes a seasonality with period d. If $X_t = t_t + s_t + Y_t$, then:

$$\nabla^d X_t = (t_t - t_{t-d}) + (s_t - s_{t-d}) + (Y_t - Y_{t-d}) \qquad (15.3.1628)$$

and $s_t - s_{t-d} = 0$.

An AR(2) process is an auto-regressive process that verifies a relation of the following type (up to an additive constant):

$$X_t = \varphi_1 X_{t-1} + \varphi_2 X_{t-2} + \varepsilon_t \qquad (15.3.1629)$$

So in such a model, the influence of the past is manifested by a linear regression on the two previous values. Depending on the values of φ_1 and φ_2 it is not always possible to find a stationary process satisfying this last relation.

In general, an "autoregressive process of order p" AR(p) is a process that depends linearly on the p previous values (up to an additive constant):

$$\boxed{\text{AR}(p) = X_t = \varphi_1 X_{t-1} + \ldots + \varphi_p X_{t-p} + \varepsilon_t = \sum_{k=1}^{p} \varphi_k X_{t-k} + \varepsilon_t} \qquad (15.3.1630)$$

Or using the lag operator (with the notation L):

$$\text{AR}(p)=X_t=\left(\sum_{k=1}^{p}\varphi_k L^k\right)X_t+\varepsilon_t \tag{15.3.1631}$$

✍**Example:**

Suppose we have an i.i.d (independent identically distributed) process where we suppose $\{X_t\}$ is a binary process, i.e. $X_t\in\{-1,+1\}$ such that $P(X_t=1)=p$ and $P(X_t=-1)=1-p$ such that the X_t are mutually independent. We can easily compute the moments as:

$$\text{E}(X_t)=p\cdot(+1)+(1-p)\cdot(-1)=2p-1 \tag{15.3.1632}$$

and:

$$\text{V}(X_t)=[p(1)^2+(1-p)(-1)^2]-(2p-1)^2=1-(1-2p)^2 \tag{15.3.1633}$$

By independence $\text{cov}(X_t,X_s)=0$ if $t\neq s$.

15.3.13.4.2 MA(q) Moving Average stationary process

First a disclaimer! Do not confuse this Moving Average stationary process with deterministic Moving Averages. Indeed, the term is not very appropriate because even if there is indeed mobility (which is the minimum for a process), it is quite wrong to speak of average...

We are in fact in the context of times series forecasts that show autocorrelated errors but nothing else (in fact it will serve for a mix a little further below).

Let us introduce the concept of autoregressive moving average by studying first the special case of autoregressive moving average of order 1, denoted MA(1) and defined by:

$$X_t=\varepsilon_t+\theta\varepsilon_{t-1} \tag{15.3.1634}$$

For such a process, we have by definition of a white noise:

$$\begin{aligned}&\text{E}(X_t)=\text{E}(\varepsilon_t)+\theta\text{E}(\varepsilon_{t-1})=0+\theta\cdot 0=0\\&\text{V}(X_t)=\text{V}(\varepsilon_t)+\theta^2\text{V}(\varepsilon_{t-1})+2\text{cov}(\varepsilon_t,\varepsilon_{t-1})=\sigma^2+\theta^2\sigma^2=\sigma^2(1+\theta^2)\end{aligned} \tag{15.3.1635}$$

So the two moments are both time independent and we are dealing with a weak stationary process. However, we must not necessarily see this as a positive fact because it is not very consistent in practice that the volatility is constant (homoscedastic process). This is why we will address more complex models whose volatility is time-dependent further below.

Regarding the autocorrelation, we have first (do not forget to review the three conditions which define the white noise and especially the third one!):

$$\begin{aligned}\gamma_t(1)&=\text{cov}(X_t,X_{t-1})=\text{cov}(\varepsilon_t+\theta\varepsilon_{t-1},\varepsilon_{t_1}+\theta\varepsilon_{t-2})=\text{E}(X_tX_{t-1})-\text{E}(X_t)\text{E}(X_{t-1})\\&=\text{E}(X_tX_{t-1})=\text{E}(\varepsilon_t\varepsilon_{t-1})+\theta\text{E}(\varepsilon_{t-1}^2)+\theta^2\text{E}(\varepsilon_{t-1}\varepsilon_{t-2})=\theta\text{E}(\varepsilon_{t-1}^2)\\&=\theta\left[\text{V}(\varepsilon_{t-1}+\text{E}(\varepsilon_{t-1})^2\right]=\theta\sigma^2\end{aligned} \tag{15.3.1636}$$

The order 1 autocorrelation coefficient is therefore equal to:

$$\rho_t(1)=\frac{\gamma_t(1)}{\sqrt{\gamma_t(0)\gamma_{t-1}(0)}}=\frac{\text{cov}(X_t,X_{t-1})}{\sqrt{\text{V}(X_t)\text{V}(X_{t-1})}}=\frac{\theta\sigma^2}{\sqrt{\sigma^2(1+\theta^2)\sigma^2(1+\theta^2)}}=\frac{\theta\sigma^2}{\sigma^2(1+\theta^2)}=\frac{\theta}{1+\theta^2} \tag{15.3.1637}$$

For $h>1$, we have immediately by doing the same development as before:

$$\gamma_t(h)=\text{cov}(X_t,X_{t-h})=\text{cov}(\varepsilon_t+\theta\varepsilon_{t-1},\varepsilon_{t-h}+\theta\varepsilon_{t-h-1})=0 \tag{15.3.1638}$$

Therefore the autocorrelation coefficients of order greater than 1 are all zero!

So finally:

$$\gamma_t(h)=\begin{cases}\sigma^2(1+\theta^2) & \text{if } h=0\\ \sigma^2 & \text{if } h=+1\\ 0 & \text{otherwise}\end{cases} \tag{15.3.1639}$$

and similarly:

$$\rho_t(h)=\begin{cases}1 & \text{if } h=0\\ \theta/(1+\theta^2) & \text{if } h=+1\\ 0 & \text{otherwise}\end{cases} \tag{15.3.1640}$$

A MA(2) process is an AR process that verifies a relation of the form:

$$X_t=\varepsilon_t+\theta_1\varepsilon_{t-1}+\theta_2\varepsilon_{t-2} \tag{15.3.1641}$$

And we can repeat the same developments as for MA(1) with enthusiasm ... to arrive also to the conclusion that the autocorrelation (ACF) is zero for $\forall h>2$.

In general, a "moving average process of order q" MA(q) is a process which depends linearly on the previous q values[42]:

$$\boxed{\text{MA}(q)=X_t=\varepsilon_t+\theta_1\varepsilon_{t-1}+\ldots+\theta_q\varepsilon_{t-q}} \tag{15.3.1642}$$

Or using the lag operator:

$$\text{MA}(q)=X_t=\left(1+\sum_{i=1}^{q}\theta_iL^i\right)\varepsilon_t \tag{15.3.1643}$$

---

[42] As we have already mentioned it, the name "moving average" is inaccurate, but the right term can be thought of as a weighted moving average of the past few forecast errors but where the weights don't sum to 1.

and thus for such a process it can be accepted without the general proof that:

$$\begin{gathered}\mathrm{E}(X_t)=0\\ \mathrm{V}(X_t)=\sigma^2\sum_{i=0}^{q}\theta_q^2\end{gathered}\qquad(15.3.1644)$$

and that the correlation is zero for $\forall h>q$. Thus, one can easily recognize that a MA(q) process since its ACF has a "cutoff" from q.

You must remember that the moving average process is an autoregression model of a time series of residual errors from prior predictions!!!

15.3.13.4.3 ARMA(p,q) Autoregressive non-seasonal moving average processes

We can obviously consider combining the two previous models (MA(q) and AR(p)) by introducing:

- A dependency of the process vis-à-vis its past with an AR(p) (i.e. an ARMA($p,0$))
- A delay in the random errors with a MA(q) process (i.e. an ARMA($0,q$))

Such a model, named "non-seasonal autoregressive mobile average" or "non-seasonal ARMA", is characterized by the parameter p of the autoregressive part and the parameter q of the moving average part.

Thus, a non-seasonal ARMA(p,q) process verifies the relation:

$$\boxed{\mathrm{ARMA}(p,q)=X_t=\varepsilon_t+\sum_{i=1}^{p}\varphi_iX_{t-i}+\sum_{i=1}^{q}\theta_i\varepsilon_{t-i}}\qquad(15.3.1645)$$

or explicitly:

$$\mathrm{ARMA}(p,q)=X_t=\varphi_1X_{t-1}+\ldots+\varphi_pX_{t-p}+\varepsilon_t+\theta_t\varepsilon_{t-1}+\ldots+\theta_q\varepsilon_{t-q}\qquad(15.3.1646)$$

Or depending of the point of view of its properties its definition could be written:

$$X_t-\sum_{i=1}^{p}\varphi_iX_{t-i}=\varepsilon_t+\sum_{i=1}^{q}\theta_i\varepsilon_{t-i}\qquad(15.3.1647)$$

And using the lag operator:

$$\left(1-\sum_{i=1}^{p}\varphi_iL^i\right)X_t=\left(1+\sum_{i=1}^{q}\theta_iL^i\right)\varepsilon_t\qquad(15.3.1648)$$

And that latter is even sometimes (sadly...) abbreviated:

$$\Phi(L)X_t=\Theta(L)\varepsilon_t\qquad(15.3.1649)$$

The main advantage of non-seasonal ARMA process is that they allow to provide long-term forecasts (at least more distant in time as the next date...). Indeed, recall that for AR (1) process, we obtained:

$$\mathrm{E}(X_t)=\varphi\mathrm{E}(X_{t-1}) \tag{15.3.1650}$$

Then we have:

$$\hat{X}_t=\mathrm{E}(X_t|X_{t-1})=\varphi X_{t-1} \tag{15.3.1651}$$

Therefore:

$$\hat{X}_{t+1}=\mathrm{E}(X_{t+1}|X_t)=\varphi X_t \tag{15.3.1652}$$

The forecasts are then obtained recursively:

$$\hat{X}_{t+2}=\mathrm{E}(X_{t+2}|X_t)=\varphi\mathrm{E}(X_{t+1}|X_t)=\varphi^2 X_t \tag{15.3.1653}$$

And therefore in a more general way:

$$\boxed{\hat{X}_{t+k}=\varphi^k X_t} \tag{15.3.1654}$$

and so when k becomes very large, then we have:

$$\boxed{\hat{X}_{t+k}\rightarrow 0} \tag{15.3.1655}$$

In other words, for a high order k, the AR(1) model provides as conditional forecasting mean... the mathematics average (history) of the process. When the conditional mean is zero, then we say in the field of time series analysis that the « *mean is orthogonal to any past* ».

So as we can see it, the ARMA process has a mean that has an exponentially decreasing type of memory because of the factor φ that is at the power of k in prior-previous relation. While a MA process type that has a function that cut the temporal memory to a value q (cutoff of q periods). These two processes are therefore considered as short memory process.

15.3.13.4.4 ARIMA(p,d,q) Autoregressive non-seasonal integrated moving average processes

The time series models view previously are in reality just special cases of a more general empirical model that is named "AutoRegressive Integrated Moving Average (ARIMA)" also known as "Box-Jenkins models".

This model assumes that the time series is generated by a random process (Brownian or other) and that future values are related to past errors.

However, this model has an important limitation, and the fact that we find through this generalization the exponential smoothing means that they also have the same limitation: the time series must be stationary. So to recap, this means that moments like mean or variance and correlation must be constant over time.

Remark

In 11970 (holocene calendar) George Box and Gwilym Jenkins popularized ARIMA (Autoregressive Integrated Moving Average) models in their seminal textbook, *Time Series Analysis: Forecasting and Control*. Technically, the forecasting technique described in the text is an ARIMA model, however many forecasters (including the author) use the phrases "ARIMA models" and "Box-Jenkins models" interchangeably.

An ARIMA model is often classified under the notation:

$$\text{ARIMA}(p,d,q) \tag{15.3.1656}$$

where p is the number of autoregressive terms, d the number of non-seasonals differences (order of integration) and q the number of terms of errors (moving average) in the prediction equation.

Specifically for a model as $\text{ARIMA}(1,0,12)$ the trick to remember the parameters is to see the content of the parenthesis as:

$$\boxed{\text{ARIMA}(p,d,q)=\text{ARIMA}(\text{AR},\text{I},\text{MA})} \tag{15.3.1657}$$

AR
AutoRegressive (AR) for looking at past observations
I
Differencing (I or Integrated) for handling changes in data patterns
MA
Moving average (MA) for considering error terms

Explicitly the definition of the $\text{ARIMA}(p,d,q)$ is based on that of an $\text{ARIMA}(p',q)$ but using the expression of the ARMA process with the lags as introduced earlier before:

$$\left(1-\sum_{i=1}^{p'}\varphi_i L^i\right)X_t=\left(1+\sum_{i=1}^{q}\theta_i L^i\right)\varepsilon_t \tag{15.3.1658}$$

Before continuing we need absolutely to come back more in-deep about the concept of "unit root" in time series analysis that we have already briefly introduced earlier before (presenting it first quickly and very naively as a trend in the stochastic signal).

As the reader may know it at this level of the lecture of this textbook, many statistical tools does not apply if the variance of the variable that we are studying is not constant (especially the central limit theorem). In the case of times series analysis, we know that this is assimilated to the concept of "nonstationary" (i.e. the mean or the variance are not constant!).

As we will see, the idea of using ARIMA, is equivalent to apply a difference (or maybe several times d) using the backshift operator B and lag operator ∇ (also denoted L for reminder) already introduced just earlier above:

$$\nabla^d=(1-\text{B})^d \tag{15.3.1659}$$

to a non-stationary time series into a stationary time series.

Let us use a companion example to introduce the concept of unit root. Given the first order equation AR(1) (without the white noise):

$$X_t = \varphi_0 + \varphi_1 X_{t-1} \tag{15.3.1660}$$

We can use the method of iteration to show that when $\varphi_1 = 1$ the series is then given explicitly by:

$$X_t = \varphi_0 t + X_0 \tag{15.3.1661}$$

So there is no stead state. The time series will be trending if $\varphi_0 \neq 0$, and the initial value has permanent effect! In other words unit root implies persistence of shocks!

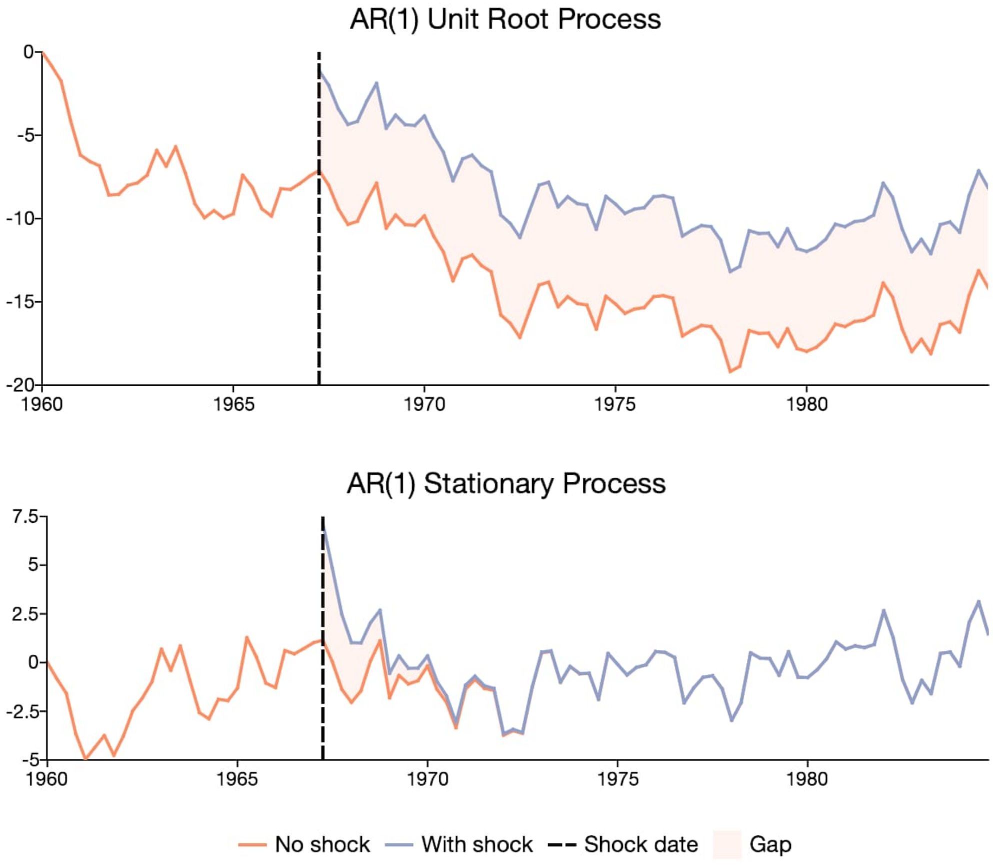

Figure 15.273: **Unit root process vs Stationary process**

Now consider the full AR(1) process:

$$X_t = \varphi_0 + \varphi_1 X_{t-1} + \varepsilon_t \tag{15.3.1662}$$

If $\varphi_1 = 1$ we say that the process has "unit root"[43] because in that case the series has again a trend that can again be expressed using the method of iteration:

$$X_t = \varphi_0 t + X_0 + (\varepsilon_1 + \varepsilon_2 + \ldots + \varepsilon_t) \tag{15.3.1663}$$

---

[43] Let us recall that if $\varphi_1 > 0$ then the process is explosive, if $\varphi_1 = 1$ then the process is a random walk, if $\varphi_1 < 1$ then the process is stationary.

If we consider that $\varepsilon_t = \mathcal{N}(0,\sigma_\varepsilon)$ then we have not only the process that is non-stationary in mean since, assuming $X_0 = 0$:

$$\mathrm{E}(X_t) = \mathrm{E}\left(\varphi_0 t + X_0 + t\varepsilon_t\right) = \varphi_0 t \tag{15.3.1664}$$

but it is also non-stationary in variance as (still assuming $X_0 = 0$):

$$\begin{aligned}\mathrm{V}(X_t) &= \mathrm{V}(X_{t-1}+\varepsilon_t)\\ \mathrm{V}(X_t) &= \mathrm{V}(X_{t-1})+\sigma_\varepsilon^2\\ \mathrm{V}(X_t) &= \mathrm{V}(X_{t-2}+\varepsilon_{t-1})+\sigma_\varepsilon^2\\ \mathrm{V}(X_t) &= \mathrm{V}(X_{t-2})+2\sigma_\varepsilon^2\end{aligned} \tag{15.3.1665}$$

repeating this for t steps:

$$\mathrm{V}(X_t) = \mathrm{V}(X_0)+t\sigma_\varepsilon^2 = t\sigma_\varepsilon^2 \tag{15.3.1666}$$

Which means that the standard deviation of the process increases with time $\propto \sqrt{t}$ (according also to Bachelier speculation model result!), and therefore not stationary!

However the above series has the stochastic part that is stationary and shocks have transitory effects. We say that the process is "mean reverting". Also we know that the process has an "attractor", namely the mean $X_0 + \varphi_0 t$.

In short, the unit root process is not stationary!

Remark

The Wiener process (random walk) is a special case of unit root process, which assumes $\varphi_1 = 1, \varphi_0 = 0$. This process is not trending because $\varphi_0 = 0$, however it is still non-stationary because of time-varying standard deviation $\propto \sqrt{t}$. If $\varphi_0 \neq 0$ we can say that it's a random walk with drift as we already know.

Let us now prove that the ACF function of a unit root series decreases to zero linearly and slowly.

For this let us compute first the covariance between X_t and X_{t-k}:

$$\mathrm{cov}(X_t,X_{t-k}) = \mathrm{E}[(X_t-X_0)(X_{t-k}-X_0)] = \mathrm{E}[(\varepsilon_1+\varepsilon_2+\ldots+\varepsilon_t)(\varepsilon_1+\varepsilon_2+\ldots+\varepsilon_{t-k})] = (t-k)\sigma_\varepsilon^2 \tag{15.3.1667}$$

and the autocorrelation is then given by:

$$\rho_t = \frac{\mathrm{cov}(X_t,X_{t-k})}{\sqrt{\mathrm{V}(X_t)\mathrm{V}(X_{t-k})}} = \frac{(t-k)\sigma_\varepsilon^2}{\sqrt{t\sigma_\varepsilon^2\cdot(t-k)\sigma_\varepsilon^2}} = \frac{t-k}{\sqrt{t(t-k)}} = \sqrt{\frac{t-k}{t}} \tag{15.3.1668}$$

which dies out very slowly with k.

Now let us recall that using the lag operator, the white noise can be rewritten:

$$(1-\mathrm{B})X_t = \varepsilon_t \tag{15.3.1669}$$

The equation:

$$1-\mathrm{B}=0 \tag{15.3.1670}$$

has the root $\mathrm{B}=1$ what is named the "unit root".

A time series possibly has multiple unit roots. For example, consider the series with two unit roots:

$$\begin{aligned}&(1-\mathrm{B})(1-\mathrm{B})X_t=\varepsilon_t\\ \Rightarrow\quad&(1-2\mathrm{B}+\mathrm{B}^2)X_t=\varepsilon_t\\ \Rightarrow\quad&X_t=2\mathrm{B}X_t-\mathrm{B}^2X_t+\varepsilon_t\\ \Rightarrow\quad&X_t=2X_{t-1}-X_{t-2}+\varepsilon_t\end{aligned} \tag{15.3.1671}$$

So the AR(2) process:

$$X_t=2X_{t-1}-X_{t-2}+\varepsilon_t \tag{15.3.1672}$$

is obviously non-stationary and has two unit roots.

So as we know, we cannot apply the ARMA model to unit root processes, unless we transform the series into stationary series. And we already know that we can do this by applying the lag operator $\nabla=1-\mathrm{B}$.

A process that has been made stationary by applying only time the backshift operator is said to be "integrated of first order" $I(1)$. More generally, a time series is integrated of order d, $I(d)$, if it contains d unit roots (i.e. if we need to take difference d times before it becomes stationary).

So now remember the following ARMA notation:

$$\left(1-\sum_{i=1}^{p'}\varphi_i\mathrm{B}^i\right)X_t=\left(1+\sum_{i=1}^{q}\theta_i\mathrm{B}^i\right)\varepsilon_t \tag{15.3.1673}$$

Assume now that the polynomial $\left(1-\sum_{i=1}^{p'}\alpha_i\mathrm{B}^i\right)$ has a unit root $(1-\mathrm{B})$ of multiplicity d. Then it can be rewritten as:

$$\left(1-\sum_{i=1}^{p'}\varphi_i\mathrm{B}^i\right)=\left(1-\sum_{i=1}^{p'-d}\phi_i\mathrm{B}^i\right)(1-\mathrm{B})^d \tag{15.3.1674}$$

An ARIMA(p,d,q) process expresses this polynomial factorization property with $p=p'-d$, and is given by:

$$\boxed{\mathrm{ARIMA}(p,d,q)=\mathrm{ARIMA}(\mathrm{AR},\mathrm{I},\mathrm{MA})=\left(1-\sum_{i=1}^{p'-d}\phi_i\mathrm{B}^i\right)(1-L)^dX_t=\left(1+\sum_{i=1}^{q}\theta_i\mathrm{B}^i\right)\varepsilon_t} \tag{15.3.1675}$$

and thus can be thought as a special case of an ARMA$(p+d,q)$ process having the autoregressive polynomial with d unit roots. In other words, ARIMA(p,d,q) model means we take difference d times and then apply the ARMA(p,q) model to the differences series.

That previous relation is sometimes (sadly...) denoted:

$$\Phi(\text{B})(1-\text{B})^d X_t = \Theta(\text{B})\varepsilon_t \tag{15.3.1676}$$

The explicit identification of the factorization of the autoregression polynomial into factors as above, can be extended to other cases, firstly to apply to the moving average polynomial and secondly to include other special factors. For example, having a factor $(1-\text{B}^s)$ in a model is one way of including a non-stationary seasonality of period s into the model.

✍**Examples:**

E1. Average: ARIMA$(0,0,0)$ with constant (white noise):

$$X_t = \mu + \varepsilon_t \tag{15.3.1677}$$

E2. Drift: ARIMA$(0,1,0)$ with constant (random walk):

$$X_t = \mu + X_{t-1} + \varepsilon_t \tag{15.3.1678}$$

When μ is taken as 0 we have then:

$$X_t = X_{t-1} + \varepsilon_t \tag{15.3.1679}$$

and this is named in some statistical packages as a "naive forecast"

E3. ARMA: ARIMA$(1,0,1)$

E4. Single Exponential Smoothing: ARIMA$(0,1,1)$ without constant:

$$X_{t+1} = X_t + \alpha\varepsilon \tag{15.3.1680}$$

As we have seen in a remark during our study of the single exponential smoothing model.

E5. Holt's additive Double Exponential Smoothing: ARIMA$(0,2,2)$

$$X_t = X_{t-1} + X_{t-2} + (\alpha+\beta-2)\varepsilon_{t-1} + (1-\alpha)\varepsilon_{t-2} + \varepsilon_t \tag{15.3.1681}$$

E6. Holt & Winters Exponential Smoothing (multiplicative): no ARIMA equivalent to our knowledge

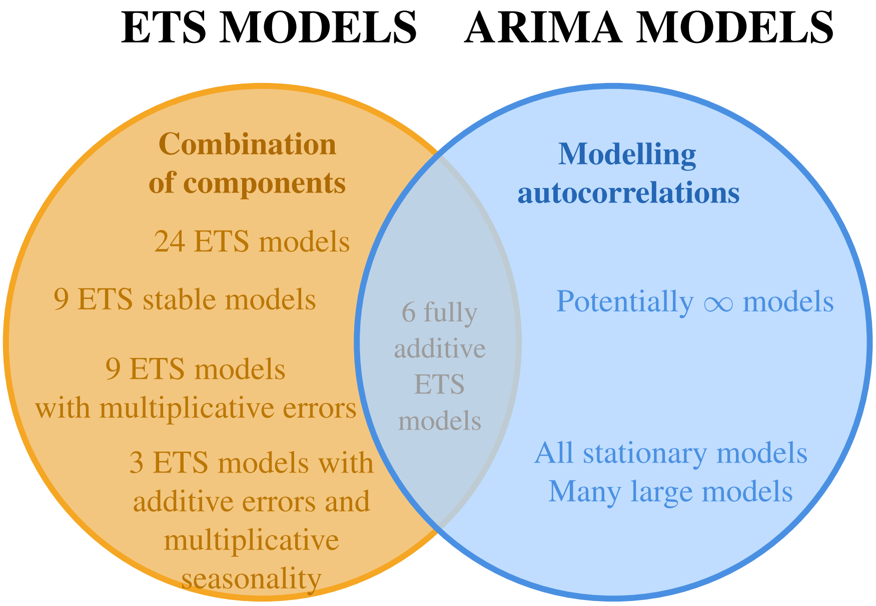
E7. Holt & Winters Exponential Smoothing (additive) : SARIMA$(0,1,m+1)(0,1,0)$

Or another type of equivalence in the shape of table:

ETS model	ARIMA model	Parameters
ETS $(\text{A},\text{N},\text{N})$	$\text{ARIMA}(0,1,1)$	$\theta_1=\alpha-1$
$\text{ETS}(\text{A},\text{A},\text{N})$	$\text{ARIMA}(0,2,2)$	$\theta_1=\alpha+\beta-2$
		$\theta_2=1-\alpha$
$\text{ETS}\,(\text{A},\text{A}_d,\ \text{N})$	$\text{ARIMA}(1,1,2)$	$\phi_1=\phi$
		$\theta_1=\alpha+\phi\beta-1-\phi$
		$\theta_2=(1-\alpha)\phi$
$\text{ETS}(\text{A},\text{N},\text{A})$	$\text{ARIMA}(0,1,m)(0,1,0)_m$	
$\text{ETS}(\text{A},\text{A},\text{A})$	$\text{ARIMA}(0,1,m+1)(0,1,0)_m$	
$\text{ETS}\,(\text{A},\text{A}_d,\ \text{A})$	$\text{ARIMA}(0,1,m+1)(0,1,0)_m$	

Table 15.65: **Some equivalence between ARIMA and ETS models**

Or using a Venn diagram with different type of similarities depicted:



ETS MODELS
ARIMA MODELS
Combination of components
24 ETS models
9 ETS stable models
9 ETS models with multiplicative errors
3 ETS models with additive errors and multiplicative seasonality
6 fully additive ETS models
Modelling autocorrelations
Potentially ∞ models
All stationary models
Many large models

Figure 15.274: **Summary of ETS models vs ARIMA models**

As the last example is a SARIMA, it may be the time now to introduce that latter! First the reader should know that there is not only one SARIMA model but a multiple! Normally we start by introducing:

$$\text{SARIMA}(s,p,d,q)=\Phi(\text{B})(1-\text{B}^s)(1-\text{B})^d X_t=\Theta(\text{B})(1-\text{B}^s)(1-\text{B})^d\varepsilon_t \qquad (15.3.1682)$$

and all others $\text{SARIMA}(s,p,d,q)$ are subsets of that latter like:

- $\text{SARIMA}(s,p,d,q)=\Phi(\text{B})(1-\text{B}^s)X_t=\Theta(\text{B})(1-\text{B})^d\varepsilon_t$
- $\text{SARIMA}(s,p,d,q)=\Phi(\text{B})(1-\text{B})^d X_t=\Theta(\text{B})(1-\text{B}^s)\varepsilon_t$
- $\text{SARIMA}(s,p,d,q)=\Phi(\text{B})X_t=\Theta(\text{B})(1-\text{B}^s)(1-\text{B})^d\varepsilon_t$
- $\text{SARIMA}(s,p,d,q)=\Phi(\text{B})(1-\text{B}^s)(1-\text{B})^d X_t=\Theta(\text{B})\varepsilon_t$

- $\text{SARIMA}(s,p,d,q)=\Phi(\text{B})(1-\text{B}^s)(1-\text{B})^d X_t=\Theta(\text{B})(1-\text{B}^s)\varepsilon_t$
- $\text{SARIMA}(s,p,d,q)=\Phi(\text{B})(1-\text{B}^s)(1-\text{B})^d X_t=\Theta(\text{B})(1-\text{B})^d\varepsilon_t$
- ... and so on (a total of 9 possible combinations)

However there exist a more general version given by the multiplicative seasonal ARIMA model and commonly defined as:

$$\boxed{\text{SARIMA}\underbrace{(p,d,q)}_{\substack{\text{Non-seasonal}\\ \text{part of the model}}}\times\underbrace{(P,D,Q)_s}_{\substack{\text{Seasonal part}\\ \text{of the model}}}=\Phi_P(\text{B}^s)\phi_p(\text{B})(1-\text{B})^d(1-\text{B}^s)^D(X_t-\mu)=\theta_q(\text{B})\Theta_Q(\text{B}^s)\varepsilon_t} \tag{15.3.1683}$$

Or also commonly written:

$$\text{SARIMA}(p,d,q)\times(P,D,Q)_s=\Phi_P(\text{B}^s)\phi_p(\text{B})\nabla_s^D\nabla^d Z_t=\theta_q(\text{B})\Theta_Q(\text{B}^s)\varepsilon_t \tag{15.3.1684}$$

where $s=$ number of periods per season, the uppercase notation for the seasonal parameters of the model, and lowercase notation for the non-seasonal parameters of the model. The seasonal part of the model consists of terms that are very similar to the non-seasonal components of the model, but they involve backshifts of the seasonal period.

Expliciting all other terms, we have:

- $\Phi_P(\text{B}^s)=(1-\Phi_1\text{B}^s-\ldots-\Phi_P\text{B}^{sP})=1-\sum_{i=1}^P\Phi_i\text{B}^{si}$ is the seasonal AR operator of order P;
- $\phi_p=(1-\phi_1\text{B}-\ldots-\phi_p\text{B}^p)=1-\sum_{i=1}^p\phi_i\text{B}^i$ is the regular AR operator of order p;
- $\nabla_s^D=(1-\text{B}^s)^D$ represents the seasonal differences and $\nabla^d=(1-\text{B})^d$ the regular differences;
- $\Theta_Q(\text{B}^s)=(1-\Theta_1\text{B}^s-\ldots-\Theta_Q\text{B}^{sQ})=1-\sum_{i=1}^Q\Theta_i\text{B}^{si}$ is the seasonal moving average operator of order Q;
- $\theta_q(\text{B})=(1-\theta_1\text{B}-\ldots-\theta_q\text{B}^q)=1-\sum_{i=1}^q\theta_i\text{B}^i$ is the regular moving average operator of order q;
- ε_t is the usual white noise

The definition may not be very clear for a significant percentage of readers (according to our experience of teaching the subject). So let us see an example:

✍**Example:**

Consider we want to explicit:

$$\text{SARIMA}(0,2,1)\times(0,0,1)_{12}=\Phi_0(\text{B}^{12})\phi_0(\text{B})(1-\text{B})^2(1-\text{B}^{12})^0 Z_t=\theta_1(\text{B})\Theta_1(\text{B}^{12})\varepsilon_t \tag{15.3.1685}$$

where:

$$\phi_0(\mathrm{B})=1 \qquad \Phi_0(\mathrm{B}^{12})=1 \qquad \theta_1(\mathrm{B})=1+\theta_1\mathrm{B} \qquad \Theta_1(\mathrm{B}^{12})=1+\Theta_1\mathrm{B}^{12} \tag{15.3.1686}$$

Therefore:

$$\text{SARIMA}(0,2,1)\times(0,0,1)_{12}=1\cdot 1\cdot(1-\mathrm{B})^2(1-\mathrm{B}^{12})Z_t=(1+\theta_1\mathrm{B})(1+\Theta_1\mathrm{B}^{12})\varepsilon_t \tag{15.3.1687}$$

And the result is:

$$\text{SARIMA}(0,2,1)\times(0,0,1)_{12}=Z_t-2Z_{t-1}+Z_{t-2}=\varepsilon_t+\Theta\varepsilon_{t-12}+\theta_1\varepsilon_{t-1}+\theta_1\Theta_1\varepsilon_{t-13} \tag{15.3.1688}$$

So we can summarize all the models seen so far by the following (quite ugly) table:

Process	**Model**	**Stationary Condition**
MA(q)	$X_t=\left(1+\sum_{i=1}^{q}\theta_i\mathrm{B}^i\right)\varepsilon_t$	None: MA(q) process is stationary by construction
AR(p)	$X_t=\left(\sum_{k=1}^{p}\varphi_k\mathrm{B}^k\right)X_t+\varepsilon_t$	$\sum_{i=1}^{p}\varphi_i<1$
ARMA(p,q)	$\left(1-\sum_{i=1}^{p}\varphi_i\mathrm{B}^i\right)X_t=\left(1+\sum_{i=1}^{q}\theta_i\mathrm{B}^i\right)\varepsilon_t$	AR(p) component must be stationary
ARIMA(p,d,q)	$\left(1-\sum_{i=1}^{p'-d}\phi_i\mathrm{B}^i\right)(1-\mathrm{B})^dX_t=\left(1+\sum_{i=1}^{q}\theta_i\mathrm{B}^i\right)\varepsilon_t$	The AR(p) component is stationary after d integration
SARIMA$(p,d,q)(P,D,Q)_m$	$\Phi_P(\mathrm{B}^s)\phi_p(\mathrm{B})\nabla_s^D\nabla^dZ_t=\theta_q(\mathrm{B})\Theta_Q(\mathrm{B}^s)\varepsilon_t$	The AR(p) component is stationary after d integration

Table 15.66: Summary of ARIMA models

The ARIMA models (and thereafter SARIMO too!) are confined in the range of integer order d. Therefore, in order to capture the property of the fractional systems, the "Autoregressive Fractional Integrated Moving Average" ARFIMA(p,d,q) model is thereby proposed a natural way by using binomial expansion for any real number d with Gamma function. Indeed, if you remember the binomial theorem (see section Algebra page 1364):

$$(a+b)^n=\sum_{p=0}^{n}C_p^n a^{n-p}b^p \tag{15.3.1689}$$

Hence:

$$(1-\mathrm{B})^d=\sum_{p=0}^{d}C_p^d(-\mathrm{B})^p=\sum_{p=0}^{d}\frac{d!}{p!(d-p)!}(-\mathrm{B})^p \tag{15.3.1690}$$

And using the Gamma function (see section Differential and Integral Calculus page 1574) that extends then d to real values (and not only to integers anymore):

$$(1-\mathrm{B})^d=\sum_{p=0}^{d}\frac{\Gamma(d+1)}{\Gamma(d+1)\Gamma(d+1-p)!}(-\mathrm{B})^p \tag{15.3.1691}$$

So finally ARFIMA(p,d,q) model shares the same form of representation as the ARIMA(p,d,q) process, at the difference that the parameter d, is allowed to take non-integer values.

Remark

It is a commonly held myth that ARIMA models are more general than exponential smoothing. While linear exponential smoothing models are all special cases of ARIMA models, the non-linear exponential smoothing models have no equivalent ARIMA counterparts. On the other hand, there are also many ARIMA models that have no exponential smoothing counterparts. In particular, all ETS models are non-stationary, while some ARIMA models are stationary.

15.3.13.4.5 ARCH-GARCH processes

The modelling of volatility is an essential issue for many fields of study of contemporary finance (and also other fields!). The simple fact that portfolio management relies mostly on mean-variance algorithms underscores the importance of constructing correctly specified variance indicators. Options management is also based on a rigorous study of the evolution of the variance!

The financial time series present a number of characteristic features that need to be emphasized before moving on to their modelling. These main facts are as we already know:

- The returns are not autocorrelated (thus the autocorrelation between the return on the date t and the date $t-1$ is a financial aberration) and this is even more pronounced as the markets are liquefied. However some markets continue to exhibit some autocorrelation
- In general, the volatility of an asset increases when the preceding returns are negative. We are also talking in this case of "leverage".
- The volatility of an asset generally displays periods of significant volatility and other periods of low volatility (corresponding to the so-named "bear" and "bull" market).
- In the financial time series, volatility is a function of time whereas in the ARIMA processes the conditional volatility is assumed as constant.

This list is of course not exhaustive. However, it has the merit of highlighting the fact that when one wishes to get out of the standards of finance (the random walk of the theories of efficiency and option evaluation), it is necessary to consider all of these properties with great care.

In essence, volatility is an unobservable phenomenon. It is then necessary to construct a certain number of empirical statistical indicators (like the famous various "indices") making it possible to judge the volatility of the returns. The fact that this type of index know an obvious success only underscores the need for financial markets to have instruments for measuring volatility.

For this purpose, the jungle of empirical families of ARCH (AutoRegressive Conditional Heteroskedasticity) processes aims to account for the fact that the conditional variance is not constant and propose a way of estimating it. It will obviously be necessary as always to use this model with suspicion because it is possible that the volatility is not constant over time but that the empirical models of the family ARCH or GARCH (Generalized Autoregressive Conditional Heteroskedasticity) do not capture this effect, or that even conclude in some cases to lack of temporal dependence of returns!

15.3.13.4.5.1 ARCH (Autoregressive Conditional Heteroskedasticity)

To introduce the ARCH(q) let us denote by ε_t the error term that will be assumed to be modelled by a stochastic term of white noise type z_t with a time-dependent volatility such that:

$$\varepsilon_t = \sigma_t z_t = \mathcal{N}(0, \sigma_t^2) \tag{15.3.1692}$$

In practice ε_t is the residual of the returns in relation to a given mean or median (the choice of the latter varies according to the practitioners). In most theoretical framework this average or median is taken as being zero (all the values being centered reduced), in the practical case one takes either the empirical average of the returns in parametric models or the median in non-parametric models, or the difference of two successive returns. In short, whatever the statistical software used, the result will be more or less very different depending on the initial choice.

The empirical idea is then to model the variance by:

$$\sigma_t^2 = \alpha_0 + \alpha_1\varepsilon_{t-1}^2 + \ldots + \alpha_q\varepsilon_{t-q}^2 = \alpha_0 + \sum_{i=1}^{q} \alpha_i \varepsilon_{t-1}^2 \tag{15.3.1693}$$

where:

$$\alpha_0 > 0 \qquad \alpha_i \geq 0 \tag{15.3.1694}$$

Remark

Notice that the model assumes that positive and negative shocks have the same effects on volatility because it depends on the square of the previous shocks. In practice, it is well known that the price of a financial asset responds differently to positive and negative shocks...

This is often summarized in the following form:

$$\begin{gathered}\varepsilon_t = \sigma_t z_t = \mathcal{N}(0, \sigma_t^2)\\ \sigma_t^2 = \alpha_0 + \sum_{i=1}^{q} \alpha_i \varepsilon_{t-1}^2\end{gathered} \tag{15.3.1695}$$

or with another common notation:

$$\begin{gathered}X_t = \sqrt{h_t} z_t = \mathcal{N}(0, h_t)\\ h_t^2 = \omega_0 + \sum_{i=1}^{q} \omega_i X_{t-1}^2\end{gathered} \tag{15.3.1696}$$

But we prefer in this textbook the following explicit notation:

$$\boxed{\begin{aligned}&X_t = \sigma_t z_t = \mathcal{N}(0, \sigma_t^2)\\ &\text{ARCH}(q) = \sigma_t^2 = \text{V}(X_t|X_{t-1}) = \omega_0 + \sum_{i=1}^{q} \omega_i X_{t-i}^2 \qquad \omega_0 > 0, \omega_i \geq 0\end{aligned}} \tag{15.3.1697}$$

So the conditional variance is indeed dependent of time (only!). Specialists like to say (according to the specialized vocabulary we have seen in the Statistics section) that an ARCH process is (conditionally) heteroscedastic whereas an ARIMA process is (conditionally) homoscedastic.

In the case of an ARCH(1), that is to say a process defined by:

$$\begin{aligned} X_t &= \sigma_t \varepsilon_t \\ \sigma_t^2 &= \omega_0 + \omega_1 X_{t-1}^2 \end{aligned} \tag{15.3.1698}$$

We then have for the (unconditional) expected mean considering the independence of the variables σ_t and ε_t:

$$\mathrm{E}(X_t) = \mathrm{E}(\sigma_t \varepsilon_t) = \mathrm{E}(\sigma_t) \underbrace{\mathrm{E}(\varepsilon_t)}_{=0} = 0 \tag{15.3.1699}$$

and this for any t (you have to remember that as later we will use the fact that $\mathrm{E}(X_{t-1}) = 0$).

For the (unconditional) variance, first demonstrate the following result:

Knowing that for a random variable X we have the Huygens relation (see section Statistics page 593) it comes:

$$\mathrm{V}(X_t) = \mathrm{V}(\sigma_t \varepsilon_t) = \mathrm{E}(\sigma_t^2 \varepsilon_t^2) - \mathrm{E}(\sigma_t \varepsilon_t)^2 \tag{15.3.1700}$$

Now we use the independence of the variables σ_t and ε_t:

$$\mathrm{V}(X_t) = \mathrm{E}(\sigma_t^2)\mathrm{E}(\varepsilon_t^2) - \mathrm{E}(\sigma_t)^2 \underbrace{\mathrm{E}(\varepsilon_t)^2}_{=0} = \mathrm{E}(\sigma_t^2)\mathrm{E}(\varepsilon_t^2) \tag{15.3.1701}$$

Knowing that obviously:

$$\mathrm{V}(\varepsilon_t) = \mathrm{E}(\varepsilon_t^2) - \mathrm{E}(\varepsilon_t)^2 = \mathrm{E}(\varepsilon_t^2) \tag{15.3.1702}$$

we then get for an ARCH(1) process:

$$\mathrm{V}(\varepsilon_t) = \mathrm{E}(\sigma_t^2)\mathrm{E}(\varepsilon_t^2) = \mathrm{E}(\sigma_t^2)\mathrm{V}(\varepsilon_t) = \mathrm{E}(\sigma_t^2) \tag{15.3.1703}$$

We then have:

$$\mathrm{V}(X_t) = \mathrm{E}(\sigma_t^2) = \mathrm{E}(\omega_0 + \omega_1 X_{t-1}^2) = \omega_0 + \omega_1 \mathrm{E}(X_{t-1}^2) = \omega_0 + \omega_1 \mathrm{E}(X_{t-1}^2) \tag{15.3.1704}$$

And we have using again the Huygens relation:

$$\mathrm{V}(X_{t-1}) = \mathrm{E}(X_{t-1}^2) - \underbrace{\mathrm{E}(X_{t-1})^2}_{=0} = \mathrm{E}(X_{t-1}^2) \tag{15.3.1705}$$

the following result:

$$\mathrm{V}(X_t) = \omega_0 + \omega_1 \mathrm{V}(X_{t-1}) \tag{15.3.1706}$$

Remark

The latter relation implies that we can estimate ω_0 and ω_1 by regressing $\mathrm{V}(X_t)$ onto an intercept term and $\mathrm{V}(X_{t-1})$. It also implies that $\mathrm{V}(X_t)$ follows an AR(1) process!

And therefore:

$$\begin{aligned} \mathrm{V}(X_t) &= \omega_0 + \omega_1 \mathrm{V}(X_{t-1}) \\ \mathrm{V}(X_{t-1}) &= \omega_0 + \omega_1 \mathrm{V}(X_{t-2}) \\ \mathrm{V}(X_{t-2}) &= \omega_0 + \omega_1 \mathrm{V}(X_{t-3}) \end{aligned} \tag{15.3.1707}$$

Hence:

$$\begin{aligned}\mathrm{V}(X_t)&=\omega_0+\omega_1(\omega_0+\omega_1(\omega_0+\omega_1\mathrm{V}(X_{t-3})))\\&=\omega_0(1+\omega_1+\omega_1^2)+\omega_1^3\mathrm{V}(X_{t-3})\end{aligned} \tag{15.3.1708}$$

So finally we get the general relation:

$$\mathrm{V}(X_t)=\omega_0\sum_{i=0}^{n}\omega_1^i+\omega_1^{n+1}\mathrm{V}(X_{t-(n+1)}) \tag{15.3.1709}$$

In the case where $|\omega_1|<1$, we have when $n\rightarrow+\infty$:

$$\mathrm{V}(X_t)_{n\rightarrow+\infty}\underset{|\omega_1|<1}{=}\omega_0\sum_{i=0}^{n}\omega_1^i \tag{15.3.1710}$$

And using the result demonstrated in the section of Sequences and Series during our study of geometric series (page 1679):

$$\sum_{i=0}^{n}x^i\underset{|x|<1}{=}\frac{1}{1-x} \tag{15.3.1711}$$

We then have:

$$\mathrm{V}(X_t)_{n\rightarrow+\infty}\underset{|\omega_1|<1}{=}\frac{\omega_0}{1-\omega_1} \tag{15.3.1712}$$

Thus, in this special case, we will have a stationary process because the variance will be finite and independent of time!

What has just been said about ARCH(1) can be generalized in the case of ARCH(p) processes where the (unconditional) expected mean remains zero and the variance (unconditional) in the case where:

$$\left|\sum_{i=1}^{p}\omega_i\right|<1 \tag{15.3.1713}$$

is then equal to:

$$\mathrm{V}(X_t)=\frac{\omega_0}{1-\displaystyle\sum_{i=1}^{p}\omega_i} \tag{15.3.1714}$$

Event without knowing the exact expression of the fourth moment κ_1 (i.e. kurtosis as defined in the section Statistics page 636) of an ARCH(p) process, it is possible to prove quite easily that latter is $\kappa_1=\mu_4/\sigma^4\geq 3$ (as we have proved that for a standard Normal distribution at page 705 that we have $\kappa_1=3$)!

Proof 15.7.2. Let us first recall that for an ARCH(p) process, we have by definition:

$$\varepsilon_t|X_{t-1},X_{t-2},\ldots=\mathcal{N}(0,\sigma_t^2) \tag{15.3.1715}$$

That means that the conditional distribution of X_t is Normal (and without loss of generality we can consider $\sigma_t = 1$), and we know that for the standardized Normal distribution, we have:

$$\kappa_1 = \frac{\frac{1}{n}\sum_{i=1}^{n}(x_i - \bar{x})^4}{\left(\sqrt{\frac{1}{n}\sum_{i=1}^{n}(x_i-\bar{x})^2}\right)^4} = \frac{\frac{1}{n}\sum_{i=1}^{n}x_i^4}{\left(\sqrt{\frac{1}{n}\sum_{i=1}^{n}x_i^2}\right)^4} = \frac{\mathrm{E}(X^4)}{\mathrm{E}(X^2)^2} = \frac{\mu_4}{\sigma^4} = 3 \tag{15.3.1716}$$

Therefore, denoting $\mathcal{I}_t$ the set of all values of X_t taken before time t such that:

$$\mathcal{I}_{t-1} = \{X_{t-i}, i > 0\} \tag{15.3.1717}$$

We then have:

$$\kappa_1 = \frac{\mathrm{E}(X_t^4|\mathcal{I}_{t-1})}{\mathrm{E}(X_t^2|\mathcal{I}_{t-1})^2} = 3 \tag{15.3.1718}$$

Hence:

$$\mathrm{E}(X_t^4|\mathcal{I}_{t-1}) = 3\left(\mathrm{E}(X_t^2|\mathcal{I}_{t-1})\right)^2 \tag{15.3.1719}$$

Let us take the expected mean on the both sides:

$$\mathrm{E}\left(\mathrm{E}(X_t^4|\mathcal{I}_{t-1})\right) = 3\mathrm{E}\left(\left(\mathrm{E}(X_t^2|\mathcal{I}_{t-1})\right)^2\right) \tag{15.3.1720}$$

and now using the iterated conditional mean for the left term (see section Statistics page 501), we get:

$$\mathrm{E}(X_t^4) = 3\mathrm{E}\left(\left(\mathrm{E}(X_t^2|\mathcal{I}_{t-1})\right)^2\right) \tag{15.3.1721}$$

Let us now recall that we have proved the Jensen inequality (see section Statistics page 576) was given for a convex function by:

$$f(\mathrm{E}(X)) \le \mathrm{E}(f(X)) \tag{15.3.1722}$$

Therefore (considering the $(\ldots)^2$ as the application $f(\ldots)$ and $X = \mathrm{E}(X_t^2|\mathcal{I}_{t-1})$), we have for the right term of the equality:

$$\left(\mathrm{E}(\mathrm{E}(X_t^2|\mathcal{I}_{t-1}))\right)^2 \le \mathrm{E}\left(\left(\mathrm{E}(X_t^2|\mathcal{I}_{t-1})\right)^2\right) \tag{15.3.1723}$$

Hence:

$$\mathrm{E}(X_t^4) \ge 3\left(\mathrm{E}(\mathrm{E}(X_t^2|\mathcal{I}_{t-1}))\right)^2 \tag{15.3.1724}$$

Using again iterated conditional mean, this can be written:

$$\mathrm{E}(X_t^4) \ge 3\mathrm{E}(X_t^2)^2 \tag{15.3.1725}$$

So finally the unconditional kurtosis is:

$$\boxed{\kappa_1^{\text{ARCH}(p)} = \frac{\mathrm{E}(X_t^4)}{\mathrm{E}(X_t^2)^2} \ge 3} \tag{15.3.1726}$$

So the ARCH(p) process have a kurtosis excess[44]!

■ Q.E.D.

---

[44] Note that a similar reasoning and result applies to GARCH processes

15.3.13.4.5.2 GARCH (Generalized Autoregressive Conditional Heteroskedasticity)

The ARCH model is appropriate when the error variance in a time series follows an autoregressive (AR) model; if an autoregressive moving average (ARMA) model is assumed for the error variance, the model is a generalized autoregressive conditional heteroskedasticity (GARCH) model.

In the case of a GARCH(p, q) process, we have:

$$\begin{aligned}\varepsilon_t&=\sigma_t z_t\\ \text{GARCH}(q,p)=\sigma_t^2&=\alpha_0+\sum_{i=1}^{q}\alpha_i\varepsilon_{t-i}^2+\sum_{i=1}^{p}\beta_i\sigma_{t-i}^2 \qquad \alpha_0>0,\alpha_i\geq 0,\beta_i\geq 0\end{aligned} \tag{15.3.1727}$$

The GARCH$(1, 1)$ is then given by:

$$\begin{aligned}\varepsilon_t&=\sigma_t z_t\\ \sigma_t^2&=\alpha_0+\alpha_1\varepsilon_{t-1}^2+\beta_1\sigma_{t-1}^2\end{aligned} \tag{15.3.1728}$$

which is also often written as following:

$$\begin{aligned}\varepsilon_t&=\sigma_t z_t\\ \sigma_t^2&=\alpha_0+\alpha\varepsilon_{t-1}^2+\beta\sigma_{t-1}^2\end{aligned} \tag{15.3.1729}$$

Remark

Notice that as for the ARCH, the GARCH model assumes that positive and negative shocks have the same effects on volatility because it depends on the square of the previous shocks. In practice, it is well known that the price of a financial asset responds differently to positive and negative shocks...

In practice we will try to determine the different parameters α_0, α, β knowing that the RiskMetrics methodology of JP Morgan recommends (at the day we write these lines...) to use the GARCH$(1, 1)$ model with the conditions:

$$\alpha+\beta=1 \tag{15.3.1730}$$

$$\alpha_0=0 \tag{15.3.1731}$$

and as in finance we normally work with returns, so we end up writing (the reader will notice that in the second line we find an expression similar to that of the simple exponential smoothing model - there is just a random factor more - so the GARCH (1,1) is just a simple generalization of an EWMA process):

$$\begin{aligned}r_t&=\sigma_t z_t\\ \sigma_t^2&=(1-\beta)r_{t-1}^2+\beta\sigma_{t-1}^2\end{aligned} \tag{15.3.1732}$$

What we find again often under the following notation:

$$\begin{aligned}r_t&=\sqrt{h_t}z_t\\ h_t&=(1-\beta)r_{t-1}^2+\beta\sigma_{t-1}\end{aligned} \tag{15.3.1733}$$

and if the mean return is not zero, then we write:

$$\begin{aligned}r_t&=\mu_t+\sqrt{h_t}z_t\\ h_t&=(1-\beta)r_{t-1}^2+\beta h_{t-1}\end{aligned} \tag{15.3.1734}$$

15.3.13.5 Forecasting Stationary Processes

Let us come back on projection techniques (forecasting) of ARIMA models. Let's start with a simple special case (that is in our opinion more educational) considering the process denoted $\text{AR}(1)$ and defined for recall by the relation (sum up over a given additive constant):

$$X_t = \varphi X_{t-1} + \varepsilon_t \tag{15.3.1735}$$

When we make a punctual estimate of a projection of this model, on h subsequent units of time, it is customary to write the punctual estimate value by different usual notations:

$$X_t(h) = \varphi X_{t-1} + \varepsilon_t \tag{15.3.1736}$$

where φ is obviously supposed to have been determined with known historical values. However, the projected point estimate is precisely an... estimate... !!!! We would have to know its mean. The simplest naive assumption is to use the conditional expectation of the forecast value, who led us for recall (see just earlier above page 7989) to the result:

$$\hat{X}_{t+h} = \varphi^h X_t \tag{15.3.1737}$$

which tends to 0 as h approaches infinity as we have already proved it. But remember that this $\text{AR}(1)$ is defined up to an additive constant (which is often the arithmetic mean or the median of known values of the time series), so in the general case it tends towards a constant!!!

On the way, notice that we explicitly have the forecast error that is given by:

$$e_t(h) = X_{t+h} - \hat{X}_t(h) = X_{t+h} - \varphi^h X_t \tag{15.3.1738}$$

And let us recall that we have proved earlier above that for $\text{AR}(1)$:

$$X_t = \varphi^h X_{t-h} + \sum_{k=0}^{h-1} \varphi^k \varepsilon_{t-k} \tag{15.3.1739}$$

And let us consider h big and $|\varphi| < 1$, then we have:

$$X_t \cong \sum_{l=0}^{+\infty} \varphi^k \varepsilon_{t-k} \tag{15.3.1740}$$

Therefore:

$$X_{t+h} \cong \sum_{k=0}^{+\infty} \varphi^k \varepsilon_{t+h-k} \tag{15.3.1741}$$

Given a $\text{MA}(\infty)$ process. Then:

$$\begin{aligned} e_t(h) = X_{t+h} - \hat{X}_t(h) = X_{t+h} - \varphi^h X_t \underset{\substack{|\varphi|<1 \\ h \to +\infty}}{\cong} & \sum_{k=0}^{+\infty} \varphi^k \varepsilon_{t+h-k} - \varphi^h \sum_{k=0}^{+\infty} \varphi^k \varepsilon_{t-k} \\ &= \varepsilon_{t+h} + \varphi \varepsilon_{t+h-1} + \ldots + \varphi^{h-1} \varepsilon_{t+1} + \varphi^h \varepsilon_t + \varphi^{h+1} \varepsilon_{t+1} + \ldots - \varphi^h \varepsilon_t - \varphi^{h+1} \varepsilon_{t-1} - \ldots \\ &= \varepsilon_{t+h} + \varphi \varepsilon_{t+h-1} + \varphi^2 \varepsilon_{t+h-2} + \ldots + \varphi^{h-1} \varepsilon_{t+1} \end{aligned} \tag{15.3.1742}$$

We notice that the forecast error $e_t(h)$ is a process of the type process MA$(h-1)$. Then it comes immediately form this last development:

$$\begin{aligned}&\mathrm{E}(e_t(h))=0\\&\mathrm{V}(e_t(h))=\sigma_\varepsilon^2(1+\varphi^2+\varphi^4+\ldots+\varphi^{2(h-1)})=\sigma_\varepsilon^2\frac{1-\varphi^{2h}}{1-\varphi^2}\end{aligned}\tag{15.3.1743}$$

where the sum of the square has been simplified using a result proved in the section Sequences and Series. Thus we see that the variance of the error forecast does not diverge (at least in the case of an AR (1)) and tends to a finite value (which is not the case of all processes!) when h approaches infinity provided that $\varphi<1$. The difficulty in practice is to select a technique to determine σ_ε^2 (there are a quantity of such techniques: adequacy, Monte Carlo, bootstrapping, Bayesian inference, etc.). This is why the practitioner should never limit himself to the use of a single statistical software to make projections, but at least three.

Why we speak again of that subject will you think maybe ??? For the simple reason that we always need a statistical prediction interval!!! Thus, given that we have a point estimator X_{t+1} which is the realization of the random variable of the forecasted value and its associated mean value $\hat{X}_{t+1}$, we can write:

$$X_{t+h}=\hat{X}_t(h)+e_t(h)\tag{15.3.1744}$$

and assume from the previous developments that the forecast error follows a Normal centered distribution:

$$\left.\begin{aligned}&\mathrm{E}(e_t(h))=0\\&\mathrm{V}(e_t(h))=\sigma_\varepsilon^2\frac{1-\varphi^{2h}}{1-\varphi^2}\end{aligned}\right\}\Rightarrow\text{Assumption: }e_t(h)=\mathcal{N}\left(0,\sigma_\varepsilon^2\frac{1-\varphi^{2h}}{1-\phi^2}\right)\tag{15.3.1745}$$

We then have a given confidence level if σ_ε^2 is completely determined:

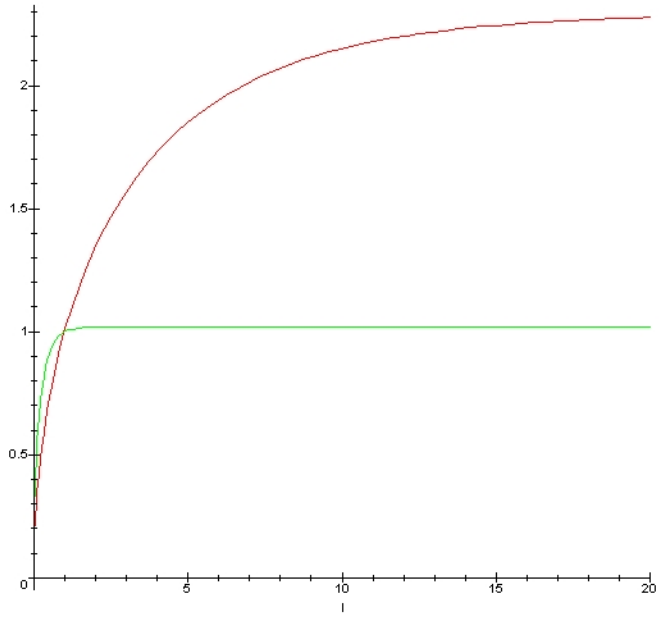
$$\hat{X}_t(h)-Z_{\alpha/2}\sigma_\varepsilon\sqrt{\frac{1-\varphi^{2h}}{1-\varphi^2}}\leq X_{t+h}\leq\hat{X}_t(h)+Z_{\alpha/2}\sigma_\varepsilon\sqrt{\frac{1-\varphi^{2h}}{1-\varphi^2}}\tag{15.3.1746}$$

and if we have only an estimator of $\hat{\sigma}_\varepsilon^2$ then we will take (see section Statistics page 865):

$$\hat{X}_t(h)-T_{\alpha/2}\hat{\sigma}_\varepsilon\sqrt{\frac{1-\varphi^{2h}}{1-\varphi^2}}\leq X_{t+h}\leq\hat{X}_t(h)+T_{\alpha/2}\hat{\sigma}_\varepsilon\sqrt{\frac{1-\varphi^{2h}}{1-\varphi^2}}\tag{15.3.1747}$$

The asymptotic shape of the error term is quite well known by practitioner as it is of the form with Maple™ 4.00b:

```
>plot([sqrt((1-0.9^(2*l))/(1-0.9^2)),sqrt((1-0.2^(2*l))/(1-0.2^2))],l=0..20);
```



Practising these forecasting model show they tend to underestimate the risk (variance). So rather than taking a 95% interval it is perhaps better to take a higher range depending on the return on experience.

Remark

The general case for an AR(p) process is actually over the scope of this textbook. Maybe it will be written for the 5th version...

Suppose now we have an MA(3) process with constant:

$$X_t = \mu + \theta_1 \varepsilon_{t-1} + \theta_2 \varepsilon_{t-2} + \theta_3 \varepsilon_{t-3} + \varepsilon_t \tag{15.3.1748}$$

We will see now what are the one step, two step, three step and four step ahead forecast for such a process.

1. For the one step ahead forecast we start from the knowledge that:

   $$X_t = \mu + \theta_1 \varepsilon_{t-1} + \theta_2 \varepsilon_{t-2} + \theta_3 \varepsilon_{t-3} + \varepsilon_t \tag{15.3.1749}$$

   Therefore:

   $$X_{t+1} = \mu + \theta_1 \varepsilon_t + \theta_2 \varepsilon_{t-1} + \theta_3 \varepsilon_{t-2} + \varepsilon_{t+1} \tag{15.3.1750}$$

   So we can write:

   $$\begin{aligned} \mathrm{E}(X_{t+1}|X_t) &= \mu + \theta_1 \mathrm{E}(\varepsilon_t|X_t) + \theta_2 \mathrm{E}(\varepsilon_{t-1}|X_t) + \theta_3 \mathrm{E}(\varepsilon_{t-2}|X_t) + \theta_2 \mathrm{E}(\varepsilon_{t+1}|X_t) \\ &= \mu + \theta_1 \varepsilon_t + \theta_2 \varepsilon_{t-1} + \theta_3 \varepsilon_{t-2} + 0 \\ &= \mu + \theta_1 \varepsilon_t + \theta_2 \varepsilon_{t-1} + \theta_3 \varepsilon_{t-2} \end{aligned} \tag{15.3.1751}$$

2. For the two step ahead forecast we start from the knowledge that:

$$X_t = \mu + \theta_1 \varepsilon_{t-1} + \theta_2 \varepsilon_{t-2} + \theta_3 \varepsilon_{t-3} + \varepsilon_t \tag{15.3.1752}$$

   Therefore:

$$X_{t+2} = \mu + \theta_1 \varepsilon_{t+1} + \theta_2 \varepsilon_t + \theta_3 \varepsilon_{t-1} + \varepsilon_{t+2} \tag{15.3.1753}$$

   So we can write:

$$\begin{aligned} \mathrm{E}(X_{t+2}|X_t) &= \mu + \theta_1 \mathrm{E}(\varepsilon_{t+1}|X_t) + \theta_2 \mathrm{E}(\varepsilon_t|X_t) + \theta_3 \mathrm{E}(\varepsilon_{t-1}|X_t) + \theta_2 \mathrm{E}(\varepsilon_{t+2}|X_t) \\ &= \mu + \theta_1 \cdot 0 + \theta_2 \varepsilon_t + \theta_3 \varepsilon_{t-1} + 0 \\ &= \mu + \theta_2 \varepsilon_t + \theta_3 \varepsilon_{t-1} \end{aligned} \tag{15.3.1754}$$

3. For the three step ahead forecast we start from the knowledge that:

$$X_t = \mu + \theta_1 \varepsilon_{t-1} + \theta_2 \varepsilon_{t-2} + \theta_3 \varepsilon_{t-3} + \varepsilon_t \tag{15.3.1755}$$

   Therefore:

$$X_{t+3} = \mu + \theta_1 \varepsilon_{t+2} + \theta_2 \varepsilon_{t+1} + \theta_3 \varepsilon_t + \varepsilon_{t+3} \tag{15.3.1756}$$

   So we can write:

$$\begin{aligned} \mathrm{E}(X_{t+3}|X_t) &= \mu + \theta_1 \mathrm{E}(\varepsilon_{t+2}|X_t) + \theta_2 \mathrm{E}(\varepsilon_{t+1}|X_t) + \theta_3 \mathrm{E}(\varepsilon_t|X_t) + \theta_2 \mathrm{E}(\varepsilon_{t+3}|X_t) \\ &= \mu + \theta_1 \cdot 0 + \theta_2 \cdot 0 + \theta_3 \varepsilon_t + 0 \\ &= \mu + \theta_3 \varepsilon_t \end{aligned} \tag{15.3.1757}$$

4. For the four step ahead forecast we start from the knowledge that:

$$X_t = \mu + \theta_1 \varepsilon_{t-1} + \theta_2 \varepsilon_{t-2} + \theta_3 \varepsilon_{t-3} + \varepsilon_t \tag{15.3.1758}$$

   Therefore:

$$X_{t+4} = \mu + \theta_1 \varepsilon_{t+3} + \theta_2 \varepsilon_{t+2} + \theta_3 \varepsilon_{t+1} + \varepsilon_{t+4} \tag{15.3.1759}$$

   So we can write:

$$\begin{aligned} \mathrm{E}(X_{t+4}|X_t) &= \mu + \theta_1 \mathrm{E}(\varepsilon_{t+3}|X_t) + \theta_2 \mathrm{E}(\varepsilon_{t+2}|X_t) + \theta_3 \mathrm{E}(\varepsilon_{t+1}|X_t) + \theta_2 \mathrm{E}(\varepsilon_{t+4}|X_t) \\ &= \mu + \theta_1 \cdot 0 + \theta_2 \cdot 0 + \theta_3 \cdot 0 + 0 \\ &= \mu \end{aligned} \tag{15.3.1760}$$

Notice that the prediction error can therefore be calculated as (if you compare with the previous four examples):

$$e_{t+h} = X_{t+h} - \hat{X}_{t+h} = X_{t+h} - \mathrm{E}(X_{t+h}|X_t) = \varepsilon_{t+h} + \sum_{i=1}^{h-1} \theta_i \varepsilon_{t+i} \tag{15.3.1761}$$

Hence the variance (mean square error) is given by:

$$\text{V}(e_{t+h})=\sigma_\varepsilon^2\left(1+\sum_{i=1}^{h-1}\theta_i^2\right) \tag{15.3.1762}$$

If ε_t is Gaussian then:

$$\hat{X}_{t+h}=\mathcal{N}\left(\text{E}(X_{t+h}|X_t),\sigma_\varepsilon^2\left(1+\sum_{i=1}^{h-1}\theta_i^2\right)\right) \tag{15.3.1763}$$

We then have a given confidence level if σ_ε^2 is completely determined (using the notation previously adopted of the AR(1) process):

$$\hat{X}_t(h)-Z_{\alpha/2}\sigma_\varepsilon\sqrt{1+\sum_{i=1}^{h-1}\theta_i^2}\leq X_{t+h}\leq \hat{X}_t(h)+Z_{\alpha/2}\sigma_\varepsilon\sqrt{1+\sum_{i=1}^{h-1}\theta_i^2} \tag{15.3.1764}$$

and if we have only an estimator of $\hat{\sigma}_\varepsilon^2$ then we will take (see section Statistics page 865):

$$\hat{X}_t(h)-T_{\alpha/2}\hat{\sigma}_\varepsilon\sqrt{1+\sum_{i=1}^{h-1}\theta_i^2}\leq X_{t+h}\leq \hat{X}_t(h)+T_{\alpha/2}\hat{\sigma}_\varepsilon\sqrt{1+\sum_{i=1}^{h-1}\theta_i^2} \tag{15.3.1765}$$

Here are some examples for a same set of data of the different forecast we can have depending on the chosen model:

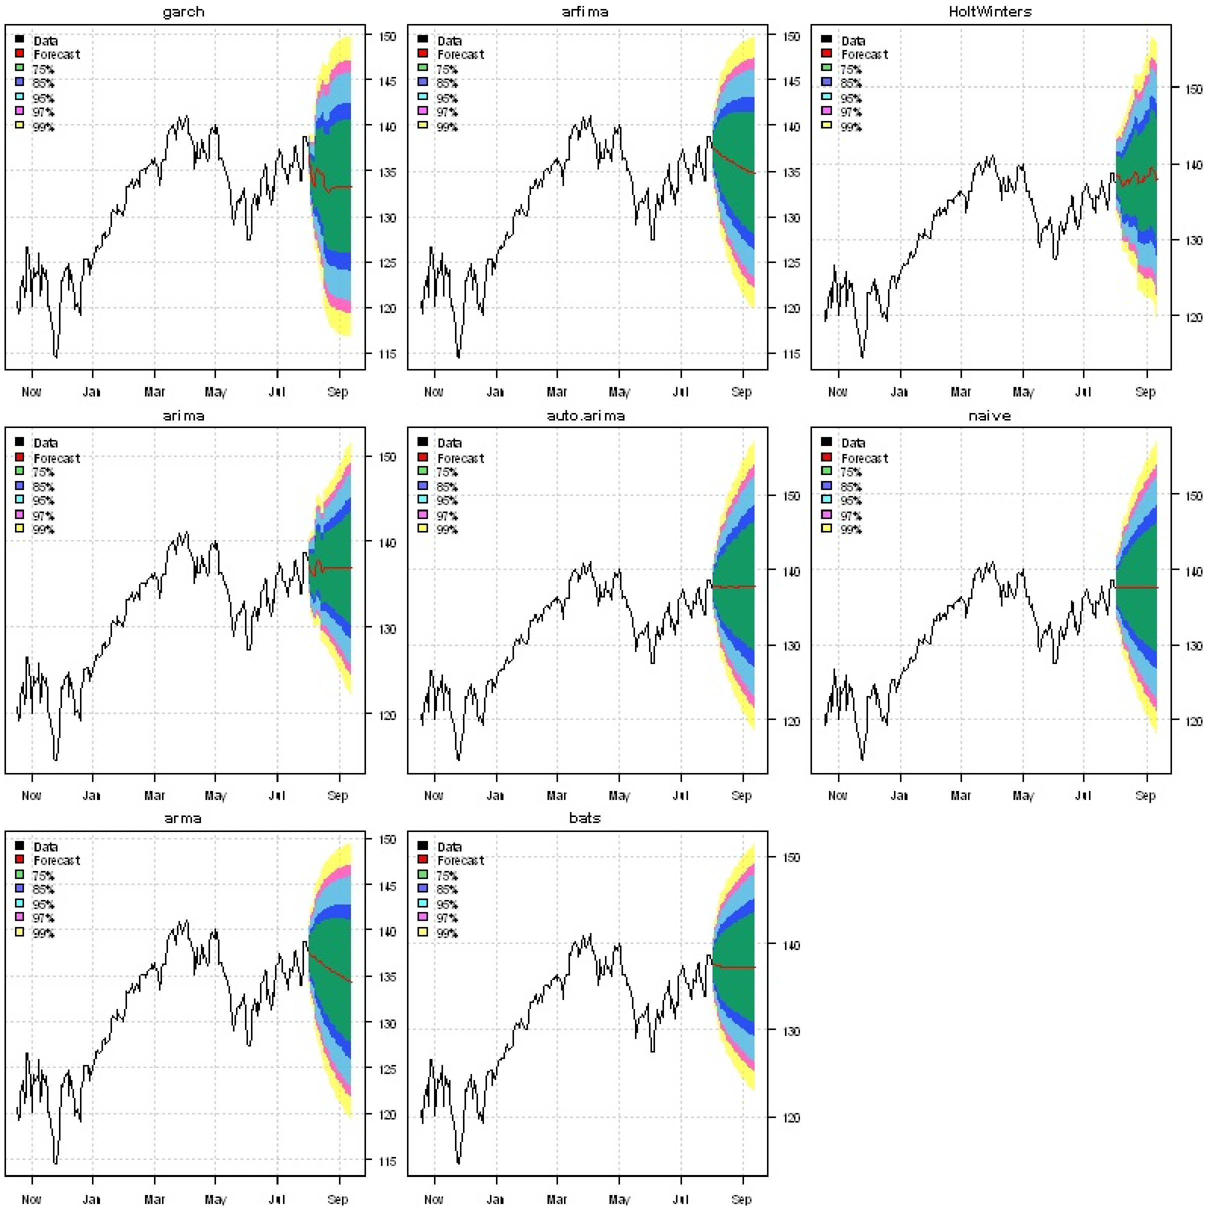


Figure 15.275: Some time series with forecasting (GARCH, ARFIMA, Holt-Winter, ARIMA, etc.) with `R`

15.3.13.5.1 Linear Minimal Mean Square Estimation (LMMSE)

According to what we have seen previously, the reader may have noticed that we can always write:

$$\hat{X}_{t+h} = \mathrm{E}(X_{t+h}|X_t) = a_0 + \sum_{i=1}^{h} a_i X_{t+h-i} \tag{15.3.1766}$$

The idea of forecasting based on Linear Minimal Mean Square Estimation (LMMSE) is to minimize the mean square error of (for practical reasons as optimal prediction in general is largely intractable reasons and due to the analogy with the Gaussian case):

$$\min_{\vec{a}} \mathrm{E}\left[\left(X_{n+h}-\hat{X}_{n+h}\right)^2\right] = \mathrm{E}\left[\left(X_{n+h}-\left(a_0+\sum_{i=1}^{h} a_i X_{t+h-i}\right)\right)^2\right] = \min_{\vec{a}} \mathrm{MSE}(\vec{a}) \tag{15.3.1767}$$

Note the expectation is over all the random variables, which are $X_1,\ldots,X_t,X_{t+h-1}$. We may solve this optimization (minimization) problem analytically:

$$\begin{aligned}\frac{\partial \mathrm{MSE}(\vec{a})}{\partial a_0} &= \mathrm{E}\left[2\left(X_{n+h}-a_0-\sum_{i=1}^{h} a_i X_{t+h-i}\right)\right]=0\\ \frac{\partial \mathrm{MSE}(\vec{a})}{\partial a_j} &= \mathrm{E}\left[2\left(X_{n+h}-a_0-\sum_{i=1}^{h} a_i X_{t+h-i}\right)X_{n+h-j}\right]=0\end{aligned} \tag{15.3.1768}$$

for $j=1\ldots h$. For the first equality above, we have:

$$\mathrm{E}(X_{n+h})-a_0-\sum_{i=1}^{h} a_i \mathrm{E}(X_{t+h-i})=0 \tag{15.3.1769}$$

Rearranging:

$$\mathrm{E}(X_{n+h})-\sum_{i=1}^{h} a_i \mathrm{E}(X_{t+h-i})=a_0 \tag{15.3.1770}$$

But under stationary:

$$\mathrm{E}(X_{n+h})=\mathrm{E}(X_{t+h-i})=\mu \tag{15.3.1771}$$

Therefore:

$$a_0=\mu\left(1-\sum_{i=1}^{h} a_i\right) \tag{15.3.1772}$$

From:

$$\mathrm{E}\left[2\left(X_{n+h}-a_0-\sum_{i=1}^{h} a_i X_{t+h-i}\right)X_{n+h-j}\right]=\mathrm{E}(X_{n+h}X_{n+h-j})-a_0\mathrm{E}(X_{n+h-j})-\sum_{i=1}^{h} a_i\mathrm{E}(X_{t+h-i}X_{n+h-j})=0 \tag{15.3.1773}$$

and substituting in it a_0, we get:

$$\mathrm{E}(X_{n+h}X_{n+h-j})-\mu\left(1-\sum_{i=1}^{h} a_i\right)\mathrm{E}(X_{n+h-j})-\sum_{i=1}^{h} a_i\mathrm{E}(X_{t+h-i}X_{n+h-j})=0 \tag{15.3.1774}$$

Again, under stationary $\mathrm{E}(X_{n+h-j})=\mu$ we can rewrite this:

$$\mathrm{E}(X_{n+h}X_{n+h-j})-\mu\left(1-\sum_{i=1}^{h} a_i\right)\mu-\sum_{i=1}^{h} a_i\mathrm{E}(X_{t+h-i}X_{n+h-j})=0 \tag{15.3.1775}$$

After rearranging:

$$\mathrm{E}(X_{n+h}X_{n+h-j}-\mu^2)-\sum_{i=1}^{h} a_i\mathrm{E}(X_{t+h-i}X_{n+h-j}-\mu^2)=0 \tag{15.3.1776}$$

We can develop even more involving nice mathematical tools. However actually, this is beyond the scope of this textbook (maybe for the 5th edition).

15.3.13.6 TBATS

Let us briefly introduce the "TBATS" (Trigonometric seasonality, Box-Cox transformation, ARMA errors, Trend and Seasonal components) empirical model that takes it roots in exponential smoothing methods and can be described by the following equations:

$$
\begin{aligned}
&y_t = \text{observation at time } t\\
&y_t^{(\lambda)} = \begin{cases} \left(y_t^{\lambda}-1\right)/\lambda & \text{if } \lambda \neq 0 \\ \log(y_t) & \text{if } \lambda = 0 \end{cases} \quad \text{Box-Cox transformation}\\
&y_t^{(\lambda)} = \ell_{t-1}+\phi b_{t-1}+\sum_{i=1}^{M} s_{t-m_i}^{(i)}+d_t \quad M \text{ seasonal periods}\\
&\ell_t = \ell_{t-1}+\phi b_{t-1}+\alpha d_t \quad \text{global and local trend}\\
&b_t = (1-\phi)b+\phi b_{t-1}+\beta d_t \quad \text{trend with mapping}\\
&d_t = \sum_{i=1}^{p}\varphi_i d_{t-i}+\sum_{j=1}^{q}\theta_j\varepsilon_{t-j}+\varepsilon_t \quad \text{ARMA}(p,q) \text{ for residuals}\\
&s_t^{(i)} = \sum_{j=1}^{k_i} s_{j,t}^{(i)} \quad i\text{th seasonal component}\\
&\left.\begin{aligned} s_{j,t}^{(i)} &= s_{j,t-1}^{(i)}\cos\left(\omega_j^{(i)}\right)+s_{j,t-1}^{*(i)}\sin\left(\omega_j^{(i)}\right)+\gamma_1^{(i)}d_t\\ s_{j,t}^{*(i)} &= -s_{j,t-1}^{(i)}\sin\left(\omega_j^{(i)}\right)+s_{j,t-1}^{*(i)}\cos\left(\omega_j^{(i)}\right)+\gamma_2^{(i)}d_t \end{aligned}\right\} \text{Fourier series terms}\\
&\omega_j^{(i)} = \frac{2\pi j}{m_i}
\end{aligned}
\tag{15.3.1777}
$$

where T is the number of seasonalities, m_i is the length of the ith season period, k_i is the number of harmonics (see section Sequences and Series page 1727) for the ith seasonal period, λ is the parameter of the Box-Cox transformation (see below page 8014), α, β are smoothing parameters, ϕ is a trend damping, φ_i, θ_i are the ARMA(p,q) coefficients, γ_1, γ_2 are seasonal smoothing (two for each period).

Each seasonality is modelled by a trigonometric representation based on Fourier series (see section Sequences and Series page 1727). One major advantage of this approach is that it requires only 2 seed states regardless of the length of period. Another advantage is the ability to model seasonal effects of non-integer lengths. For example, given a series of daily observations, one can model leap years with a season of length 365.25.

So in comparison, the main disadvantage of the ARIMA approach is that the seasonality is forced to be periodic, whereas a TBATS model allows for dynamic seasonality.

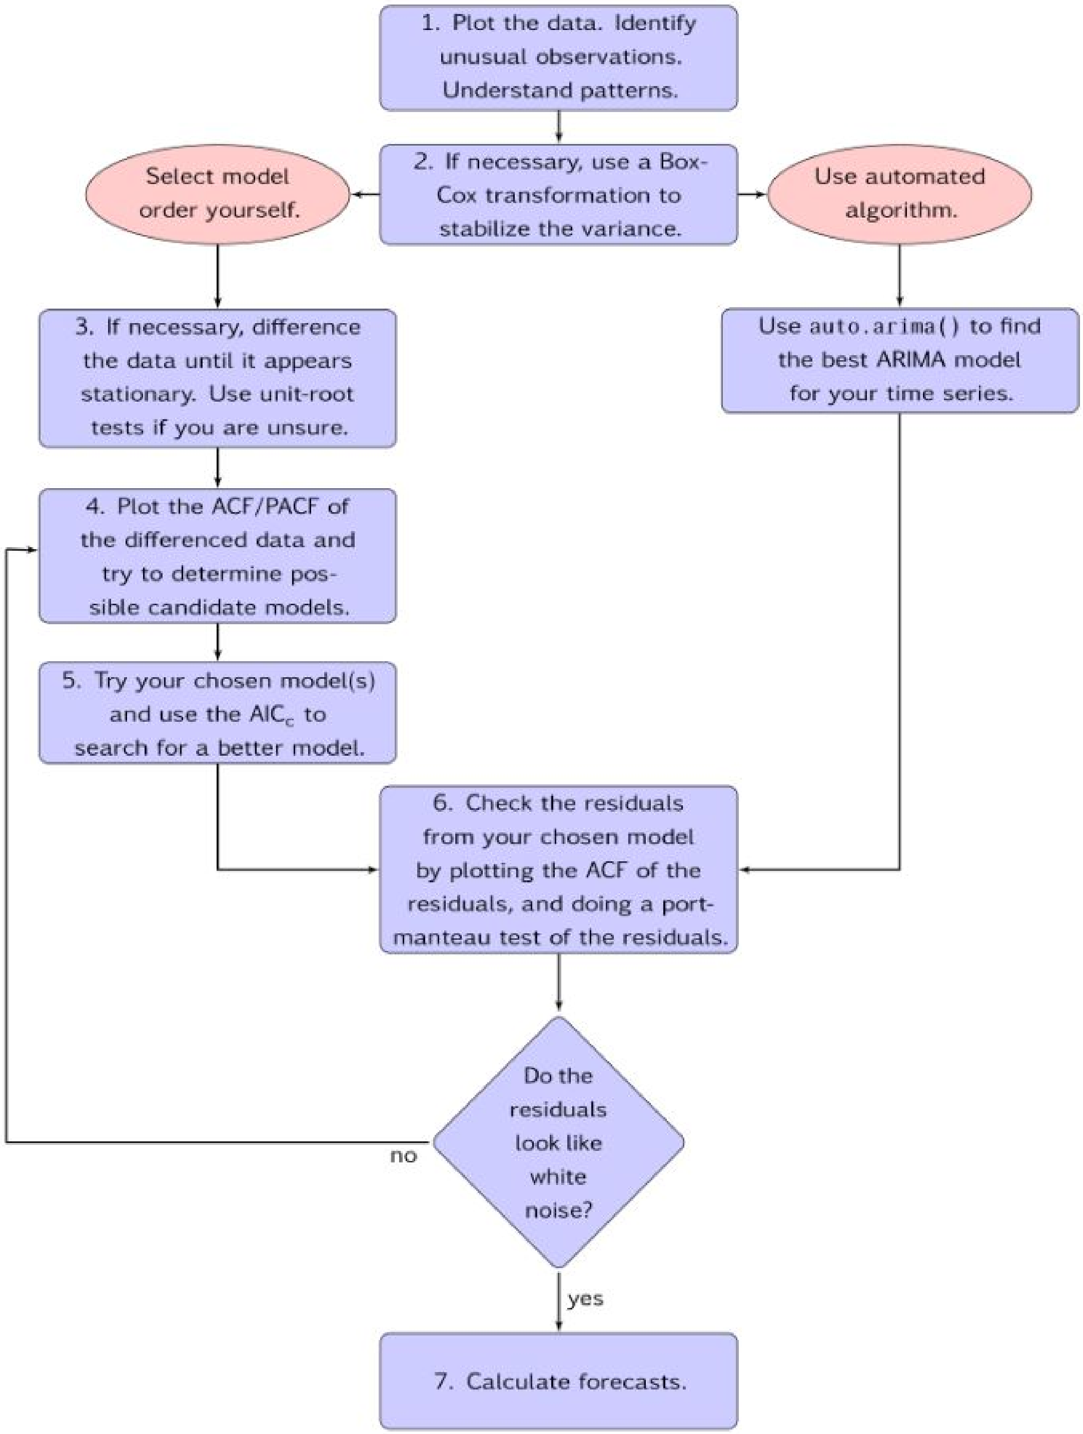
Unfortunately BATS and TBATS capabilities do not come for free. The method is very generic. Under the hood it builds and evaluates many model candidates and TBATS choose the final model using AIC (see section Numerical Methods page 6420). This results in slowness of the computation.

Remark

For a practical application, the reader can refer to our `R` companion book.

15.3.13.7 Recipes for modelling time series data

To make forecasting using ARIMA models, we need to follow a classical process illustrated below:



1. Plot the data. Identify unusual observations. Understand patterns.
2. If necessary, use a Box-Cox transformation to stabilize the variance.
Select model order yourself.
Use automated algorithm.
3. If necessary, difference the data until it appears stationary. Use unit-root tests if you are unsure.
Use auto.arima() to find the best ARIMA model for your time series.
4. Plot the ACF/PACF of the differenced data and try to determine possible candidate models.
5. Try your chosen model(s) and use the AICc to search for a better model.
6. Check the residuals from your chosen model by plotting the ACF of the residuals, and doing a portmanteau test of the residuals.
Do the residuals look like white noise?
no
yes
7. Calculate forecasts.

Figure 15.276: **Recipes for modelling time series data**

Our purpose starting from now will be to detail each of the step that need quite technical skills (the steps that will not be detailed like the differentiation[45], will then obviously not be detailed as it is such a simple subtraction).

---

[45] Compute the differences between consecutive observations.

The purpose of "variance stabilization" is to make the variance independent of the mean μ. Keeping in mind that this is one of the assumption of a stationary time series and that it is not only a useful property for time series but in a lot of other fields in statistics!

Suppose that the variance of a time series (or statistical distribution in general) X_t satisfies:

$$\text{V}(X_t)=c^{te}f(\mu) \tag{15.3.1778}$$

We wish to find a transformation denoted $T(\cdot)$ such that $\text{V}(T(X_t))$ is constant. A first-order Taylor series of $T(X_t)$ about μ is:

$$T(X_t)\cong T(\mu)+T'(\mu)(X_t-\mu) \tag{15.3.1779}$$

Now $\text{V}(T(X_t))$ is approximated as (keep in mind that μ is constant and hence $T(\mu)$ is also another constant):

$$\text{V}(T(X_t))\cong\text{V}(T(\mu))+(T'(\mu))^2\text{V}(X_t)+(T'(\mu))\text{V}(\mu)=(T'(\mu))^2\text{V}(X_t)=c^{te}(T'(\mu))^2f(\mu) \tag{15.3.1780}$$

Therefore $T(\cdot)$ is chosen such that:

$$T'(\mu)=\frac{1}{\sqrt{f(\mu)}} \tag{15.3.1781}$$

which implies:

$$T(\mu)=\int\frac{1}{\sqrt{f(\mu)}}\text{d}X_t \tag{15.3.1782}$$

Assuming for example that (after having centered all the X_t):

$$f(\mu)=\sum_i(X_{c,t}-\mu)^2=\sum_i X_{c,t}^2 \tag{15.3.1783}$$

and taking for example only one term, we have:

$$T(\mu)=\int\frac{1}{\sqrt{X_{c,t}^2}}\text{d}X_{c,t}=\int\frac{1}{X_{c,t}}\text{d}X_{c,t}=\ln(X_{c,t}) \tag{15.3.1784}$$

This is why the most standard transformation is the log-transformation where the new series Y_t is given by:

$$Y_t=\log(X_{c,t}) \tag{15.3.1785}$$

An alternative to the log transformation is the "Box-Cox transformation":

$$\boxed{Y_t=\begin{cases}(X_t^\lambda-1)/\lambda & \lambda\neq 0\\ \ln(X_t) & \lambda=0\end{cases}} \tag{15.3.1786}$$

Notice that some other transformations exist!

15.3.13.7.1 Durbin-Watson autocorrelation test

The "Durbin-Watson test" also named "Durbin-Watson statistics" consists typically in testing the null hypothesis that the autocorrelation between the residuals of a regression ε_i is zero (against the alternative hypothesis that this same correlation is non-zero). That is to say:

$$\begin{aligned}H_0 &: \rho_\varepsilon = 0\\ H_1 &: \rho_\varepsilon \neq 0\end{aligned} \tag{15.3.1787}$$

Even if this test is used a lot in linear or non-linear regression to check if the model assumption are satisfied (so it could have its place in the section of Numerical Methods), it is used much more in time series analysis where the practitioner is most often more skilled than people doing regression in corporations and therefore more apt to read the result of the test and perform the necessary corrective actions.

The idea of this test is to write (read well until the end before thinking that the choice of the ratio is empirical!):

$$\begin{aligned}\text{DW} &= \frac{\sum\limits_{i=2}^{n}(\varepsilon_i-\varepsilon_{i-1})^2}{\sum\limits_{i=1}^{n}\varepsilon_i^2} = \frac{\sum\limits_{i=2}^{n}\varepsilon_i^2-2\varepsilon_i\varepsilon_{i-1}+\varepsilon_{i-1}^2}{\sum\limits_{i=1}^{n}\varepsilon_i^2} = \frac{\sum\limits_{i=2}^{n}\varepsilon_i^2}{\sum\limits_{i=1}^{n}\varepsilon_i^2}+\frac{\sum\limits_{i=2}^{n}\varepsilon_{i-1}^2}{\sum\limits_{i=1}^{n}\varepsilon_i^2}-2\frac{\sum\limits_{i=2}^{n}\varepsilon_i\varepsilon_{i-1}}{\sum\limits_{i=1}^{n}\varepsilon_i^2}\\ &\cong 1+1-2\frac{\sum\limits_{i=2}^{n}\varepsilon_i\varepsilon_{i-1}}{\sum\limits_{i=1}^{n}\varepsilon_i^2} = 2-2\frac{\sum\limits_{i=2}^{n}\varepsilon_i\varepsilon_{i-1}}{\sum\limits_{i=1}^{n}\varepsilon_i^2}\end{aligned} \tag{15.3.1788}$$

Remark

Notice the similarity between:

$$\text{DW} = \frac{\sum\limits_{i=2}^{n}(\varepsilon_i-\varepsilon_{i-1})^2}{\sum\limits_{i=1}^{n}\varepsilon_i^2} \tag{15.3.1789}$$

and the equivalent relation of the values of the series itself (instead of the residuals):

$$\text{VN} = \frac{\sum\limits_{i=2}^{n}(x_i-x_{i-1})^2}{\sum\limits_{i=1}^{n}(x_i-\bar{x})^2} \tag{15.3.1790}$$

named the "(Von) Neumann trend test" (obviously on the residuals, by assumption $\bar{\varepsilon}=0$ that's why the denominator is different).

For the latter term:

$$\frac{\sum\limits_{i=2}^{n}\varepsilon_i\varepsilon_{i-1}}{\sum\limits_{i=1}^{n}\varepsilon_i^2} \tag{15.3.1791}$$

notice that we can write it in the following form since the expected mean of the residues are assumed to be zero (therefore this writing is the same!) such as $\text{E}(\varepsilon)=0$. Therefore:

$$\begin{aligned}\frac{\sum\limits_{i=2}^{n}(\varepsilon_i-\text{E}(\varepsilon))(\varepsilon_{i-1}-\text{E}(\varepsilon))}{\sum\limits_{i=1}^{n}(\varepsilon_i-\text{E}(\varepsilon))^2}&=\frac{\dfrac{1}{n}\sum\limits_{i=2}^{n}(\varepsilon_i-\text{E}(\varepsilon))(\varepsilon_{i-1}-\text{E}(\varepsilon))}{\dfrac{1}{n}\sum\limits_{i=1}^{n}(\varepsilon_i-\text{E}(\varepsilon))^2}\\&=\frac{\text{E}\left[(\varepsilon_i-\mu_\varepsilon)(\varepsilon_{i-1}-\mu_\varepsilon)\right]}{\sigma_\varepsilon\sigma_\varepsilon}=\frac{\text{cov}(\varepsilon_i,\varepsilon_{i-1})}{\sigma_\varepsilon^2}=\rho_\varepsilon\end{aligned} \tag{15.3.1792}$$

We thus fall back on the general expression of the autocorrelation seen earlier above. It then comes:

$$\boxed{\text{DW}\cong 2-2\frac{\sum\limits_{i=2}^{n}\varepsilon_i\varepsilon_{i-1}}{\sum\limits_{i=1}^{n}\varepsilon_i^2}=2(1-\rho_\varepsilon)} \tag{15.3.1793}$$

The approximation (valid only if n is sufficiently large) that we have done above justifies the fact that some softwares offer an approximate or exact version.

So far as we know there is not exact distribution law that this statistic follows. Therefore it is tabulated based on Monte Carlo methods. Simulations give that when:

- ρ_ε is close to 1, the DW statistic is close to 0
- ρ_ε is close to 0 (no serial correlation), the DW statistic is close to 2
- ρ_ε is close to -1, the DW statistic is close to 4

Upper and lower critical values, denoted DW_U (or sometimes Q_U) and respectively DW_L (or sometimes Q_L), have been tabulated for different values of k (the number of explanatory variables also sometimes denoted Λ) and of n (also sometimes denoted N) and the rules are:

- If $\text{DW}<\text{DW}_L$ we reject H_0
- If $\text{DW}>\text{DW}_U$ we cannot reject H_0
- If $\text{DW}_L<\text{DW}<\text{DW}_U$ the test is inconclusive

Remark

In the `R` software (see the corresponding companion book) there are actually two functions to run this test. One written `durbinWatsonTest( )` from the `car` package and one written `dwtext()` from the `lmtest` package. Even if they give veeeery close p-values and DW values for small values of n, they diverge quite significantly when n becomes big. This is because of the chosen algorithm. Indeed, the help associated with the `dwtext()` function gives us: «*The* p*-value is computed using a Fortran version of the Applied Statistics Algorithm AS 153 by Farebrother (1980, 1984). This algorithm is named "pan" or "gradsol". For large sample sizes the algorithm might fail to compute the* p *-value; in that case a warning is printed and an approximate* p*-value will be given; this* p *value is computed using a Normal approximation with mean and variance of the Durbin-Watson test statistic*». While the help associated with the `durbinWatsonTest( )` function gives us: «*simulate: if 'TRUE' p-values will be estimated by bootstrapping*».

For the people that may not have access to a spreadsheet or statistical software here are some useful tables:

15.4. Quantitative Management

THE aim of this chapter is to introduce the main mathematical techniques of production and management, maintenance and quality whose use has become essential for engineers, managers and executives of modern companies (those who can make science, the others make methodology ...) and which are the minimum-minimorum of business knowledge in general management. These are techniques that date back to the early 120th century (holocene calendar) and were first used for the majority by the U.S. military and then gradually implemented in the largest global companies.

Moreover, it is an excellent section for the general culture of the physicist or mathematician ... and an achievement for the engineer! And as high level practitioners say: a management model without maths is an incomplete model!

Many techniques are however not presented in this section because they have already been proved in other chapters of this textbook. Indeed, complex, critical and cutting edge management techniques make a huge usage of statistics, probabilities, decision theory, graph theory (Markov chains or not, complete graphs for the management of communication, etc.), financial analysis and optimization algorithms. Because whole chapters in this textbook are already dedicated to those enumerated subjects, it would be redundant to return on them!

Remark

We often speak about 3M (Mathematical Methods for Management) or even sometimes about "scientific management" to describe the set of mathematical tools applied to management (there exists also a training curriculum on the subject of fifty days...). Some people also use the abbreviation "SciProM" for "Scientific Project Management) when it is project oriented and more generally of "Evidence-Based Management". A common English term that became fashionable in Europe to describe this area of application is also the "Decisioneering" referring to the fact that these are tools decision support for engineers.

Before starting let us indicate that despite their intrinsic importance, quantitative management techniques (also including operational research techniques, Monte Carlo simulation and Bootstrapping as studied in the section of Numerical Methods and also Six Sigma as studied in the section of Industrial Engineering and the Decision Theory) are still little used in industry, either because of lack of training of policy makers (except in the financial sector), or by the lack of relevance of the tool or the difficulty to implement it. The main concerns raised by decision makers in the application of mathematical models in corporations are:

1. **The tools are too abstract**: In such situations, we must always remember that... concrete stuff are abstract concepts to which we are accustomed!

2. **A limited consideration of external and internal factors**: For strategic reasons, the pure and perfect answer to a mathematical solution seems rarely applicable de facto. Although

quantitative techniques incorporate many factors, though some aspects are relatively easy to model in the mathematical sense of the term (cost, profitability, distance, time, pace... for example), other elements, however, are more difficult to model: legal constraints, commercial motivation to block a competitor, importance of networking, social climate, etc. The weight of these elements in the decision is however important, sometimes decisive!

3. **A significant investment**: The mathematical tool itself requires a high level of mathematical knowledge, a good ability to model problems and to describe factors. These constraints are consuming a lot of time and a certain amount of money (whether through internal development, which consumes resources - or by external development, which consumes money). It is then necessary to find a balance between the investment required and expected returns.

4. **For infrequent events**: The company does not have the opportunity the use the "effect of experience" and therefore a time to another, the problem is with a different service or managers that have changed between two studies or do not communicate between them. It is therefore difficult to maintain the skills within the company. The decision-maker will have to take these aspects into account when deciding whether or not to implement quantitative techniques in his business.

We can also argue that the fact that Scientific Management Techniques (SMT) or the Mathematical Methods of Management (3M) are not used generally is because:

1. Depending on the context, the extra power offered by SMT/3M does not necessarily justify the efforts necessary to their learning.

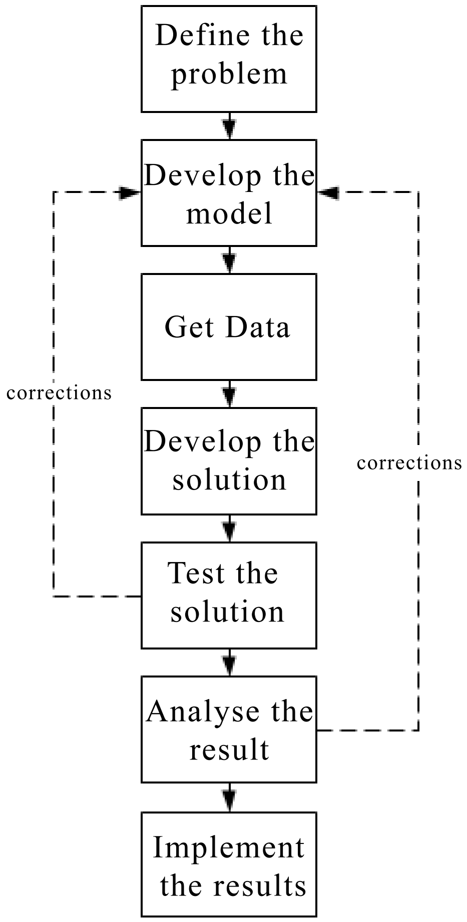
2. The SMT/3M are demanding in reasoning and rigorous, they may not be suitable for people who know neither one nor the other ...

Remark

Beware of corporations - especially multinationals - that are looking for specialists or graduate in project management or supply chain that master Microsoft® Excel®, Microsoft Access or VBA. Because it means that they use low-level tools to do a job which ought to be done with high-level efficient tools (what Microsoft® Excel® and Microsoft Access aren't obviously!!!). So in terms of internal organization, you can ensure that such corporations organize and analyse anything, anyhow, with unsuitable tools and therefore that there is a general mess internally.

We have chosen in this section to present the more conventional quantitative techniques in an ascending order of difficulty (technical level). This seems to us to this date the most relevant pedagogical choice...

Let us give a schematic summary of the scientific method that we studied in the Introduction chapter and that applies pretty well to the business world regarding scientific management:



Define the problem
Develop the model
Get Data
Develop the solution
Test the solution
Analyse the result
Implement the results
corrections
corrections

Figure 15.277: **Typical simple process**

The simple subjects below are given without practical examples while those that exceed the high-school level are accompanied by practical examples more or less detailed.

One last word to close this introduction... the quantitative manager or quantitative analyst has to know something... Sure you want to write verbose explanations of your analysis but never forget that Executives (at least actually) are looking only for what they name WIIFM (What's In It For Me). So you must understand that you are paid most of times to produce headlines and not to write novels...

Remark

For people interested only on the methodological aspect of quantitative management, we strongly recommend the lecture of the book Evidence-Based Management: *How to Use Evidence to Make Better Organizational Decisions* ([41]).

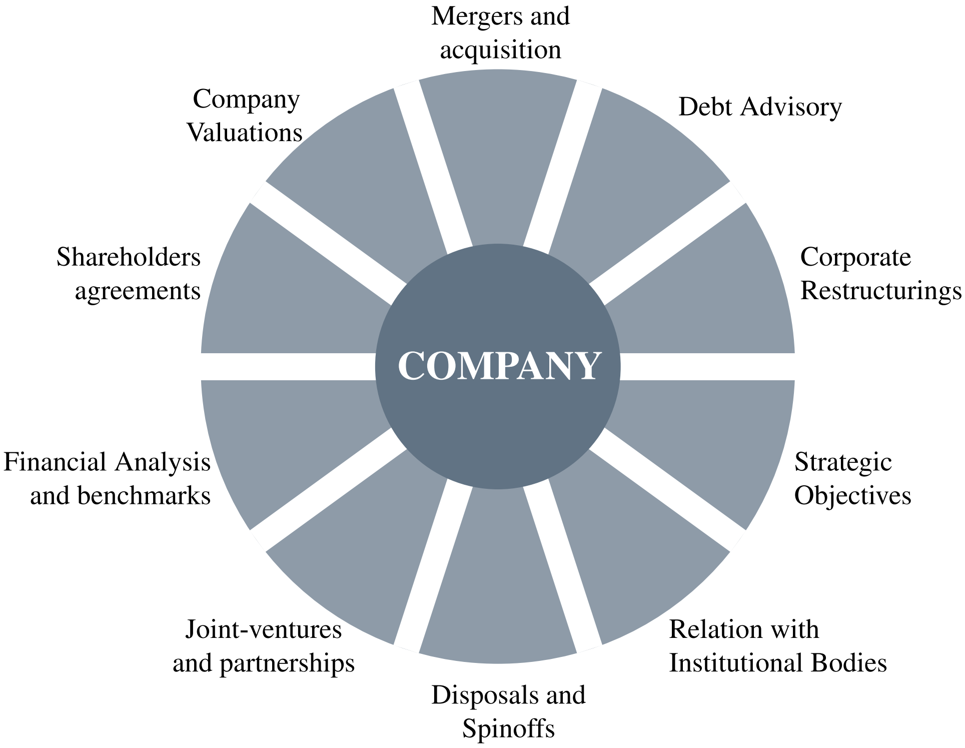
15.4.1 Corporate and Government Finance Management

Corporate and Government finance is the area of finance dealing with the sources of funding and the capital structure of corporations and governments and the actions that managers and politicians should take to increase the value of the firm/administration to the shareholders, the competitiveness/attractiveness of their business/nation as well as the tools and analysis used to allocate financial resources in a certain or probabilistic world (i.e. Universe). The primary goal of corporate and governments finance is to maximize or increase shareholder/citizen value through various adjustment variables and anticipate market trends and risks.

Investment analysis (or capital budgeting) is concerned with the setting of criteria about which value-adding projects should receive investment funding, and whether to finance that investment with equity or debt capital.

As many subject in Corporate and Government Finance are related to investment banking topics we will not repeat in this section the study of Actuarial, Interests calculations, Loan Amortization/Repayment, Portfolio Theory and Forecasting that we have already study in detail in the section Economy (page 7485).

Also the reader has to know that Corporate and Government Finance is not only related to investment but also to benchmarking and optimization and as we have already study these subject in the sections of Game and Decision Theory and Numerical Methods/Analysis we will not come back on these latter.



Mergers and acquisition
Debt Advisory
Corporate Restructurings
Strategic Objectives
Relation with Institutional Bodies
Disposals and Spinoffs
Joint-ventures and partnerships
Financial Analysis and benchmarks
Shareholders agreements
Company Valuations
COMPANY

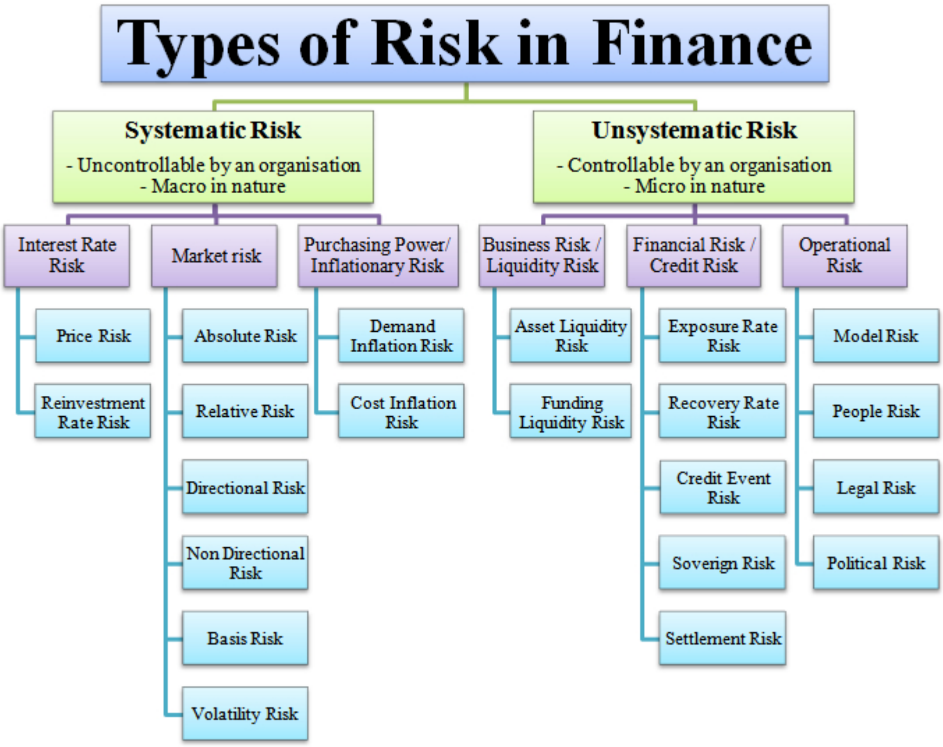
Corporate Finance management is an every day challenge for every good CXO (CEO, CFO, CTO, CRO, etc.) and costs optimization should be his everyday way of life by always taking care of his own cognitive biases, market uncertainties (nothing is "sure" in Economy/Finance[46]) and having always a reserve of alternative strategies in case of economic conjuncture variations (that in the probabilistic point of view may always have the possibility to occur!).

All CXO have always to face risks (especially "risk–benefit ratio[47]") and uncertainties hence the fact that any good manager associate arguments with probabilities or with precautions (some bad managers avoid risks subjectively but the main purpose of a real entrepreneur is to take risks to innovate and perform always better!):

		Uncertainty	
		Low	*High*
Risk	*Low*	Benchmark	Operational Hedging
	High	Flexible Financial Hedging	Flexible Operationa Hedging

Table 15.67: **Risk-Uncertainty Matrix CXO knowledge**

The list of possible risks is huge and we can find some exhaustive lists in good project management books, but here is a quite good summary of most important financial related type of risks:



Types of Risk in Finance
Systematic Risk
- Uncontrollable by an organisation
- Macro in nature
Unsystematic Risk
- Controllable by an organisation
- Micro in nature
Interest Rate Risk
Market risk
Purchasing Power/ Inflationary Risk
Business Risk / Liquidity Risk
Financial Risk / Credit Risk
Operational Risk
Price Risk
Reinvestment Rate Risk
Absolute Risk
Relative Risk
Directional Risk
Non Directional Risk
Basis Risk
Volatility Risk
Demand Inflation Risk
Cost Inflation Risk
Asset Liquidity Risk
Funding Liquidity Risk
Exposure Rate Risk
Recovery Rate Risk
Credit Event Risk
Soverign Risk
Settlement Risk
Model Risk
People Risk
Legal Risk
Political Risk

Figure 15.278: **Typical type of financial risks**

---

[46] Never forget the adage: "The problem in the world is that intelligent people are full of doubts, while the idiots are full of confidence"

[47] It is the ratio of the risk of an action to its potential benefits. For example, driving an automobile is a risk most people take daily, also since it is mitigated by the controlling factor of their perception of their individual ability to manage the risk-creating situation.

15.4.1.1 Basic Accounting Equation

The "basic accounting equation", also named the "balance sheet equation", represents the relationship between the assets, liabilities, and owner's equity of a business. It is the foundation for the double-entry bookkeeping system. For each transaction, the total debits equal the total credits. It can be expressed as:

$$\text{Assets (what you own)} = \text{Liabilities (what you owe)} + \text{Equities (what you possess)} \tag{15.4.1}$$

or more formally:

$$\boxed{\mathcal{A}=\mathcal{E}+\mathcal{L}} \tag{15.4.2}$$

Since every business transaction affects at least two of a company's accounts, the accounting equation will always be "in balance", meaning the left side should always equal the right side. Thus, the accounting formula essentially shows that what the firm owns (its assets) is purchased by either what it owes (its liabilities) or by what its owners invest (its shareholders equity or capital).

✍**Example:**

A student buys a computer for 945.-. This student borrowed 500.- from his friend and spent another 445.- earned from his part-time job. Now his asset is worth 945.-, liabilities are 500.-, and equity 445.-.

We have typically:

ASSETS:

- Cash
- Temporary Investments
- Accounts Receivable
- Merchandise Inventory
- Office Supplies
- Buildings
- Property & Equipment
- Patents
- Goodwill

LIABILITIES:

- Accounts Payable
- Rent Payable
- Salaries Payable
- Estimated Warranty Liability
- Dividends Payable
- Long Term Liabilities
- Discount on Bonds Payable
- Tax Payable

EQUITIES:

- Owner's Equity
- Owner's Withdrawals
- Common Shares
- Preferred Shares
- Retained Earnings
- Dividends

15.4.1.2 Ratio Analysis

A problem involved when comparing companies (or organizations) of different sizes is to calculate and compare ratios that can provide very useful managerial information about efficiency. Using ratios eliminates as we know the size problem because the size effectively divides out. We are then left with percentages, multiples, or time periods.

There is a problem in discussing ratios. Because a ratio is simply one number divided by another they are incapable of accommodating multiple inputs and outputs when accurate objective relative weights for inputs and outputs are not known, and because there are so many accounting numbers out there, we could examine a huge number of possible ratios (remember the reference on the UBS catalogue on financial indicators that we have mentioned in the section Economy[48]).

Remark

Sadly as far as we know and still in 12016 (holocene calendar) there are no ISO standard for corporate indicators.

Most people have a favourite indicator. We will restrict here ourselves to a representative sampling. In this section, we only want to introduce some very common used financial ratios and as the reader will see it is quick boring as the variables are never robustly well defined (furthermore most teachers and practitioners of corporate finance do not know how to write a technical paper or book properly...). The chosen indicators are not necessarily the ones we think are the best. In fact, some of them may strike the reader as illogical or not as useful as some alternatives. If they do, the reader must no be concerned. As an practitioner, the reader can always decide how to compute his own ratios.

What the reader needs to worry about is the fact that different people and different sources seldom compute these ratios in exactly the same way, and this leads to much confusion. The specific definitions we use here may or may not be the same as the one the reader have seen or will see elsewhere. If the reader is ever using ratios as a tool for analysis, he should be careful to document how he calculate each one. And if the reader is comparing his numbers to numbers from another source, be sure you know how those numbers are computed!

We will defer much of our discussion of how ratios are used and some problems that come up with using them. For now, for each of the ratios we discuss, we consider several questions:

1. How is it computed?
2. What is it intended to measure, and why might we be interested?
3. What is the unit of measurement?
4. What might a high or low value tell us? How might such values be misleading?
5. How could this measure be improved?

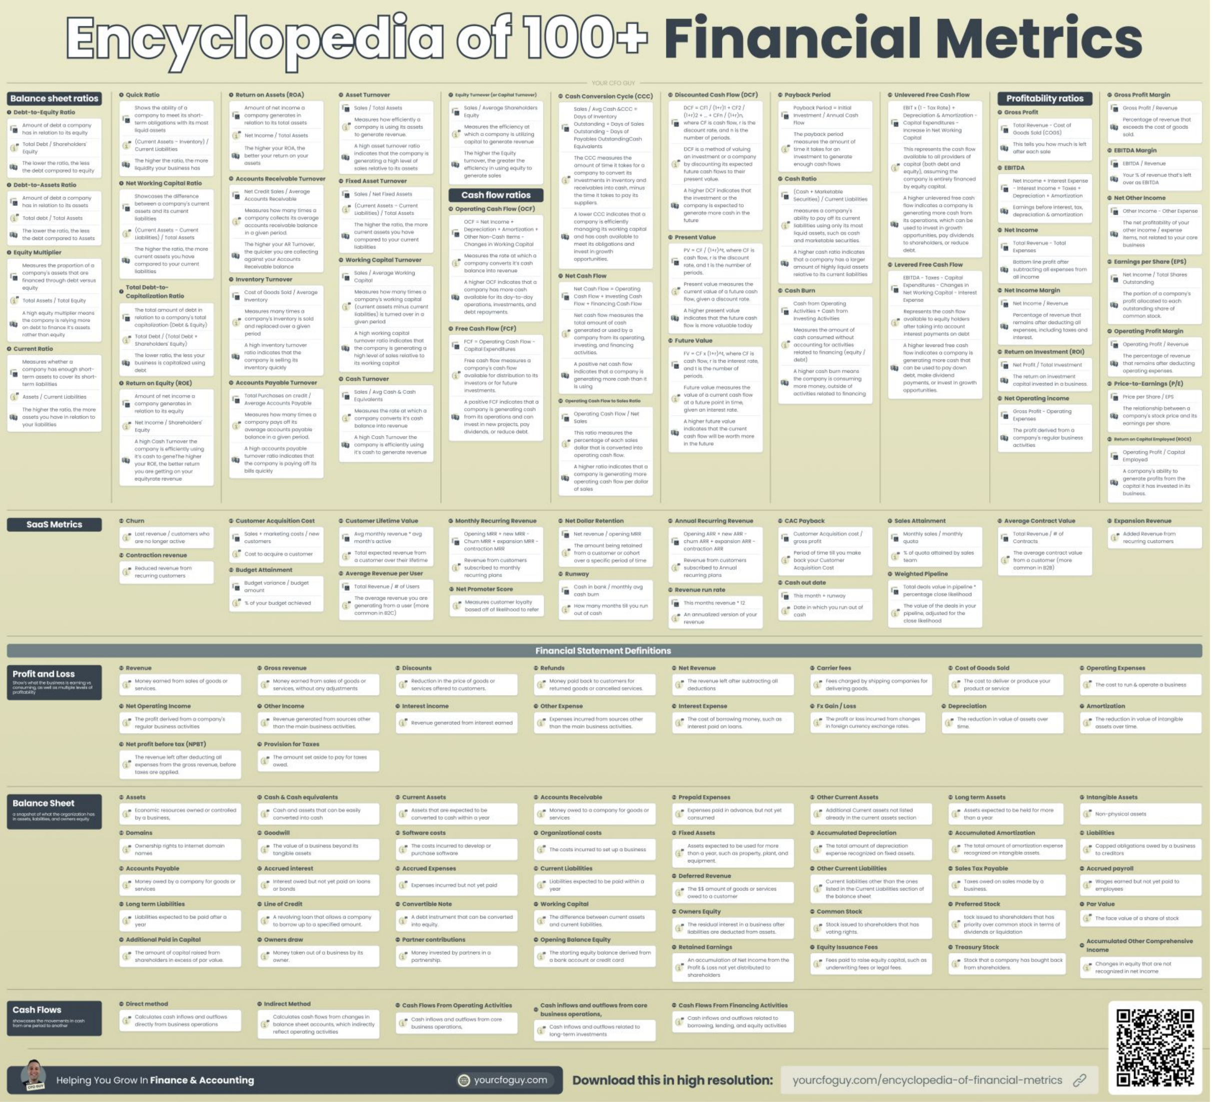
---

[48] The reader can also refer to a book like *Financial Ratios for Executives, How to Assess Company Strength, Fix Problems, and Make Better Decisions* of Michael Rist and Albert J. Pizzica

Financial ratios are traditionally grouped into the following categories:

1. Short-term solvency, or liquidity, ratios.
2. Long-term solvency, or financial leverage, ratios.
3. Asset management, or turnover, ratios.
4. Profitability ratios.
5. Market value ratios.

There are plenty of corporate and accounting ratios/indicators and other metrics in practice, easily more than a hundred. Here is a quite well known poster giving a definition of one hundred of the most important one[49]:



Encyclopedia of 100+ Financial Metrics

YOUR CFO GUY

Balance sheet ratios

Debt-to-Equity Ratio
- Amount of debt a company has in relation to its equity
- Total Debt / Shareholders' Equity
- The lower the ratio, the less the debt compared to equity

Debt-to-Assets Ratio
- Amount of debt a company has in relation to its assets
- Total debt / Total Assets
- The lower the ratio, the less the debt compared to Assets

Equity Multiplier
- Measures the proportion of a company's assets that are financed through debt versus equity
- Total Assets / Total Equity
- A high equity multiplier means the company is relying more on debt to finance it's assets rather than equity

Current Ratio
- Measures whether a company has enough short-term assets to cover its short-term liabilities
- Assets / Current Liabilities
- The higher the ratio, the more assets you have in relation to your liabilities

Quick Ratio
- Shows the ability of a company to meet its short-term obligations with its most liquid assets
- (Current Assets - Inventory) / Current Liabilities
- The higher the ratio, the more liquidity your business has

Net Working Capital Ratio
- Showcases the difference between a company's current assets and its current liabilities
- (Current Assets - Current Liabilities) / Total Assets
- The higher the ratio, the more current assets you have compared to your current liabilities

Total Debt-to-Capitalization Ratio
- The total amount of debt in relation to a company's total capitalization (Debt & Equity)
- Total Debt / (Total Debt + Shareholders' Equity)
- The lower ratio, the less your business is capitalized using debt

Return on Equity (ROE)
- Amount of net income a company generates in relation to its equity
- Net Income / Shareholders' Equity
- A high Cash Turnover the company is efficiently using it's cash to geneThe higher your ROE, the better return you are getting on your equityrate revenue

Return on Assets (ROA)
- Amount of net income a company generates in relation to its total assets
- Net Income / Total Assets
- The higher your ROA, the better your return on your assets

Accounts Receivable Turnover
- Net Credit Sales / Average Accounts Receivable
- Measures how many times a company collects its average accounts receivable balance in a given period
- The higher your AR Turnover, the quicker you are collecting against your Accounts Receivable balance

Inventory Turnover
- Cost of Goods Sold / Average Inventory
- Measures many times a company's inventory is sold and replaced over a given period
- A high inventory turnover ratio indicates that the company is selling its inventory quickly

Accounts Payable Turnover
- Total Purchases on credit / Average Accounts Payable
- Measures how many times a company pays off its average accounts payable balance in a given period.
- A high accounts payable turnover ratio indicates that the company is paying off its bills quickly

Asset Turnover
- Sales / Total Assets
- Measures how efficiently a company is using its assets to generate revenue.
- A high asset turnover ratio indicates that the company is generating a high level of sales relative to its assets

Fixed Asset Turnover
- Sales / Net Fixed Assets
- (Current Assets - Current Liabilities) / Total Assets
- The higher the ratio, the more current assets you have compared to your current liabilities

Working Capital Turnover
- Sales / Average Working Capital
- Measures how many times a company's working capital (current assets minus current liabilities) is turned over in a given period
- A high working capital turnover ratio indicates that the company is generating a high level of sales relative to its working capital

Cash Turnover
- Sales / Avg Cash & Cash Equivalents
- Measures the rate at which a company converts it's cash balance into revenue
- A high Cash Turnover the company is efficiently using it's cash to generate revenue

Equity Turnover (or Capital Turnover)
- Sales / Average Shareholders Equity
- Measures the efficiency at which a company is utilizing capital to generate revenue
- The higher the Equity turnover, the greater the efficiency in using equity to generate sales

Cash flow ratios

Operating Cash Flow (OCF)
- OCF = Net Income + Depreciation + Amortization + Other Non-Cash Items - Changes in Working Capital
- Measures the rate at which a company converts it's cash balance into revenue
- A higher OCF indicates that a company has more cash available for its day-to-day operations, investments, and debt repayments.

Free Cash Flow (FCF)
- FCF = Operating Cash Flow - Capital Expenditures
- Free cash flow measures a company's cash flow available for distribution to its investors or for future investments.
- A positive FCF indicates that a company is generating cash from its operations and can invest in new projects, pay dividends, or reduce debt.

Cash Conversion Cycle (CCC)
- Sales / Avg Cash &CCC = Days of Inventory Outstanding + Days of Sales Outstanding - Days of Payables OutstandingCash Equivalents
- The CCC measures the amount of time it takes for a company to convert its investments in inventory and receivables into cash, minus the time it takes to pay its suppliers.
- A lower CCC indicates that a company is efficiently managing its working capital and has cash available to meet its obligations and invest in growth opportunities.

Net Cash Flow
- Net Cash Flow = Operating Cash Flow + Investing Cash Flow + Financing Cash Flow
- Net cash flow measures the total amount of cash generated or used by a company from its operating, investing, and financing activities.
- A positive net cash flow indicates that a company is generating more cash than it is using

Operating Cash Flow to Sales Ratio
- Operating Cash Flow / Net Sales
- This ratio measures the percentage of each sales dollar that is converted into operating cash flow.
- A higher ratio indicates that a company is generating more operating cash flow per dollar of sales

Discounted Cash Flow (DCF)
- DCF = CF1 / (1+r)1 + CF2 / (1+r)2 + ... + CFn / (1+r)n, where CF is cash flow, r is the discount rate, and n is the number of periods.
- DCF is a method of valuing an investment or a company by discounting its expected future cash flows to their present value.
- A higher DCF indicates that the investment or the company is expected to generate more cash in the future

Present Value
- PV = CF / (1+r)^t, where CF is cash flow, r is the discount rate, and t is the number of periods.
- Present value measures the current value of a future cash flow, given a discount rate.
- A higher present value indicates that the future cash flow is more valuable today

Future Value
- FV = CF x (1+r)^t, where CF is cash flow, r is the interest rate, and t is the number of periods.
- Future value measures the value of a current cash flow at a future point in time, given an interest rate.
- A higher future value indicates that the current cash flow will be worth more in the future

Payback Period
- Payback Period = Initial Investment / Annual Cash Flow
- The payback period measures the amount of time it takes for an investment to generate enough cash flows

Cash Ratio
- (Cash + Marketable Securities) / Current Liabilities
- measures a company's ability to pay off its current liabilities using only its most liquid assets, such as cash and marketable securities.
- A higher cash ratio indicates that a company has a larger amount of highly liquid assets relative to its current liabilities

Cash Burn
- Cash from Operating Activities + Cash from Investing Activities
- Measures the amount of cash consumed without accounting for activities related to financing (equity / debt)
- A higher cash burn means the company is consuming more money, outside of activities related to financing

Unlevered Free Cash Flow
- EBIT x (1 - Tax Rate) + Depreciation & Amortization - Capital Expenditures - Increase in Net Working Capital
- This represents the cash flow available to all providers of capital (both debt and equity), assuming the company is entirely financed by equity capital.
- A higher unlevered free cash flow indicates a company is generating more cash from its operations, which can be used to invest in growth opportunities, pay dividends to shareholders, or reduce debt.

Levered Free Cash Flow
- EBITDA - Taxes - Capital Expenditures - Changes in Net Working Capital - Interest Expense
- Represents the cash flow available to equity holders after taking into account interest payments on debt
- A higher levered free cash flow indicates a company is generating more cash that can be used to pay down debt, make dividend payments, or invest in growth opportunities.

Profitability ratios

Gross Profit
- Total Revenue - Cost of Goods Sold (COGS)
- This tells you how much is left after each sale

EBITDA
- Net Income + Interest Expense - Interest Income + Taxes + Depreciation + Amortization
- Earnings before interest, tax, depreciation & amortization

Net Income
- Total Revenue - Total Expenses
- Bottom line profit after subtracting all expenses from all income

Net Income Margin
- Net Income / Revenue
- Percentage of revenue that remains after deducting all expenses, including taxes and interest.

Return on Investment (ROI)
- Net Profit / Total Investment
- The return on investment capital invested in a business.

Net Operating income
- Gross Profit - Operating Expenses
- The profit derived from a company's regular business activities

Gross Profit Margin
- Gross Profit / Revenue
- Percentage of revenue that exceeds the cost of goods sold.

EBITDA Margin
- EBITDA / Revenue
- Your % of revenue that's left over as EBITDA

Net Other Income
- Other Income - Other Expense
- The net profitability of your other income / expense items, not related to your core business

Earnings per Share (EPS)
- Net Income / Total Shares Outstanding
- The portion of a company's profit allocated to each outstanding share of common stock.

Operating Profit Margin
- Operating Profit / Revenue
- The percentage of revenue that remains after deducting operating expenses.

Price-to-Earnings (P/E)
- Price per Share / EPS
- The relationship between a company's stock price and its earnings per share.

Return on Capital Employed (ROCE)
- Operating Profit / Capital Employed
- A company's ability to generate profits from the capital it has invested in its business.

SaaS Metrics

Churn
- Lost revenue / customers who are no longer active

Contraction revenue
- Reduced revenue from recurring customers

Customer Acquisition Cost
- Sales + marketing costs / new customers
- Cost to acquire a customer

Budget Attainment
- Budget variance / budget amount
- % of your budget achieved

Customer Lifetime Value
- Avg monthly revenue * avg month's active
- Total expected revenue from a customer over their lifetime

Average Revenue per User
- Total Revenue / # of Users
- The average revenue you are generating from a user (more common in B2C)

Monthly Recurring Revenue
- Opening MRR + new MRR - Churn MRR + expansion MRR - contraction MRR
- Revenue from customers subscribed to monthly recurring plans

Net Promoter Score
- Measures customer loyalty based off of likelihood to refer

Net Dollar Retention
- Net revenue / opening MRR
- The amount being retained from a customer or cohort over a specific period of time

Runway
- Cash in bank / monthly avg cash burn
- How many months till you run out of cash

Annual Recurring Revenue
- Opening ARR + new ARR - churn ARR + expansion ARR - contraction ARR
- Revenue from customers subscribed to Annual recurring plans

Revenue run rate
- This months revenue * 12
- An annualized version of your revenue

CAC Payback
- Customer Acquisition cost / gross profit
- Period of time till you make back your Customer Acquisition Cost

Cash out date
- This month + runway
- Date in which you run out of cash

Sales Attainment
- Monthly sales / monthly quota
- % of quota attained by sales team

Weighted Pipeline
- Total deals value in pipeline * percentage close likelihood
- The value of the deals in your pipeline, adjusted for the close likelihood

Average Contract Value
- Total Revenue / # of Contracts
- The average contract value from a customer (more common in B2B)

Expansion Revenue
- Added Revenue from recurring customers

Financial Statement Definitions

Profit and Loss

Show's what the business is earning vs consuming, as well as multiple levels of profitability

Revenue: Money earned from sales of goods or services.

Gross revenue: Money earned from sales of goods or services, without any adjustments

Discounts: Reduction in the price of goods or services offered to customers.

Refunds: Money paid back to customers for returned goods or cancelled services.

Net Revenue: The revenue left after subtracting all deductions

Carrier fees: Fees charged by shipping companies for delivering goods.

Cost of Goods Sold: The cost to deliver or produce your product or service

Operating Expenses: The cost to run & operate a business

Net Operating Income: The profit derived from a company's regular business activities

Other Income: Revenue generated from sources other than the main business activities.

Interest income: Revenue generated from interest earned

Other Expense: Expenses incurred from sources other than the main business activities.

Interest Expense: The cost of borrowing money, such as interest paid on loans.

Fx Gain / Loss: The profit or loss incurred from changes in foreign currency exchange rates.

Depreciation: The reduction in value of assets over time.

Amortization: The reduction in value of intangible assets over time.

Net profit before tax (NPBT): The revenue left after deducting all expenses from the gross revenue, before taxes are applied.

Provision for Taxes: The amount set aside to pay for taxes owed.

Balance Sheet

a snapshot of what the organization has in assets, liabilities, and owners equity

Assets: Economic resources owned or controlled by a business,

Cash & Cash equivalents: Cash and assets that can be easily converted into cash

Current Assets: Assets that are expected to be converted to cash within a year

Accounts Receivable: Money owed to a company for goods or services

Prepaid Expenses: Expenses paid in advance, but not yet consumed

Other Current Assets: Additional Current assets not listed already in the current assets section

Long term Assets: Assets expected to be held for more than a year

Intangible Assets: Non-physical assets

Domains: Ownership rights to internet domain names

Goodwill: The value of a business beyond its tangible assets

Software costs: The costs incurred to develop or purchase software

Organizational costs: The costs incurred to set up a business

Fixed Assets: Assets expected to be used for more than a year, such as property, plant, and equipment.

Accumulated Depreciation: The total amount of depreciation expense recognized on fixed assets.

Accumulated Amortization: The total amount of amortization expense recognized on intangible assets.

Liabilities: Capped obligations owed by a business to creditors

Accounts Payable: Money owed by a company for goods or services

Accrued interest: Interest owed but not yet paid on loans or bonds

Accrued Expenses: Expenses incurred but not yet paid

Current Liabilities: Liabilities expected to be paid within a year

Deferred Revenue: The $$ amount of goods or services owed to a customer

Other Current Liabilities: Current liabilities other than the ones listed in the Current Liabilities section of the balance sheet

Sales Tax Payable: Taxes owed on sales made by a business.

Accrued payroll: Wages earned but not yet paid to employees

Long term Liabilities: Liabilities expected to be paid after a year

Line of Credit: A revolving loan that allows a company to borrow up to a specified amount.

Convertible Note: A debt instrument that can be converted into equity.

Working Capital: The difference between current assets and current liabilities.

Owners Equity: The residual interest in a business after liabilities are deducted from assets.

Common Stock: Stock issued to shareholders that has voting rights.

Preferred Stock: tock issued to shareholders that has priority over common stock in terms of dividends or liquidation

Par Value: The face value of a share of stock

Additional Paid in Capital: The amount of capital raised from shareholders in excess of par value.

Owners draw: Money taken out of a business by its owner.

Partner contributions: Money invested by partners in a partnership.

Opening Balance Equity: The starting equity balance derived from a bank account or credit card

Retained Earnings: An accumulation of Net Income from the Profit & Loss not yet distributed to shareholders

Equity Issuance Fees: Fees paid to raise equity capital, such as underwriting fees or legal fees.

Treasury Stock: Stock that a company has bought back from shareholders.

Accumulated Other Comprehensive Income: Changes in equity that are not recognized in net income

Cash Flows

showcases the movements in cash from one period to another

Direct method: Calculates cash inflows and outflows directly from business operations

Indirect Method: Calculates cash flows from changes in balance sheet accounts, which indirectly reflect operating activities

Cash Flows From Operating Activities: Cash inflows and outflows from core business operations,

Cash inflows and outflows from core business operations,: Cash inflows and outflows related to long-term investments

Cash Flows From Financing Activities: Cash inflows and outflows related to borrowing, lending, and equity activities

Figure 15.279: 100+ **financial metrics (author: Josh Aharonoff)**

---

[49] In fact you can have an empirical choice with a poor scientific point of view of such a list by the same publisher of *The* 100 *most important financial performance indicators* that you can order on the web (see [549]). They have such small books also for others various fields like supply chain, IT, asset management, marketing, etc.

Let us now define only a few of them in this textbook.

15.4.1.2.1 Short term solvency or liquidity measure

As the name suggests, "short-term solvency ratios" as a group are intended to provide information about a firm's liquidity, and these ratios are sometimes named "liquidity measures".

The primary concern is the firm's ability to pay its bills over the short run without undue stress. Consequently, these ratios focus on current assets and current liabilities.

For obvious reasons, liquidity ratios are particularly interesting to short-term creditors. Because financial managers work constantly with banks and other short-term lenders, an understanding of these ratios is essential.

One of the best known and most widely used ratios is the "current ratio". As you might guess, the current ratio at time t is defined as follows:

$$\text{CR}(t)=\frac{\mathcal{A}(t)}{\mathcal{L}(t)} \tag{15.4.3}$$

Because current assets and liabilities are, in principle, converted to cash over the following 12 months, the current ratio is a measure of short-term liquidity.

To a creditor (particularly a short-term creditor such as a supplier) the higher the current ratio, the better. To the firm, a high current ratio indicates liquidity, but it also may indicate an inefficient use of cash and other short-term assets. Absent some extraordinary circumstances, we would expect to see a current ratio of at least 1 because a current ratio of less than 1 would mean that net working capital (current assets less current liabilities) is negative. This would be unusual in a healthy firm, at least for most types of businesses.

Inventory is often the least liquid current asset. It's also the one for which the book values are least reliable as measures of market value because the quality of the inventory isn't considered. Some of the inventory may later turn out to be damaged, obsolete, or lost.

More to the point, relatively large inventories are often a sign of short-term trouble. The firm may have overestimated sales and overbought or overproduced as a result. In this case, the firm may have a substantial portion of its liquidity tied up in slow-moving inventory.

To further evaluate liquidity, the "quick ratio", or "acid-test", is computed just like the current ratio (CR), except inventory $\mathcal{I}$ is omitted at a given time t:

$$\text{QR}(t)=\frac{\mathcal{A}-\mathcal{I}}{\mathcal{A}} \tag{15.4.4}$$

Notice that using cash to buy inventory does not affect the current ratio (CR), but it reduces the quick ratio (QR). Again, the idea is that inventory is relatively illiquid compared to cash.

We briefly mention three other measures of liquidity. A very short-term creditor might be interested in the "cash ratio" (CR):

$$\text{CR}(t)=\frac{\mathcal{A}_{\text{cash only}}(t)}{\mathcal{L}(t)} \tag{15.4.5}$$

The "interval measure" (IM) is also useful. It gives us how long the company can operate until it needs another round of financing. The average daily operating cost for companies is often named the "burn rate" meaning the rate at which cash is burned in the race to become profitable:

$$\text{IM}(t)=\frac{\mathcal{A}_{\text{cash only}}(t)}{\bar{C}_d} \tag{15.4.6}$$

where $\bar{C}_d$ is the average daily cost.

15.4.1.2.2 Long term solvency or Liquidity measure

Long-term solvency ratios are intended to address the firm's long-term ability to meet its obligations, or, more generally, its financial leverage. These are sometimes named "financial leverage ratios" or just "leverage ratios".

The "total debt ratio" takes into account all debts of all maturities to all creditors. It can be defined in several ways. One possible way is at a given time t:

$$\text{TDR}(t)=\frac{\mathcal{A}(t)-\mathcal{E}(t)}{\mathcal{A}(t)} \tag{15.4.7}$$

We can define two useful variations of the total debt ratio! The "debt–equity ratio" (DER) defined by:

$$\text{DER}(t)=\frac{\mathcal{D}(t)}{\mathcal{E}(t)} \tag{15.4.8}$$

where $\mathcal{D}$ is the total debt at time t and the "equity multiplier" (EM):

$$\text{EM}(t)=\frac{\mathcal{A}(t)}{\mathcal{E}(t)} \tag{15.4.9}$$

To complicate matters, different people (and different books) mean different things by the term debt ratio. Some mean a ratio of total debt, some mean a ratio of long-term debt only, and, unfortunately, a substantial number are simply vague about which one they mean.

Another common measure of long-term solvency is the "times interest earned ratio". Once again, there are several possible (and common) definitions. One is given by:

$$\text{TIER}(t)=\frac{\text{EBIT}(t)}{I(t)} \tag{15.4.10}$$

where EBIT is the "Earnings Before Interest And Taxes" and I the interests paid.

Obviously as the name suggests, this ratio measures how well a company has its interest obligations covered.

15.4.1.2.3 Profitability Measures

The best known and most widely used of all financial ratios. In one form or another, they are intended to measure how efficiently a firm uses its assets and manages its operations. The focus in this group is on the bottom line, net income.

Companies pay a great deal of attention to their "profit margins":

$$\text{PM}(t)=\frac{\text{Net Income}(t)}{\text{Sales}(t)} \tag{15.4.11}$$

and obviously this give the amount of profit for every currency unit in sales.

All other things being equal, a relatively high profit margin is obviously desirable. This situation corresponds to low expense ratios relative to sales.

The "return on assets" (RoA) is a measure of profit per currency unit of assets. It can be defined several ways, but the most common is this:

$$\text{RoA}(t)=\frac{\text{Net Income}(t)}{\mathcal{A}(t)} \tag{15.4.12}$$

The "return on equity" (RoE) is a measure of how the stockholders fared during the year. Because benefiting shareholders is our goal, RoE is, in an accounting sense, the true bottom-line measure of performance. RoE is usually measured as follows:

$$\text{RoE}(t)=\frac{\text{Net Income}(t)}{\mathcal{E}(t)} \tag{15.4.13}$$

The fact that RoE exceeds RoA reflects typically the use of financial leverage (debts).

As we mentioned in discussing RoA and RoE, the difference between these two profitability measures is a reflection of the use of debt financing, or financial leverage. We illustrate the relationship between these measures in this section by investigating a famous way of decomposing RoE into its component parts.

Let us recall the definition of RoE:

$$\text{RoE}(t)=\frac{\text{Net Income}(t)}{\mathcal{E}(t)} \tag{15.4.14}$$

If we were so inclined, we could multiply this ratio by Assets/Assets without changing anything:

$$\text{RoE}(t)=\frac{\text{Net Income}(t)}{\mathcal{E}(t)}\frac{\mathcal{A}(t)}{\mathcal{A}(t)}=\frac{\text{Net Income}(t)}{\mathcal{A}(t)}\frac{\mathcal{A}(t)}{\mathcal{E}(t)} \tag{15.4.15}$$

Notice that we can expressed the RoE as the product of two other ratios that are respectively the RoA and an the equity multiplier $\mathcal{E}_M$:

$$\text{RoE}(t)=\text{RoA}(t)\mathcal{E}_M(t) \tag{15.4.16}$$

We can further decompose ROE by multiplying the top and bottom by total sales:

$$\text{RoE}(t)=\frac{\text{Sales}}{\text{Sales}}\frac{\text{Net Income}(t)}{\mathcal{A}(t)}\frac{\mathcal{A}(t)}{\mathcal{E}(t)}=\frac{\mathcal{S}}{\mathcal{S}}\frac{\text{Net Income}(t)}{\mathcal{A}(t)}\frac{\mathcal{A}(t)}{\mathcal{E}(t)} \tag{15.4.17}$$

If we rearrange things a bit, RoE looks like this:

$$\text{RoE}(t)=\underbrace{\frac{\text{Net Income}(t)}{\mathcal{S}}\frac{\mathcal{S}}{\mathcal{A}(t)}}_{\text{RoA}}\frac{\mathcal{A}(t)}{\mathcal{E}(t)}=\text{PM}(t)\text{RoA}(t)\mathcal{E}_M(t) \qquad (15.4.18)$$

What we have now done is to partition RoA into its two component parts, profit margin and total asset turnover. The last expression of the preceding equation is named the "DuPont identity", after the DuPont Corporation, which popularized its use.

✍**Example:**

General Motors provides a good example of how DuPont analysis can be very useful and also illustrates why care must be taken in interpreting RoE values. In 11989 (holocene calendar), GM had an RoE of 12.1%. By 1993 (holocene calendar), its RoE had improved to 44.1%, a dramatic improvement. On closer inspection, however, we find that over the same period GM's profit margin had declined from 3.4 to 1.8%, and RoA had declined from 2.4 to 1.3% percent. The decline in RoA was moderated only slightly by an increase in total asset turnover from 0.71 to 0.73 over the period.

Given this information, how is it possible for GM's RoE to have climbed so sharply? From our understanding of the DuPont identity, it must be the case that GM's equity multiplier increased substantially. In fact, what happened was that GM's book equity value was almost wiped out overnight in 11992 (holocene calendar) by changes in the accounting treatment of pension liabilities. If a company's equity value declines sharply, its equity multiplier rises. In GM's case, the multiplier went from 4.95 in 11989 (holocene calendar) to 33.62 in 11993 (holocene calendar). In sum, the dramatic "improvement" in GM's RoE was almost entirely due to an accounting change that affected the equity multiplier and didn't really represent an improvement in financial performance at all.

15.4.1.2.4 Growth Rate

The first growth rate of interest is the maximum growth rate that can be achieved with no external financing of any kind. We will named this the "internal growth rate" because this is the rate the firm can maintain with internal financing only.

Given that there is therefore either no Equities or Debts only the RoA will be useful to create this rate. Considering that a part of the RoA will be use for internal expenses, or taxes, we multiply the RoA (remember that it is a ratio, therefore without units) by a factor p named the "plowback" factor to get the net PoA!

Afterwards the most naive high-school level model make the assumption that the growing rate is a linear function of time (forge any ARMA/ARIMA, GARCH forecasting model in Corporate Finance trainings even at a graduate level!) such that:

$$\text{IGR}(t)=\text{RoA}(t)(1+\text{IGR}(t-1)) \qquad (15.4.19)$$

and therefore after making the assumption of small variations we get:

$$\text{IGR}(t)\cong\text{RoA}(t)(1+\text{IGR}(t)) \qquad (15.4.20)$$

Hence:

$$\text{IGR}(t) \cong \frac{\text{RoA}(t)}{1-\text{RoA}(t)} \tag{15.4.21}$$

But it is quite naive and very academic relation. In reality no serious practitioners should use such a method! But instead stochastic related forecasting techniques!!

15.4.1.2.5 Asset management or turnovers measures

The measures in this section are sometimes named "asset utilization ratios". The specific ratios we discuss can all be interpreted as measures of turnover. What they are intended to describe is how efficiently or intensively a firm uses its assets to generate sales.

The "inventory turnover ratio" is defined as:

$$\text{ITR}(\Delta t) = \text{ITR}(t_f - t_0) = \frac{\text{Cost of goods sold}(\Delta t)}{\mathcal{I}(t_f)} \tag{15.4.22}$$

the higher this ratio is, the more efficiently we are managing inventory.

Our inventory measures give some indication of how fast we can sell product. We now look at how fast we collect on those sales. The "receivables turnover ratio" is defined much like the inventory turnover ratio:

$$\text{RTR}(\Delta t) = \frac{\text{Sales}(\Delta t)}{\text{Accounts receivable}(t_f)} \tag{15.4.23}$$

15.4.1.2.6 Market Value Measures

Our final group of measures is based, in part, on information not necessarily contained in financial statements: the market price per share of stock. Obviously, these measures can be calculated directly only for publicly traded companies.

We begin with what we have already defined in the section Economy. The earning per share:

$$\text{EPS}(t) = \frac{\text{Net Income}(t)}{\text{Shares Issued}(t)} \tag{15.4.24}$$

We also have the "price earning ratio" defined by:

$$\text{PER}(t) = \frac{\text{Price per Share}(t)}{\text{EpS}(t)} = \frac{\text{PpS}(t)}{\text{EpS}(t)} \tag{15.4.25}$$

the ratio measures how much investors are willing to pay per dollar of current earnings, higher PERs are often taken to mean the firm has significant prospects for future growth. Of course, if a firm had no or almost no earnings, its PE would probably be quite large. So, as always, care is needed in interpreting this ratio.

Another commonly quoted market value measure is the "market to book ratio":

$$\text{MtBR}(t) = \frac{\text{Market Value per Share}(t)}{\text{Book Value per Share}(t)} = \frac{\text{MVpS}(t)}{\text{BVpS}(t)} \tag{15.4.26}$$

The book value per share is total equity (not just common stock) divided by the number of issued shares!!

In a loose sense, the market-to-book ratio therefore compares the market value of the firm's investments to their cost. A value less than 1 could mean that the firm has not been successful overall in creating value for its stockholders.

This completes our definitions of some common one-to-one ratios. We could tell you about more of them, but these are enough for now and its already quite boring enough in absence of ISO norms. So now let us deal with multiple-to-multiple ratios performance analysis:

15.4.1.2.7 Data Envelopment Analysis

"Data envelopment analysis" (DEA) is a operational research methodology (see section Numerical methods page 6662) to evaluate the relative efficiency score η[50] of multiple decision-making units (DMUs or "comparable production units") when the production process presents a structure of multiple inputs x_i and outputs y_i. It is a quite powerful service management and benchmarking technique originally developed by Chames, Cooper and Rhodes (11978 according to holocene calendar) to evaluate non-profit and public sector organizations[51]. DEA has since been proven to locate ways to improve service not visible with other techniques. Yet there is an anomaly surrounding this developing methodology. One of the largest US banks located over $\$100$ million of excess annual personnel and operating costs, enough to affect their earnings per share and these savings were not identifiable with other techniques in use. While other banks have also realized improved profits through initiatives driven by DEA, we could not locate more than 10 banks in this category. While businesses have no obligation to report their internal methods, DEA has not been widely adopted by banks. Why is DEA a method that can generates new paths to improve profits not used when other less powerful techniques continue to be used? We believe that greater adoption of DEA will only be possible when it is more accessible to non-technical skills (as most managers and CXO are soft-skills).

Remark

In the literature, the two most widely used variants of the DEA method are: the CCR model (Charnes, Cooper and Rhodes, 11978 according to holocene calendar) which assumes constant scale returns and the BCC model (Banker, Charnes et al. Cooper, 11984 according to holocene calendar) which assumes variable scale yields. In the case of constant scale returns, it is assumed that an increase in the amount of inputs consumed will lead to a proportional increase in the quantity of outputs produced. On the other hand, in the case of returns of variable scales (increasing or decreasing), the quantity of outputs produced is considered to increase more or less proportionally than the increase in inputs.

---

[50] When we focus on service organizations we generally cannot determine what the engineered, optimum or absolute efficient output-to-input ratio is. Consequently we cannot determine whether a service unit is absolutely efficient. We can, however, compare several service unit output-to-input ratios and determine that one unit is more or less efficient than another - benchmarking. The difference in efficiency will be due to the technology or production process used, how well that process is managed, and/or the scale or size of the unit.

[51] It has been developed in fact to analyse the efficiency of the US resources allocation strategy to the schools and have afterwards be applied to all other government services. The India government also use it for the same purposes.

Managers have not widely adopted DEA to improve organization performance, in part, because most DEA publications are in academic journals or books requiring the ability to understand operational research and supporting mathematical notation. In fact, some managers trying to use DEA based on their understanding of academic publications have misunderstood the way to apply DEA. They erroneously attribute weak results to the technique when the problem is often due to the misapplication of DEA. Another problem (maybe it is the biggest), DEA will be more used when CXO will stop to fear the fact to listen that their organization is non-efficient.

We will explain here what DEA does, how DEA evaluates efficiency, how DEA identifies paths to improve efficiency, limitations of DEA, and how to use DEA. This will enable managers or governments to explore and assess the value of their organization using DEA in their service operations.

What does DEA do?

1. DEA compares service units considering all resources used and services provided, and identifies the most efficient units or best practice units (branches, departments, individuals) and the inefficient units in which real efficiency improvements are possible. This is achieved by comparing the mix and volume of services provided and the resources used by each unit compared with those of all the other units. In short, DEA is a very powerful benchmarking technique.

2. DEA calculates the amount and type of cost and resource savings that can be achieved by making each inefficient unit as efficient as the most efficient - best practice - units.

3. Specific changes in the inefficient service units are identified, which management can implement to achieve potential savings located with DEA. These changes would make the efficient units performance approach the best practice unit performance. In addition, DEA estimates the amount of additional service an inefficient unit can provide without the need to use additional resources.

4. Management receives information about performance of service units that can be used to help transfer system and managerial expertise from better-managed, relatively efficient units to the inefficient ones. This has resulted in improving the productivity of the inefficient units, reducing operating costs and increasing profitability.

The above four types of DEA information are proven to be extremely valuable because they identify relationships not identifiable with alternative techniques that are commonly used in service organizations. As a result, improvements to operations extend beyond any performance improvements management may have achieved using other techniques.

It is considered that the non-efficiency of an organization is mainly due to two main factors:

- The organization may be non-efficient because its management may perform better (not to say deficient...).
- The organization may be non-efficient because it hasn't reached it's optimal size

Remark

Some managers pretend that their organization that performs badly according to a DEA analysis because they cannot be compared with other organization because of special other factors. This may be true but then... the "*burden of proof*" lies on them (as we have proved it in the section Statistics page 944).

Obviously the efficiency score must be considered as an order of amplitude, a result of binary judgement that helps manager to know if there is something to change or not. We could obviously used combinatorics methods on the inputs and outputs to get an interval rather than a punctual value.

Let us introduce now the corresponding mathematical framework! The operational research technique is used to find the set of coefficients (u's and v's) that will give the highest possible efficiency ratio of outputs to inputs for the service unit being evaluated.

In the model:

- j is the number of service units (SU) being compared in the DEA analysis
- SU$_j$ is the service unit number j
- η_j is the efficiency of the service unit j being evaluated by DEA
- y_{rj} is the amount of output r used by service unit j
- x_{ij} is the amount of input i used by the service unit j
- i number of inputs used by the SUs
- r number of outputs generated by the SUs
- u_r coefficient or weight assigned by DEA to output r
- v_i coefficient or weight assigned by DEA to input i

The data required to apply DEA are the actual observed outputs produced y_{rj} and the actual inputs used x_{ij}, during one time period for each service unit in the set of units being evaluated. Hence, x_{ij} is the observed amount of the ith input used by the jth service unit, and y_{rj} is the amount of rth output produced by the jth service unit.

If the value of θ for the service unit being evaluated is less than 100%, then that unit is inefficient, and there is the potential for that unit to produce the same level of outputs with fewer inputs.

The objective function is given by:

$$\max \eta_j=\dfrac{u_1y_{1j}+u_2y_{2j}+\ldots+u_ny_{nj}}{v_1x_{1j}+v_2x_{2j}+\ldots+v_mx_{mj}}=\dfrac{\displaystyle\sum_{r=1}^{n}u_ry_{rj}}{\displaystyle\sum_{i=1}^{m}v_ix_{ij}} \qquad (15.4.27)$$

This is subject to the constraint that when the same set of u and v coefficients is applied to all other service units being compared, no service unit (SU) will be more than 100% efficient as follows:

$$\forall k \neq j \quad \text{SU}_k : \eta_k = \frac{u_1 y_{1k} + u_2 y_{2k} + \ldots + u_m y_{mk}}{v_1 x_{1k} + v_2 x_{2k} + \ldots + v_n x_{nk}} = \frac{\displaystyle\sum_{r=1}^{n} u_r y_{rk}}{\displaystyle\sum_{i=1}^{m} v_i x_{ik}} \leq 1 \tag{15.4.28}$$

Finally all this compacted into the classical form of optimization problem will be written:

$$\boxed{\begin{array}{lll} \underset{\vec{u},\vec{v}}{\text{maximize}} & & \eta_j(\vec{u},\vec{v}) = \dfrac{\displaystyle\sum_{r=1}^{n} u_r y_{rj}}{\displaystyle\sum_{i=1}^{m} v_i x_{ij}} \\ \text{subject to} & \forall k \neq j & \text{SU}_k : \eta_k = \dfrac{\displaystyle\sum_{r=1}^{n} u_r y_{rk}}{\displaystyle\sum_{i=1}^{m} v_i x_{ik}} \leq 1 \\ & & u_r, v_i > 0 \qquad r, i = 1 \ldots n, m \end{array}} \tag{15.4.29}$$

Remark

It is recommended that the number of inputs and outputs attributes to not be bigger that then number of organizations divided by 3.

Note that optimal multipliers calculated by DEA are objectively determined weights that may not correspond to relative values that an analyst would assign to outputs and inputs and this is a good point as therefore there a are not subjective (or biased) human choice to do! Furthermore the weights can be different for each SU and this is more realistic! This is actually a strength and is not a weakness of DEA. A unit located as inefficient using DEA is so identified only after all possible weights have been considered to give that branch the highest rating possible consistent with the constraint that no branch in the data set can be more than 100% efficient. Hence, any other set of weights applied to all branches would only make an inefficient branch appear equally or less efficient; that is, DEA gives the benefit of the doubt to each branch or service unit in calculating the efficiency value. In addition DEA will not erroneously locate an efficient unit as inefficient. Hence, DEA gives the "benefit of the doubt" to each unit being evaluated trying to make it look as efficient as possible in comparison with the other units. This bias makes this a tool that managers can use with confidence.

Figure 15.280: **Data Envelopment Analysis**

To appreciate the power and limitations of DEA in improving efficiency, let us see an example with Microsoft® Excel® (the reader can also found the corresponding example in the R companion book):

✍**Example:**
Consider we have five administrations (office) that delivers birth and marriage acts in various quantities during the same period of time and that each office has one employee only. We want to run a DEA analysis on the following situation summarized in the table below:

Government Office	Input 1 Employees	Output 1 Birth acts	Output 2 Marriage acts
Office A	1	1	6
Office B	1	3	8
Office C	1	4	3
Office D	1	5	6
Office E	1	6	2

For this purpose in Microsoft® Excel® 14.0.7190 we build the following structure:

	A	B	C	D	E
1	Government Office	**Input 1** Employees	**Output 1** Birth acts	**Output 2** Marriage acts	**Efficiency**
2	Office A	1	1	6	0.0007
3	Office B	1	3	8	0.0011
4	Office C	1	4	3	0.0007
5	Office D	1	5	6	0.0011
6	Office E	1	6	2	0.0008
7					
8		Poids **Input 1**	Poids **Output 1**	Poids **Output 2**	
9		0.01	0.01	0.01	

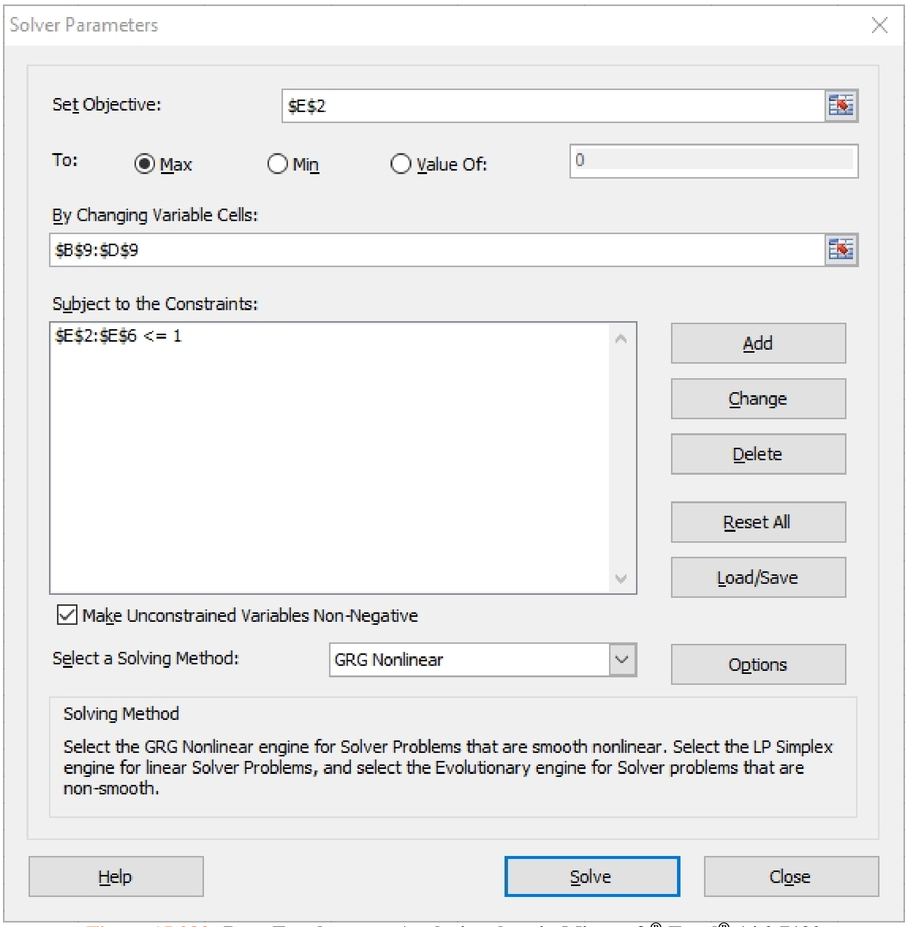
Figure 15.281: **Data Envelopment Analysis example in Microsoft® Excel® 14.0.7190**

Or explicitly:

	A	B	C	D	E
1	**Government Office**	**Input 1** Employees	**Output 1** Birth acts	**Output 2** Marriage acts	**Efficiency**
2	Office A	1	1	6	=SUMPRODUCT(C2:D2,$C$9:$D$9)/B2*$B$9
3	Office B	1	3	8	=SUMPRODUCT(C3:D3,$C$9:$D$9)/B3*$B$9
4	Office C	1	4	3	=SUMPRODUCT(C4:D4,$C$9:$D$9)/B4*$B$9
5	Office D	1	5	6	=SUMPRODUCT(C5:D5,$C$9:$D$9)/B5*$B$9
6	Office E	1	6	2	=SUMPRODUCT(C6:D6,$C$9:$D$9)/B6*$B$9
7					
8		Poids **Input 1**	Poids **Output 1**	Poids **Output 2**	
9		0.01	0.01	0.01	

Figure 15.282: Data Envelopment Analysis formulas in Microsoft® Excel® 14.0.7190

Once this done we run a first time the solver with the following settings:



Solver Parameters

Set Objective: $E$2

To: ● Max ○ Min ○ Value Of: 0

By Changing Variable Cells: $B$9:$D$9

Subject to the Constraints:

$E$2:$E$6 <= 1

☑ Make Unconstrained Variables Non-Negative

Select a Solving Method: GRG Nonlinear

Solving Method

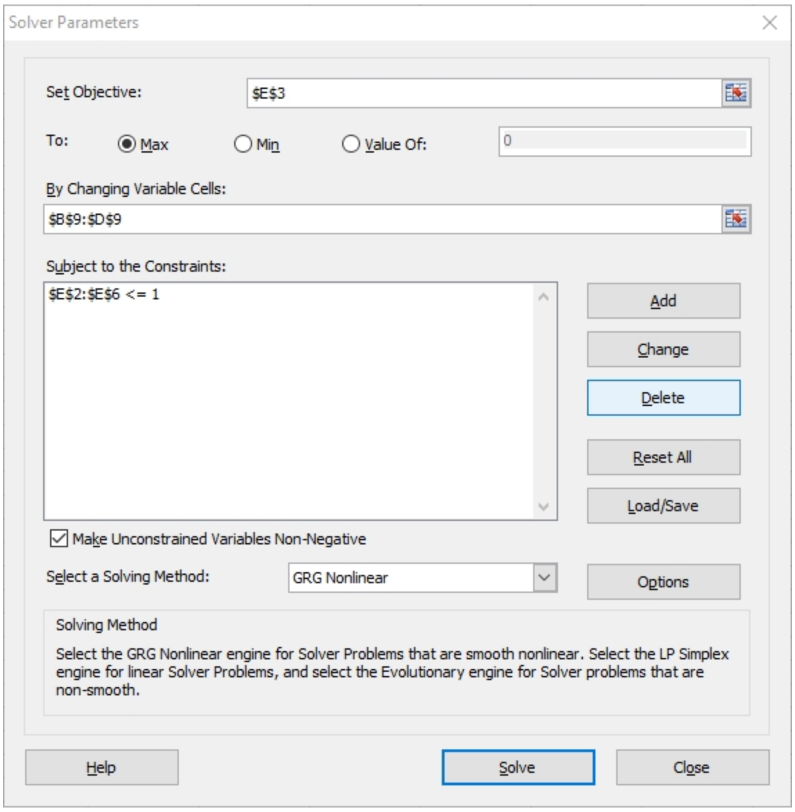
Select the GRG Nonlinear engine for Solver Problems that are smooth nonlinear. Select the LP Simplex engine for linear Solver Problems, and select the Evolutionary engine for Solver problems that are non-smooth.

Figure 15.283: Data Envelopment Analysis solver in Microsoft® Excel® 14.0.7190

Then we get for Office A:

	A	B	C	D	E
1	**Government Office**	**Input 1** Employees	**Output 1** Birth acts	**Output 2** Marriage acts	**Efficiency**
2	Office A	1	1	6	0.7500
3	Office B	1	3	8	1.0000
4	Office C	1	4	3	0.3750
5	Office D	1	5	6	0.7500
6	Office E	1	6	2	0.2500
7					
8		Poids **Input 1**	Poids **Output 1**	Poids **Output 2**	
9		0.4928541	0	0.253624863	

Doing the same for Office B but with the following settings:



Set Objective: $E$3

To: ● Max ○ Min ○ Value Of: 0

By Changing Variable Cells: $B$9:$D$9

Subject to the Constraints:

$E$2:$E$6 <= 1

☑ Make Unconstrained Variables Non-Negative

Select a Solving Method: GRG Nonlinear

Solving Method

Select the GRG Nonlinear engine for Solver Problems that are smooth nonlinear. Select the LP Simplex engine for linear Solver Problems, and select the Evolutionary engine for Solver problems that are non-smooth.

we get:

	A	B	C	D	E
1	**Government Office**	**Input 1** Employees	**Output 1** Birth acts	**Output 2** Marriage acts	**Efficiency**
2	Office A	1	1	6	0.6957
3	Office B	1	3	8	1.0000
4	Office C	1	4	3	0.5000
5	Office D	1	5	6	0.8695
6	Office E	1	6	2	0.4782
7					
8		Poids **Input 1**	Poids **Output 1**	Poids **Output 2**	
9		0.432464	0.100507	0.251351351	

And proceeding same for Office C, we get:

	A	B	C	D	E
1	**Government Office**	**Input 1** Employees	**Output 1** Birth acts	**Output 2** Marriage acts	**Efficiency**
2	Office A	1	1	6	0.3846
3	Office B	1	3	8	0.7692
4	Office C	1	4	3	0.7308
5	Office D	1	5	6	1.0000
6	Office E	1	6	2	1.0000
7					
8		Poids **Input 1**	Poids **Output 1**	Poids **Output 2**

We see that all five efficiencies $\{0.7500, 1.0000, 0.7308, 1.0000, \}$ matches perfectly with the results we get with `R` in the corresponding companion book.

First, as we know, efficiency can be simply defined as the ratio of output to input. More output per unit of input reflects relatively greater efficiency. If the greatest possible output per unit of input is achieved, a state of absolute or optimum efficiency has been achieved and it is not possible to become more efficient without new technology or other changes in the production process.

Some of the advantages of DEA are:

- no need to explicitly specify a mathematical form for the production function
- proven to be useful in uncovering relationships that remain hidden for other methodologies
- capable of handling multiple inputs and outputs
- capable of being used with any input-output measurement
- the sources of inefficiency can be analysed and quantified for every evaluated unit

Some of the disadvantages of DEA are:

- results are sensitive to the selection of inputs and outputs
- you cannot test for the best specification
- the number of efficient firms tends to increase with the number of inputs and output variables

DEA is commonly applied in the electric utilities sector. For instance a government authority can choose Data Envelopment Analysis as their measuring tool to design an individualized regulatory rate for each firm based on their comparative efficiency. The input components would include man-hours, losses, capital (lines and transformers only), and goods and services. The output variables would include number of customers, energy delivered, length of lines, and degree of coastal exposure (Berg 12010). DEA is also regularly used to assess the efficiency of public and not-for-profit organizations, e.g. hospitals (Kuntz, Scholtes & Vera 12007; Kuntz & Vera 12007; Vera & Kuntz 12007) or police forces (Thanassoulis 11995; Sun 12002; Aristovnik et al. 12013, 12014).

DEA has been recognized as a valuable analytical research instrument and a practical decision support tool. DEA has been credited for not requiring a complete specification for the functional form of the production frontier nor the distribution of inefficient deviations from the frontier. Rather, DEA requires general production and distribution assumptions only. However, if those assumptions are too weak, inefficiency levels may be systematically underestimated in small samples. In addition, erroneous assumptions may cause inconsistency with a bias over the frontier. Therefore, the ability to alter, test and select production assumptions is essential in conducting DEA-based research. However, the DEA models currently available offer a limited variety of alternative production assumptions only.

We have described the basic DEA model, the insights it provides in a simple example where similar insight could be gained from observation and where the operational research programming calculations could easily be done with a simple spreadsheet software.

The reader should know however that in the specialized literature about these subjects he will be able to find a lot of other DEA models. Respectively (with their corresponding abbreviations):

- FDH: Free disposability hull, no convexity assumption
- VRS: Variable returns to scale, convexity and free disposability
- DRS: Decreasing returns to scale, convexity, down-scaling and free disposability
- CRS: Constant returns to scale, convexity and free disposability
- IRS: Increasing returns to scale, (up-scaling, but not down-scaling), convexity and free disposability
- IRS2: Increasing returns to scale (up-scaling, but not down-scaling), additivity, and free disposability
- ADD: Additivity (scaling up and down, but only with integers), and free disposability; also known as replicability and free disposability, the free disposability and replicability hull (frh) – no convexity assumption

- FDH+: A combination of free disposability and restricted or local constant return to scale

The model that we have seen above is named the "CRS model" for "Constant Returns to Scale".

Each model exists also for information in two variations (or "orientations") that so far I'm not very a fan of (so I will not introduce them in this textbook):

- "Input oriented": the DEA model minimize the inputs for a given level of outputs. In other words, it indicates of how much an organization can increase its inputs by still producing the same level of outputs. Then the performance margin is obviously on the input (i.e. it must decrease[52]).
- "Output oriented": the DEA model maximize the outputs for a given level of inputs. In other words, it indicates of how much an organization can increase its outputs by still having the same level of inputs. Then the performance margin is obviously on the output (i.e. it must increase).

The orientation of the model must be chosen according to the variables (inputs or outputs) over which decision-makers exercise the greatest management power. For example, a public school principal probably has more management power over the teaching staff (input) than the number of students received or the student results (outputs). In this case, an input orientation is more appropriate.

In the public sector, but sometimes also in the private sector, a certain level of resources is allocated and guaranteed to organizations. In such a case, the decision makers seek to maximize the benefits provided, and therefore choose an output orientation. Otherwise, if the objective of the decision-makers is to produce a certain level of outputs (for example an imposed quota), the latter seek to minimize the consumption of resources. They therefore opt for an input orientation.

If no constraints are imposed on the decision-makers and if they exercise a management power over both the inputs and the outputs, the orientation of the model depends on the objectives set for the organizations. Is the goal to reduce costs (input orientation) or to maximize production (orientation output)?

---

[52] This is typically the case in organizations that has become too big and must apply a cost compression optimization plan

15.4.1.3 Weighted Average Cost of Capital (WACC)

When a firm issues debt, equity, or other securities to fund a new investment, there are many potential consequences of its decision. By far the most important question for a CFO is whether different choices will affect the return of the firm and thus the amount of capital it can raise. Companies can use also the WACC to see if the investment projects available to them are worthwhile to undertake.

To answer this question we will assume a "perfect capital market" world in which:

1. Securities are fairly priced: Investors and firms can trade the same set of securities at competitive market prices equal to the present value of their future cash flows.
2. There are no tax consequences or transactions cost: There are no tax consequences, transaction cost, or other issuance costs associated with financing decisions or security trading.
3. Investment cash flows are independent of financing choices. A firm's financing decisions do not change the cash flows generated by its investments, nor do they reveal new information about those cash flows.

The are many ways to introduce the WACC that are more or less complex. In fact you know that in this textbook we like the easiest one.

Remark

The absence of debts means the absence of financial leverage (in fact there is a leverage but not so fast and big as with debts). Equity in a firm with no debt is therefore named "unlevered equity". Equity in a firm that also has debt is named levered equity".

Consider a firm that has an amount of dept $\mathcal{D}$ (share of stocks) with a return $r_{\mathcal{D}}=(1+t_{\mathcal{D}}\%)$ and an amount of equities $\mathcal{E}$ (bonds) with a return $r_{\mathcal{E}}=(1+t_{\mathcal{E}}\%)$

By application of simple interest rate composition we write:

$$\mathcal{D}r_{\mathcal{D}}+\mathcal{E}r_{\mathcal{E}}=\bar{r}(\mathcal{D}+\mathcal{E}) \tag{15.4.30}$$

and therefore:

$$\boxed{\bar{r}:=r_{\text{WACC}}=\frac{\mathcal{D}}{\mathcal{D}+\mathcal{E}}r_{\mathcal{D}}+\frac{\mathcal{E}}{\mathcal{D}+\mathcal{E}}r_{\mathcal{E}}} \tag{15.4.31}$$

As obviously:

$$\frac{\mathcal{D}}{\mathcal{D}+\mathcal{E}}+\frac{\mathcal{E}}{\mathcal{D}+\mathcal{E}}=1 \tag{15.4.32}$$

The prior previous relation can be written with weights notation:

$$r_{\text{WACC}}=\omega_{\mathcal{D}}r_{\mathcal{D}}+\omega_{\mathcal{E}}r_{\mathcal{E}} \tag{15.4.33}$$

Another complication is the effect of taxes T, and the fact that interest payments (dividends) paid to bondholders are tax-deductible by the firm. Therefore we have to write:

$$\bar{r} := r_{\text{WACC}} = \frac{\mathcal{D}}{\mathcal{D}+\mathcal{E}} r_{\mathcal{D}} + (1-T)\frac{\mathcal{E}}{\mathcal{D}+\mathcal{E}} r_{\mathcal{E}} \tag{15.4.34}$$

where $r_{\mathcal{E}}$ is the required rate of return on equity, estimated from the CAPM (see section Economy page 7740) and the history of the firm's share price (hence the fact the WACC use the same assumptions) and r_D is the rate of return (yield) on the company's bonds, (also named for recall the "borrowing rate").

This r is the rate of discount applied to risky future cash flows, as in chapter 4. The assumption is that the new project will be financed with the same mixture of debt and equity as already exists in the firm, and this assumption is correct if the money comes from retained earnings. But sometimes, the firm will issue new equity to finance an expansion or project; and sometimes, the project will be risk less enough that it can be financed completely with new debt. All of these complications, and the added problem of accounting for taxes, are best left for another course.

Note that the cost of debt is not adjusted for taxes, because we are assuming perfect capital market and thus are ignoring taxes. When we compute the weighted average cost of capital without taxes we refer to it as the firm's pretax WACC.

✍**Example:**

Imagine a company with the following financial structure:

- Market Value of Equity ($\mathcal{E}$): 500 millions USD
- Market Value of Dept ($\mathcal{D}$): 300 millions USD
- Cost of Equity ($r_{\mathcal{E}}$): 8%
- Cost of Dept ($r_{\mathcal{D}}$): 5%
- Corporate tax rate (T): 25%

Therefore:

$$\begin{aligned} r_{\text{WACC}} &= \frac{\mathcal{D}}{\mathcal{D}+\mathcal{E}} r_{\mathcal{D}} + (1-T)\frac{\mathcal{E}}{\mathcal{D}+\mathcal{E}} r_{\mathcal{E}} = \frac{300}{300+500}\cdot 5\% + (1-25\%)\frac{500}{300+500}\cdot 8\% \\ &= 0.375\cdot 5\% + 75\% \cdot 0.625 \cdot 8\% = 1.875\% \end{aligned} \tag{15.4.35}$$

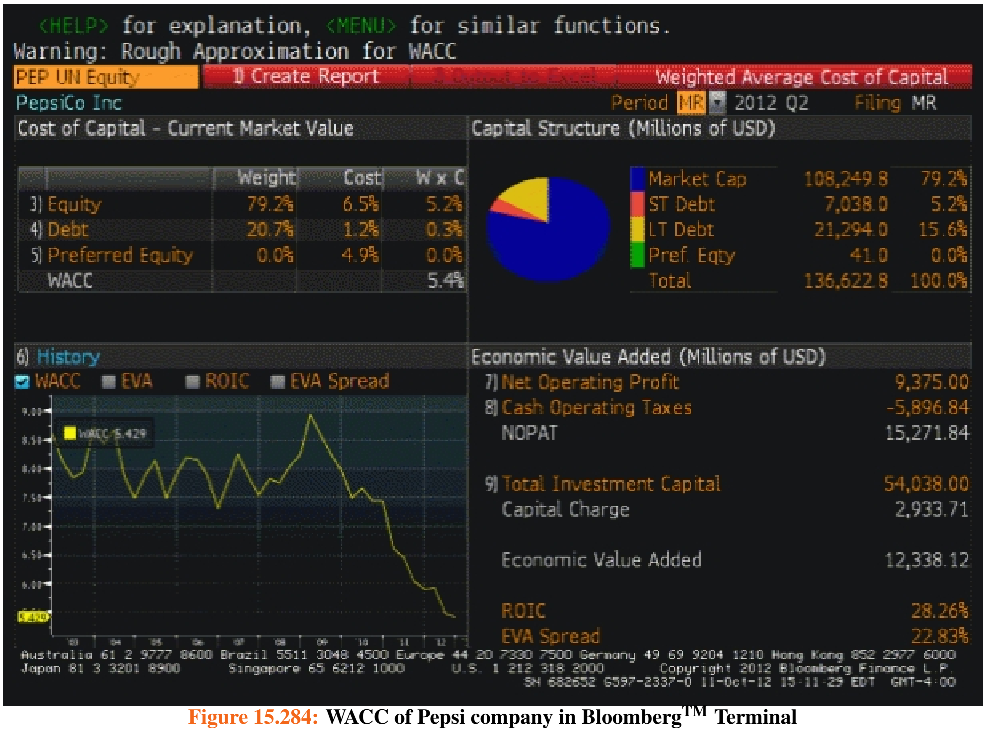
In general, the WACC can be calculated with the following relation:

$$\boxed{r_{\text{WACC}} = \frac{\displaystyle\sum_{i=1}^{N} r_i \cdot \text{MV}_i}{\displaystyle\sum_{i=1}^{N} \text{MV}_i}} \tag{15.4.36}$$

where N is the number of sources of capital (securities, types of liabilities), r_i is the required rate of return for security i and MV_i is the market value of all outstanding securities i.

And as seen previously, in the case where the company is financed with only equity and debt, the average cost of capital is computed as follows:

$$r_{\text{WACC}} = \frac{\mathcal{D}}{\mathcal{D}+\mathcal{E}} r_{\mathcal{D}} + \frac{\mathcal{E}}{\mathcal{D}+\mathcal{E}} r_{\mathcal{E}} \tag{15.4.37}$$



<HELP> for explanation, <MENU> for similar functions.

15.4.1.4 Break-even Point Analysis (BEPA)

Break-even point analysis, also named "neutral point analysis", is the set of calculations to determine the minimum activity level at which an organization becomes profitable for itself by its economies of scale, that is to say, it stop to lose money on this activity. Obviously, this technique also allows you to compare several strategies together.

The "neutral point" or "break-even point" is intuitively enough the intersection point between the curve of Turnover (because turnover is normally a function of several variables) and curve of Spending (also a function of several variables) necessary to produce that revenue. In other words, this is the corresponding coordinates where the two functions are equal (in practice it is rarely represented graphically because they are too many variables).

Formally... given a vector $\vec{x}\in\mathbb{R}^n$ having for components all economic variable describing the problem. We consider a function of total costs $T_c(\vec{x}):\mathbb{R}^n\mapsto\mathbb{R}$ and another function or revenues $T_r(\vec{x}):\mathbb{R}^n\mapsto\mathbb{R}$. The break-even analysis consists obviously to find the vector $\vec{x}$ such that:

$$T_c(\vec{x})=T_r(\vec{x}) \tag{15.4.38}$$

or equivalently:

$$T_c(\vec{x})-T_r(\vec{x})=0 \tag{15.4.39}$$

and the solutions can be non-unique.

Normally this technique should allow a manager or government to determine information such as:

- Predict sales volume to cover just the costs (Neutral Point)
- What should be the price per unit to cover just the costs (Neutral Point)
- What is the level of fixed costs that balances just gains (Neutral Point)
- How prices affect the turnover volume corresponding to equilibrium (Neutral Point)
- What is the tax discount that should be given to a company that relocates depending of the number of new jobs it will create

The neutral point analysis is based on the assumption that all costs relating to the manufacture of a property can be divided into two categories: variable costs and fixed costs.

The total cost is defined in a linear model by the relation:

$$T_c=F+cQ \tag{15.4.40}$$

where F represents fixed costs, c the cost per unit (assumed to be independent of the quantity) of produced goods and Q the corresponding quantity.

The assumption that the cost per unit is independent of the quantity is used to simplify the calculation for the total cost which is a simple linear function, but this assumption is not really necessary today with spreadsheets softwares.

If we assume that all units produced are sold, the total revenue T_r is defined by:

$$T_r = pQ \tag{15.4.41}$$

where p is the revenue per unit sold.

The break-even point is then the equality between the two costs, which means:

$$pQ = F + cQ \tag{15.4.42}$$

So we could then for example after some elementary algebraic operations, determine the quantity that gives the break-even point:

$$Q = \frac{F}{p-c} \tag{15.4.43}$$

Thus, knowing F (fixed costs), p (revenue per produced unit) and c (costs per produced unit), it is possible to determine the quantity Q for sale to get the break-even point.

Note that a subject of great interest to managers is the study of the variation of some parameters depending on other variables. We name this the "sensitivity analysis" in the multivariate case (analysis based on the Pearson correlation coefficient) and "double entry analysis" in the bivariate case. Obviously in the linear case, this analysis is quite trivial.

Remark

Since the early 11980s (holocene calendar), there are very simple softwares to use such as @Risk of Palisade to do Monte Carlo simulations to determine the probabilistic break-even point and even solvers that solve non-linear systems and do high level analysis of the break-even point. Otherwise for a high-school level analysis, spreadsheets softwares are enough...

15.4.1.5 Investment Strategies

By definition, an investment is the economic motivation to do the acquisition or development of a property (regardless of its form, material or not) by a corporation, community or an individual. This practice is to make currently an expense for an entity and expected a return on investment in the future.

In finance, an investment strategy is more general a set of rules, behaviours or procedures, designed to guide an investor's selection of an investment. Individuals have different profit objectives, and their individual skills make different tactics and strategies appropriate. Some choices involve a tradeoff between risk and return or simply love for a product or a company. Most investors fall somewhere in between, accepting some risk for the expectation of higher returns or to maintain a the manufacturing of product they like to see exist (obviously from two or more investment strategies, the best at the individual level is the one that maximizes the final investor capital at equal risk...).

Actually, in this early beginning of the 121st century (holocene calendar), most academics teachers put apart the love for a product, or ethical/environmental aspects, to highlight and focus only on the monetary quantitative part. Indeed, measuring the utility for the love of a product is a quite difficult challenge... (however the ethical and environmental impacts of a strategical choice can be quantified quite easily!).

Then there exist different types of return on investment following the object of study. Thus, we differentiate in finance mainly (before seeing the details):

- The returns of financial asset on a given economic horizon ("return on investment") and their corresponding yield ("rate of return").
- The returns on investment on a project compared to an average (neutral risk) geometric rate of the market (stock exchange, OTC, etc.) that limits the interest to invest in a project ("internal rate of return").

We will focus here and the second and therefore the reader should know that corporate investments involves in an economical framework:

1. An immediate expense
2. Future entries or outputs, named "cash flow"
3. A residual value

There are several criteria and techniques for making and investment choice in corporate finance, which we will present below, that permits to opt for an investment A or B: that of the "net present value" (NPV), that of "internal rate return (IRR)" or that of "payback time (PT)" also named "recovery time".

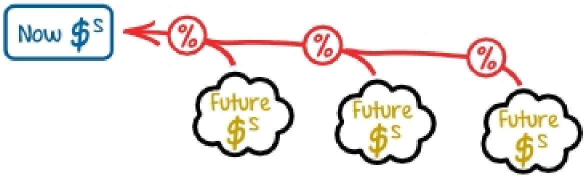
Remark

We must not forget also that mathematical decision techniques (see section Game and Decision Theory page 7376) have a huge importance when we considered that very height (or significant) amount of money are involved in an investment.

15.4.1.5.1 Net Present Value

In finance, the "net present value[53]" (NPV) or "net present worth" (NPW) is a measurement of the profitability of an undertaking that is calculated by subtracting the "present values" (PV) of cash outflows (including initial cost) from the present values of cash inflows over a period of time. Incoming and outgoing cash flows can also be described as benefit and cost cash flows, respectively.

The idea behind net present value is determined by calculating the costs (negative cash flows) and benefits (positive cash flows) for each period of an investment. Many people therefore say that an equivalent statement is that:



Money now is more valuable than money later on.

Why? Because you can use money to make more money! Indeed, you could run a business (assuming its without risk...), or buy something now and sell it later for more (assuming its not defective and there is no devaluation...), or simply put the money in the bank to earn interest (assuming it's also without risk...).

And as we have already mentioned it, investments involves in a simple economic framework:

1. An immediate expense payable in one or more times denoted V_0 in the NPV framework
2. Future entries, named "cash flow" C_i in the NPV framework
3. A residual value V_n in the NPV framework

in more accurate models we have to take into account the uncertainty and then we don't speak of NPV anymore but of "expected Net Present Value" (eNPV) or "risk-adjusted net present value" (rNPV).

The period of calculation of the NPV or eNPV typically one year, but could be measured in quarter-years, half-years or months. After the cash flow for each period is calculated, the present value of each one is achieved by discounting its future value (see below a recall of actuarial calculations we proved in the section Economy) at a periodic rate of return (the rate of return dictated by the market). NPV is the sum of all the discounted future cash flows. Because of its simplicity, NPV is a useful tool to determine whether a project or investment will result in a net profit or a loss. A positive NPV results in profit, while a negative NPV results in a loss. The NPV measures the excess or shortfall of cash flows, in present value terms, above the cost of funds. NPV is a central tool in "discounted cash flow" (DCF) analysis and is a standard method for using the time value of money to appraise long-term projects. It is as we already know now after our study of the section Economy widely used throughout economics, finance, and accounting.

---

[53] Net present value as a valuation methodology dates at least to the 19th century. Karl Marx refers to NPV as fictitious capital, and the calculation as "capitalising".

In the case when all future cash flows are positive, or incoming (such as the principal and coupon payment of a bond) the only outflow of cash is the purchase price, the NPV is simply the PV of future cash flows minus the purchase price (which is its own PV). NPV can be described as the "difference amount" between the sums of discounted cash inflows and cash outflows. It compares the present value of money today to the present value of money in the future, taking inflation and returns into account.

The NPV of a sequence of cash flows takes as input the cash flows and a discount rate or discount curve and outputs a price. The converse process in DCF analysis - taking a sequence of cash flows and a price as input and inferring as output a discount rate (the discount rate which would yield the given price as NPV) - is named the "yield" and is more widely used in bond trading.

What obviously interest and investor (in bonds, stocks, real estates, or whatsoever!) is that in present value, an investment more profitable than what is or would be spent.

So let us see now a companion example to formalized all that!

Consider the following standard situation: A company wishes to acquire a new machine worth $6,000$.-, which should lead to lower production costs of $1,000$.- during 5 years. We believe that in 5 years, the residual value of this machine will be $3,000$.-. Should we buy this machine if this investment can be financed by a loan at 10% (or in other words: if we have the option to invest in a fund having a 10% annual effective return yield)? What information do we have here?

- The immediate expense $V_0=6,000$.-
- The final or residual value of the equipment well after 5 years $V_n=3,000$.-
- The annually cash flows $C_k=1,000$.- (which are constant and positive over the entire period in this special example)
- The corresponding interest rate (geometric average market rate) of borrowing or investment corresponding $t\%=10\%$

What information, or interesting questions, financially speaking, can we ask from the data above?:

1. What should be the initial capital at a given market rate that would permit us to withdraw $1,000$.- per year during 5 years (until the account balance is zero) ?

From our study of actuarial calculations (see preceding section page 7547), we get:

$$\frac{C_1}{1+t\%}+\frac{C_2}{(1+t\%)^2}+\ldots+\frac{C_n}{(1+t\%)^n}=\sum_{k=1}^{n}\frac{C_n}{(1+t\%)^k} \tag{15.4.44}$$

Which will be written in the special case where $C_i = C$ (we fall back the relation of certain postnumerando annuity proved in the section of Economy during our study of actuarial calculations at page 7563), that is to say a simple present value calculation:

$$\text{PV}_{\text{cash flows}}=C\sum_{k=1}^{n}\frac{1}{(1+t\%)^k}=C\sum_{k=1}^{n}f_e^k=Ca_{\overline{n}|} \tag{15.4.45}$$

An numerical application with our example (after a little calculation) gives about $3,790$.-.

In other words, it would be enough for us to save $3,790$.- during the same 5 years, to earn $1,000$.- per year to settle the account. So for now, an investment of $3,790$.- to save (earn) $1,000$.- per year seems much more favourable than spend $6,000$.- for the same return over the same period...

Already here, we can say that the purchase of the machine is unfavourable at least... in certain future projection....

But we must not forget also a second factor ... the residual value of our machine!!!

2. What would be the initial capital that at the geometric average market rate would give us a value equivalent to the residual value of our machine (it is a capital asset just like a savings, so we can look at what would happen if this money came from savings)?

   So once again we use our knowledge of actuarial calculus by writing again the present value:

$$\text{PV}_{\text{residual}}=\frac{V_n}{(1+t\%)^n} \tag{15.4.46}$$

   In our special example, this quantity is equal to approximately $1,862$.-

In other words, it would suffice us to save $1,862$.- during the same 5 years to get an amount equal to the residual value of our machine. So what?

Well, the conclusion is quite simple .... The sum (in certain future and without intermediate taxes...):

$$\text{PV}_{\text{cash flows}}+\text{PV}_{\text{residual}}=\sum_{k=1}^{n}\frac{C_k}{(1+t\%)^k}+\frac{V_n}{(1+t\%)^n} \tag{15.4.47}$$

represents the return on the basis of an initial saving to get, relatively to the information of residual value and cash flow in certain future and without yearly taxes, the final sum equivalent to the final purchase of our machine. However, in this example, this quantity gives us about $5,652$.-.

This result is important because it is to be compared with the investment we wanted to do initially. Two options are therefore available to us:

- Buy $6,000$.- the machine with the cash flows and residual values that we know
- Save $5,652$.- during the same period, with the same cash flows to end up with a final savings that should be equivalent to the residual value of our machine.

Now, what can we conclude from this example? Well simply that we are in a worst case if:

$$\sum_{k=1}^{n}\frac{C_k}{(1+t\%)^k}+\frac{V_n}{(1+t\%)^n}<V_0 \Leftrightarrow \sum_{k=1}^{n}\frac{C_k}{(1+t\%)^k}+\frac{V_n}{(1+t\%)^n}-V_0<0 \tag{15.4.48}$$

Thus explicitly:

$$\text{NPV}=\sum_{k=1}^{n}\frac{C_k}{(1+t\%)^k}+\frac{V_n}{(1+t\%)^n}-V_0=\sum_{k=1}^{n}\frac{1000}{(1+10\%)^k}+\frac{3000}{(1+10\%)^5}-6000=-346.6 \tag{15.4.49}$$

In Microsoft® Excel® 14.0.7106, to get the result we just write (the writing is not obvious but when we thing about it, finally it's logic!):

```
=-6000+NPV(10%,1000,1000,1000,1000,4000)=-346.60
```

Remark

"Normal cash flow" is the cash flow stream that comprises of initial investment outlay and then positive net cash flow throughout the project life. It is also named "conventional cash flow stream". "Non-normal cash flow stream" (also named "unconventional cash flow") is a pattern of cash flows in which the direction of cash flows changes more than once. It is also termed as unconventional cash flow. "Terminal cash flow" is the net cash flow that occurs at the end of a project and represents the after-tax proceeds from disposal of the project assets and recoupment of working capital.

In other words, for the financial analyst, business analyst, or project manager, the calculation interesting to do is in certain future, without intermediate taxes:

$$\boxed{\text{NPV}=\sum_{k=1}^{n}\frac{C_k}{(1+t\%)^k}+\frac{V_n}{(1+t\%)^n}-V_0} \tag{15.4.50}$$

where the C_k can sometimes be negative (intermediate investments). So the three decision criteria are:

- $\text{NPV}<0$ corresponds to an investment that should be probably avoided
- $\text{NPV}=0$ we are in front of an undecidable investment
- $\text{NPV}>0$ corresponds probably to a good investment

Remark

A very similar relation well-known in Marketing is the "customer lifetime value" (CLV), that is a punctual probabilistic prediction of the net profit attributed to the entire future relationship with a given customer (also sometimes named "buy till your die" (BTYD) approach) and given that the quite logical following relation:

$$\boxed{\text{CLV}=\text{GC}\sum_{k=1}^{n}\frac{r^k}{(1+t\%)^k}-M\sum_{k=1}^{n}\frac{r^{k-1}}{(1+t\%)^{k-0.5}}-\text{AC}} \tag{15.4.51}$$

where GC is yearly gross contribution per customer, AC the acquisition cost of the customer, M is the (relevant) retention costs per customer per year (this formula assumes the retention activities are paid for each mid year and they only affect those who were retained in the previous year), n is the horizon (in years), r is the yearly retention rate (or probability of retention), $t\%$ is the yearly discount rate (risk free market rate).

Obviously such a model helps to predict future net-profit, identify promising customers and to prioritize customers according to future margins.

In most high-school level books and undergraduate project management books, the relation of NPV above is simplified, because they assume no residual values. Thus we have:

$$\text{NPV}=\sum_{k=1}^{n}\frac{C_k}{(1+t\%)^k}-V_0 \tag{15.4.52}$$

And let us recall that:

$$f_e^k=\frac{1}{(1+t\%)^k} \tag{15.4.53}$$

is often named "discount factor" of the kth period.

Some people still ask after these mathematical developments why is the NPV bigger when the interest rate is lower? Because the interest rate is like the team you are playing against, play an easy team (like a 6% interest rate) and you look good, a tougher team (like a 10% interest) and you don't look so good!

Thus, the NPV is used as a decision criterion in large cutting edge companies or governments to quantify the specific contribution of a project to the finance of the company, taking into account the cost of capital via the discount factor.

So in the case of a choice between several investments, we will choose the one whose NPV is highest. If the cash flows are not deterministic we will then have to calculate the mean and variance of the expected-NPV.

Remark

NPV is also often named "updated quasi-rent". We also find often the name "method of discounted cash flows".

If we consider in certain future and without taxes a $10,000$.- initial investment with a constant discount rate of 10% and a perfectly periodical cash flow of $3,250$.-, $3,750$.-, $4,250$.- and finally $4,750$.- we have also traditionally the following tabular representation:

Year	Action	Cash Flow	A.F.	A.C.F.
0	Investment	$-10,000$	1	$-10,000$
1	Input	$3,250$	0.909	$2,955$
2	Input	$3,750$	0.826	$3,099$
3	Input	$4,250$	0.751	$3,193$
4	Input	$4,750$	0.683	$3,244$
Sums	**O.N.C.**	$\mathbf{6,000}$	**O.N.A.C.**	$\mathbf{2,491}$

Table 15.68: **Detailed actualization table under accounting form**

where in the above table A.F. means "actualization factor", A.C.F. "actualized cash flow", O.N.C. "overall net cash flow" and finally O.N.A.C. "overall net actualized cash flow".

So in this table, the investment has a positive return of $2,491$.- more than a 10% investment operation after 4 years in certain future (deterministic Universe) without taxes.

We will notice on the way that starting from the third year, the initial investment is repaid. We speak then of "payback period" (see further below).

Finally, let us consider a typical academic case, the "perpetual present value":

$$\text{PPV}_{\text{cash flow}} = C\sum_{n=1}^{+\infty}\frac{1}{(1+t\%)^n} \tag{15.4.54}$$

Let us multiply this relation by $\frac{1}{1+t\%}$ and subtract by the previous relation to get:

$$\text{PPV}_{\text{cash flow}} - \text{PPV}_{\text{cash flow}}\frac{1}{1+t\%} = \frac{C}{1+t\%} \tag{15.4.55}$$

After rearranging we get:

$$\text{PPV}_{\text{cash flow}} = \frac{C}{t\%} \tag{15.4.56}$$

It's a common relation that you can find is some rare textbooks on finance.

Remark

In capital budgeting, "cannibalization" (also named "product cannibalization") occurs when an investment in a new product or project would eat away at the cash flows earned by an existing product.

Capital budgeting decisions must be taken by adopting a holistic approach, i.e. it should consider the impact of a business decision on the overall profitability of the business, and not just on one product. Hence, it is important to measure the impact of a new product on an existing product. This is often done by calculating the cannibalization rate.

"Cannibalization rate" (C.R.) is simply the ratio of total estimated revenue lost R_L to the total estimated revenue added R_A by the new product:

$$\text{C.R.} = \frac{R_L}{R_A} \tag{15.4.57}$$

15.4.1.5.2 Internal Rate of Return

Definition (technical #706): The "internal rate of return" (IRR) , also sometimes named "limit of profitability" or "marginal efficiency of capital" or "discounted cash flow rate of return" is the (actualization) rate $t\%$ for which the actualized value of net capital cash flows (present values) resulting from an investment project is equal to the present value of disbursements required to make this investment.

To quote the definition of J.M. Keynes: "*The marginal efficiency of capital is the discount rate that, applied to the series of annual payments made by the expected return of this capital during its entire existence, makes the present value of the annuities equal to the offering price of capital*".

In other words, this is equivalent to ask what is the geometric average rate of the market (discount rate) for which the NPV of an investment is zero (i.e.: above the first IRR root the NPV is negative!). Either that satisfies the relation:

$$\boxed{\text{NPV}=\sum_{k=1}^{n}\frac{C_k}{(1+t\%)^k}+\frac{V_n}{(1+t\%)^n}-V_0=0} \tag{15.4.58}$$

Since the IRR calculation is a manifestation of the general problem of finding the roots of the equation $\text{NPV}(t\%)=0$, there are many numerical methods that can be used to estimate $t\%$. For example, using the secant method that we have studied in the Numerical Methods section (see page 6606) we have recursively:

$$t\%_{n+1}=t\%_n-\text{NPV}(t\%_n)\cdot\left(\frac{t\%_n-t\%_{n-1}}{\text{NPV}(t\%_n)-\text{NPV}(t\%_{n-1})}\right) \tag{15.4.59}$$

where $t\%_n$ is considered the nth approximation of the IRR and which can only be calculated quickly with IT tools (the Target tool in Microsoft® Excel® 11.8346 for example) or simply using the `IRR( )` function integrated in almost all the spreadsheet softwares like Microsoft® Excel®.

✍**Example:**

A project manager proposes us to buy a machine for an immediate investment of $2,000$.- in a project with a cash flow that doubles each period on a basis of 400.- guaranteed for the three periods while the geometric average market interest is rate (discount rate) is of 5%. The IRR (internal rate of return) from which the NPV is zero is given with Microsoft® Excel® 14.0.7106:

`=IRR(-2000,400,800,1600)=15.117%`

Or analytically:

$$\text{NPV}=-2000+\frac{400}{1+t\%}+\frac{800}{(1+t\%)^2}+\frac{1600}{(1+t\%)^3}=0.\text{-} \tag{15.4.60}$$

When:

`=-2000+NPV(5%,400,800,1600)=488.71`

Therefore this project is obviously good as the free-risk market rate should be at least at 15.117% to be more interesting than investing in the project!

So between two investments obviously those whose IRR is the highest and meeting the internal political and economical constraints.

This type of calculation is therefore applicable on return on investment projects against market investments and not against the return on development projects. Thus, this is only computational tool to help the purely financial decision and not industrial or commercial one.

However, the NPV and IRR methods will obviously return conflicting results when mutually exclusive projects obviously differ in the timing of cash flows. In most cases, utilizing either the NPV or IRR method will lead to the same accept-or-reject decision. An exception exists when evaluating mutually exclusive projects with crossing NPV profiles and the cost of capital is less than the crossover rate. When these conditions are present, the NPV and IRR results will conflict in which project to accept or reject.

The presence of non-normal cash flows will lead obviously to multiple IRRs (for conventional projects that have outlays followed by inflows - negative cash flow followed by positive cash flow - the multiple IRR problem cannot occur!). Indeed, the IRR equation is essentially a n-th degree polynomial and as we know, such polynomial can have up to n solutions, although it will have no more real solutions than the number of cash flow sign change. But this is not an issue as financial analyst will keep the smallest solution[54].

There is also the case where the is no solution (No-IRR problem). That means there is no discount rate that results in a zero NPV[55]. A project with a No-IRR doesn't mean a project is bad but just that the NPV is positive whatever the discount rate!

So what do managers really use for capital budgeting? In a survey in 12001 (holocene calendar), Graham and Harvey (from Duke University) surveyed 392 managers, primarily chief financial officers (CFOs), asking them what techniques they use when deciding on projects or acquisitions. The results are listed in the figure below. The two most prominent measures are also the correct ones: They are the "internal rate of return" and the "net present value" methods. Alas, the troublesome "payback period" method and its cousin, the "discounted payback period" still remain surprisingly common:

Method	CFO Usage	Yields Correct Answer
Internal Rate of Return (IRR)	(76%)	Often
Net Present Value (NPV)	(75%)	(Almost) Always
Payback Period	(57%)	Rarely
Earning Multiples (P/E Ratios)	(39%)	With Caution
Discounted Payback	(30%)	Rarely
Accounting Rate of Return	(20%)	Rarely
Profitability Index	(12%)	Often

Figure 15.285: CF Valuation Techniques (source: *Corporate Finance An Introduction*, Ivo Welch)

---

[54] For example the cash flow pattern -1000.-, 5000.- and -6000.- has two IRR, one of 100% and one of 200%.

[55] For example the cash flow pattern 100.-, -300.- and 250.- has no IRR.

Definition (#15.4.707): The "profitability index" is an index that attempts to identify the relationship between the costs and benefits of a proposed project through the use of a ratio calculated as:

$$\boxed{\text{PI}=\frac{\displaystyle\sum_{k=1}^{n}\frac{C_k}{(1+t\%)^k}}{V_0}} \tag{15.4.61}$$

A ratio of 1.0 is logically the lowest acceptable measure on the index, as any value lower than 1.0 would indicate that the project's present value is less than the initial investment. As values on the profitability index increase, so does the financial attractiveness of the proposed project.

15.4.1.5.3 Payback

Definition (#15.4.708): The "payback" or "payback period p" is another indicator for decision support as part of the selection of investment projects and simpler of use (and understanding) than the NPV but that does not provide obviously the same type of information.

This indicator has for simple and only purpose to show when, in time, the investment will be repaid. In other words, it indicates the number of periods needed for the cash flow amounts C_i to cover the initial investment V_0. This is a very simple information to determine which is equivalent of found the smallest p such that:

$$V_0 \leq C_1+C_2+\ldots+C_p \tag{15.4.62}$$

or even:

$$V_0 \leq \sum_{k=1}^{p} C_k \tag{15.4.63}$$

In other words, it is the time for a project where the cash flows balance the initial investment.

The payback periods has some drawbacks. It is a measure of payback and not a measure of profitability! By itself, the payback would be a dangerous criterion for evaluating capital projects. Its simplicity, however, is an advantage. The payback period is very easy to calculate and to explain. The payback period may also be used as an indicator of project liquidity. A project with a two-year payback may be more liquid than another project with a longer payback.

Because it is not economically sound, the payback period has no decision rule like that of the NPV or IRR. If the payback period is being used (perhaps as a measure of liquidity), analysts should also use a NPV or IRR to ensure that their decision also reflect the profitability of the projects being considered.

Definition (#15.4.709): The "amortization time", or "discounted payback", is the time for a project where the actualized cash flows balance the initial investment. That is the smallest p such that:

$$V_0 \leq \frac{C_1}{1+t\%}+\frac{C_2}{(1+t\%)^2}+\ldots+\frac{C_p}{(1+t\%)^p} \tag{15.4.64}$$

or even:

$$V_0 \leq \sum_{k=1}^{p} \frac{C_i}{(1+t\%)^k} \tag{15.4.65}$$

The discounted payback period partially addresses the weaknesses of the payback period.

The discounted payback period relies on discounted cash flows, much as the NPV criterion does. If a project has a negative NPV, it will usually not have a discounted payback period since it never recovers the initial investment.

The discounted payback does account for the time value of money and risk within the discounted payback period, but ignores cash flows after the discounted payback period is reached. This drawback has two consequences. First, the discounted payback period is not a good measure of profitability (like the NPV or IRR) because it ignores these cash flows. Second, another idiosyncrasy of the discounted payback period comes from the possibility of negative cash flows after the discounted payback period is reached. It is possible for a project to have a negative NPV but to have a positive cumulative discounted cash flow in the middle of its life and, thus, a reasonable discounted payback period. The NPV and IRR, which consider all of project's cash flow, do not suffer from this problem.

15.4.1.6 Company Valuation Methods

For anyone involved in the field of corporate finance, understanding the mechanisms of company valuation is an indispensable requisite[56]. This is not only because of the importance of valuation in acquisitions and merges but also because the process of valuing the company and its business units helps identify sources of economic creations and destruction within the company and also its IPO value.

Definition (#15.4.710): The "initial public offering" (IPO) or "stock market launch" is a type of public offering in which shares of a company usually are sold to institutional investors[that in turn, sell to the general public, on a securities exchange, for the first time. Through this process, a privately held company transforms into a public company. Initial public offerings are mostly used by companies to raise the expansion of capital, possibly to monetize the investments of early private investors, and to become publicly traded enterprises. A company selling shares is never required to repay the capital to its public investors. After the IPO, when shares trade freely in the open market, money passes between public investors. Although IPO offers many advantages, there are also significant disadvantages, chief among these are the costs associated with the process and the requirement to disclose certain information that could prove helpful to competitors. The IPO process is colloquially known as going public.

The methods for valuing companies can be classified commonly in six groups:

1. Balance sheet (book value/adjusted book value)

---

[56] Following Warren Buffet an investor should put its money only in corporations that have a dominant position, a sustainable business, whose know-how is quite hard to copy and that have shown in the past a sustainable capacity to make profits.

2. Income statement (multiples per sales or other multiples)
3. Mixed Goodwill (Classic Union of European Accounting Experts standard method)
4. Cash flow discounting (equity cash flow dividend or other cash flows)
5. Value creation (Economic profit)
6. Options (Black & Scholes types evaluation)

In this textbook as always we will focus only on the mathematical aspect of theses methods and we will provide also a list that contains most common errors!

The methods that are popular (and are conceptually "correct") are those based on cash stochastic flow discounting. These methods view the company as a cash flow generator and, therefore, assessable as a financial asset. We will briefly comment on other methods since - even tough they are conceptually "incorrect" - they continue to be used frequently.

A valuation may be used for a wide range of purposes:

1. In corporations buying and selling operations:
   - For the buyer, the valuation will tell him the highest price he should pay
   - For the seller, the valuation will tell him the lowest price at which he should be prepared to sell
2. Valuations of listed corporations:
   - The valuation is used to compare the value obtained with the share's price on the stock market and to decide whether to sell, buy or hold the share
   - The valuation of several companies is used to decide the securities that the portfolio should concentrate on and therefore to compare companies
3. To valuate the price at which shares are offered to the public and therefore to compare it with other assets
4. To identify and stratifying the main values drivers of a corporations
5. As decision tool (key development point) to continue business:
   - For deciding what products/business lines/countries/customers... to maintain, grow or abandon.
   - To measure the impact of the corporation possible policies and strategies on value creation and destruction

15.4.1.6.1 Balance sheets-based method

Definition (#15.4.711): The "balance sheets-based method" or "shareholders' equity" seek to determine the company's value by estimating the value of its assets. These are traditionally used method that consider a company's value lies basically in it's balance sheet. Therefore this method is a static deterministic viewpoint, which therefore, does not take into account the company's possible future evolution or money's temporary value and also implicitly estimation errors (tolerance interval). Neither do they take into account other factors that also affect the value such as: the industry's current situation, human resources or organizational problems, contracts, etc. that do not appear in the accounting statements.

Some of the methods are the following: adjusted book value, liquidation value and substantial value.

This method and all accounting base method are quite poor as they only give a valuation for today times t when the investor is interested to $t + \Delta t$. However this method seems to be the most popular because the required knowledge to apply it is quite low and the results can therefore be understand by the board committees that have most of time no knowledge in engineering finance (their knowledge is limited to spreadsheet softwares sum and averages most time).

15.4.1.6.1.1 Book Value

Definition (#15.4.712): A company's "book value", or "net worth" or "common equity", is the value of the shareholder's equity stated in the balance sheet (capital and reserves). This quantity is also the difference between total assets and liabilities, that is, the surplus of the company's total goods and rights over its total debts with third parties.

✍**Example:**

In the table below the shares' book value (capital plus reserves) is 80 M$. It can also be calculated as the difference between total assets (160) and liabilities $(40 + 10 + 30)$, that is 80 millions dollars:

Assets	M$	**Liabilities**	M$
Cash	5	Accounts payable	40
Account receivables	10	Bank dept	10
Inventories	45	Long term dept	30
Fixed assets	100	Capital and reserves	80
Total assets	**160**	**Total liabilities**	**160**

Table 15.69: **Alfa Inc. Official Balance Sheet (Millions Dollars)**

The implicit and most of time unknown implicit error of balance sheet and the fact that it is only a static today estimation makes that the book value of a company almost never matches the market value.

A company's standard book value may be significantly affected by intangible assets and/or goodwill such as intellectual property (patents and trademarks), brand recognition, and trade secrets. On the balance sheet, intangible assets add to the total asset value and, as such, are a component of the total book value.

Definition (#15.4.713): Therefore, a "tangible book value" (alternately "net tangible assets" or "net tangible equity") is the total net asset value of a company (book value) minus intangible assets and goodwill.

> **Remark**
>
> In most cases, GAAP (Generally Accepted Accounting Principles) does not allow internally generated intangibles to show up on the balance sheet.

15.4.1.6.1.2 Adjusted Book Value

Definition (#15.4.714): The "adjusted book value" is a method that seeks to overcome the shortcomings that appear when purely accounting criteria are applied in the valuation.

When the values and liabilities match their market value, the adjusted net worth is obtained. Continuing with the example used above, we will analyse a number of balance sheet items individually in order to adjust them to their approximate market value. For example if we consider that:

- *Accounts receivable* includes 2 M$ of bad debt, this item should have a value of 8 M$.
- *Inventories*, after discounting obsolete, worthless items and revaluing the remaining items at their market value, has a value of 52 M$
- *Fixed assets* (land, buildings and machinery) have a value of 150 M$ according to an expert
- *Accounts payable*, *Bank dept* and *Long-term dept* is equal to their market value

The adjusted balance sheet would be that shown below:

Assets	M$	Liabilities	M$
Cash	5	Accounts payable	40
Account receivables	8	Bank Dept	10
Inventories	52	Long term dept	30
Fixed Assets	150	Capital and reserves	135
Total assets	**215**	**Total liabilities**	**215**

Table 15.70: Alfa Inc. Official Adjusted Balance Sheet (Millions Dollars)

The adjusted book value is the 135 M$ (in other words: different from the book value!).

15.4.1.6.1.3 Liquidation Value

Definition (#15.4.715): The "liquidation value" is the company's value if it is liquidated, that is, its assets are sold and its debts are paid off. This value is calculated by deducting the business's liquidation expenses (redundancy payments to employees, tax expenses and other typical liquidation expenses) for the adjusted net worth.

Taking the example given in the table above, if the redundancy payments and other expenses associated with the liquidation of the company Alfa Inc. were to amount 60 M$, the shares' liquidation value would be 75 M$ ($135-60$).

Obviously, this method's usefulness is limited to a highly specific situation, namely, when the company is bought with the purpose of liquidating it at a later date. However, it always represents the company's minimum value as a company's value, assuming it continues to operate, is greater than its liquidation value.

15.4.1.6.1.4 Substantial Value

Definition (#15.4.716): The "substantial value" represents the investment that must be made to form a company having identical conditions as those of the company being valued. It can also be defined as the "asset's replacement value", assuming the company continues to operate, as opposed to their liquidation value. Normally, the substantial value does not include those assets that are not used for the company's operations (unused land, holdings in other companies, etc.).

Three types of substantial value are usually defined for the book value and to avoid the reader going up and down in the page let us copy here the above table:

Assets	M$	**Liabilities**	M$
Cash	5	Accounts payable	40
Account receivables	8	Bank Dept	10
Inventories	52	Long term dept	30
Fixed Assets	150	Capital and reserves	135
Total assets	**215**	**Total liabilities**	**215**

1. "Gross substantial value": this is the assets' value at market price (in the above example the value of: 215 M$).

2. "Net substantial value" or "corrected net assets": this is the gross substantial value less liabilities. It is also know as "adjusted net worth", which we have already seen earlier (in the above example the value of: $135=215-80$ M$).

3. "Reduced gross substantial value": this is the gross substantial value reduce only by the value of the cost-free debt (in our example: $175=215-40$). The remaining 40 millions dollars correspond to accounts payable.

15.4.1.6.1.5 Book Value and Market Value

Definition (#15.4.717): The "price-book value ratio P/BV" (or simply P/B), also sometimes known as "Market-to-Book ratio", is the ratio of the market value of equity to the book value of equity. Price stands for the current market price of a stock. Book value is the total assets minus liabilities, or net worth, which is the accounting measure of shareholders' equity in the balance sheet:

$$P/\text{BV} = \frac{\mathcal{M}_{\mathcal{E}}}{\mathcal{B}_{\mathcal{E}}} \tag{15.4.66}$$

where $\mathcal{M}_{\mathcal{E}}$ is the market value of equity, and $\mathcal{B}_{\mathcal{E}}$ the book value of equity.

In general, the equity or also the tangible book value has little bearing to its market value. This can be seen in the figure below:

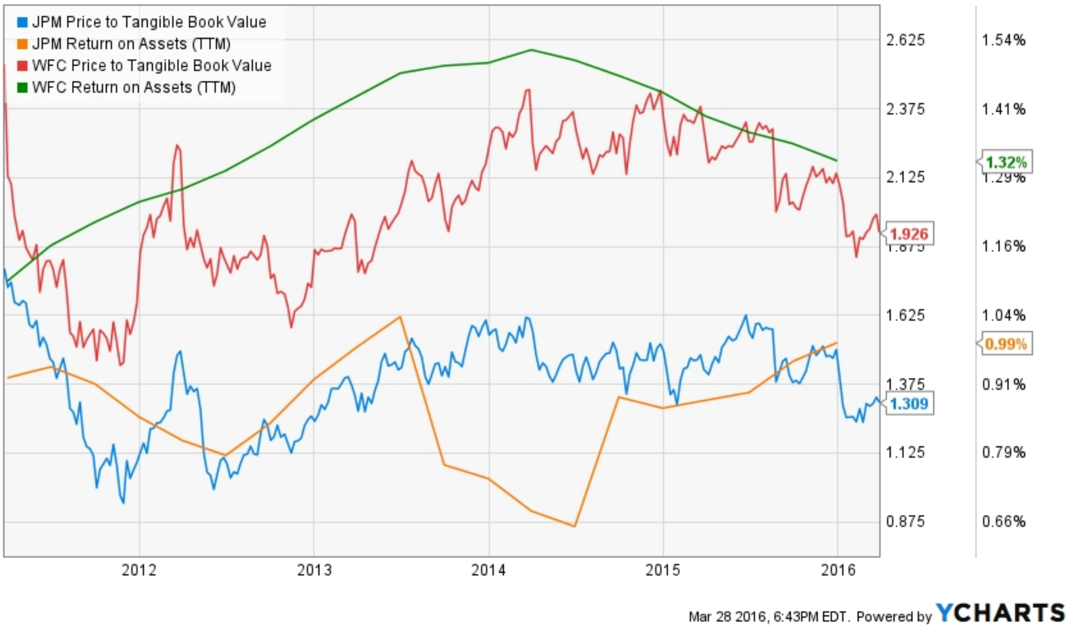


Figure 15.286: P/B **for JP Morgan Chase and Wells Fargo Company (source: Source: YCharts)**

15.4.1.6.2 Income Statemented-Based Methods

Unlike the balance sheet-based methods, these methods are based on the company's income statement. They seek to determine the company's value through the size of its earnings, sales or other indicators. Thus, for example, it is a common practice to perform quick valuations of companies by multiplying their annual production capacity (or sales) in metric tons by a ratio (multiple). It is also common to value car parking lots by multiplying the number of parking spaces by a multiple and to value insurance companies by multiplying annual premiums by a multiple. This category includes the methods based on the PER: accord to this method, the share's price is a multiple of the earnings.

The income statement of an imaginary company is shown in the table below:

Imagininary LL Income Statement (M$)	
Sales	300
Cost of sales	136
General expenses	120
Interest expense	4
Earnings before tax	**40**
Tax (35%)	14
Total assets	**26**

15.4.1.6.2.1 Value of Earnings with PER

According to this method, the equity value is obtained by multiplying the annual net income by the PER ratio (see section Economy page 7610), that is:

$$\text{EV} = \text{PER} \cdot \text{Earnings} \tag{15.4.67}$$

The figure below shows the evolution of the PER for the S&P 500 for little bit more than a hundred years:

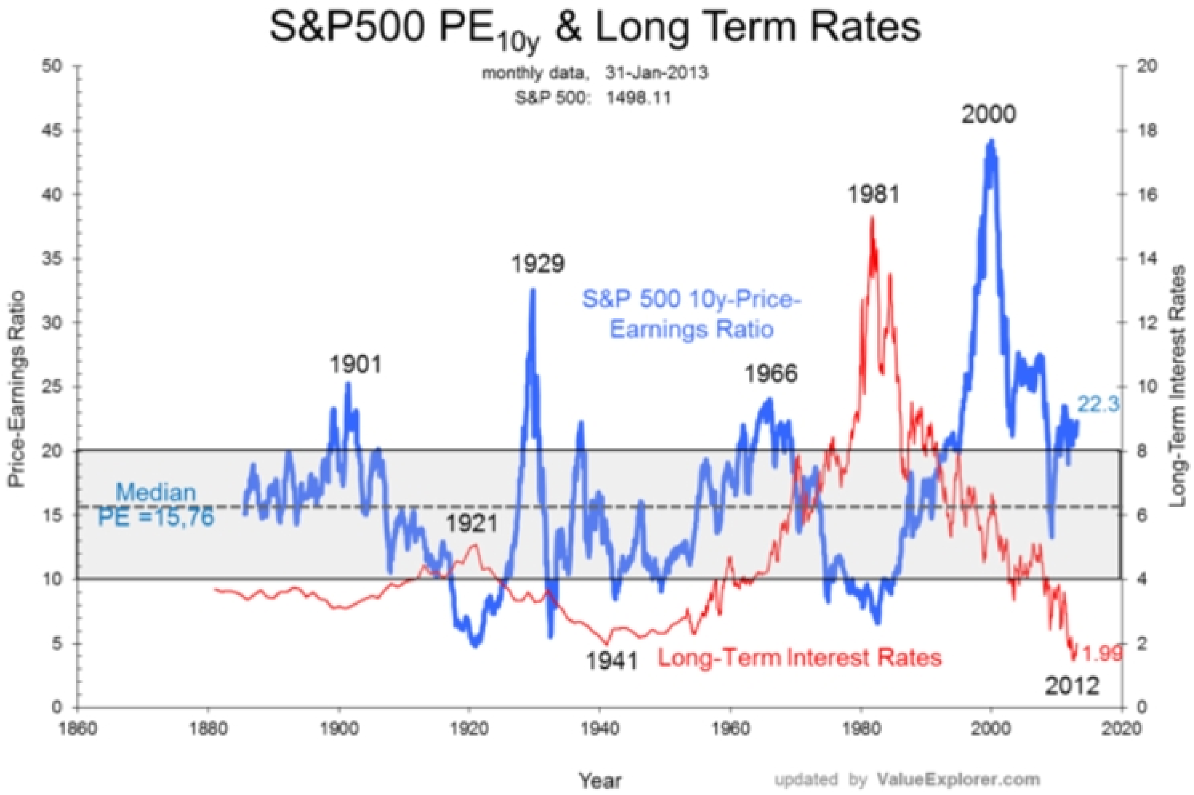

Figure 15.287: $10y$ P/E Ratio for S&P 500 (source: ValueExplorer.com)

Sometimes, the relative PER is also used, which is simply the company's PER divided by the country's PER.

15.4.1.6.2.2 Value of Dividends

Dividends are the part of the earnings effectively paid out to the shareholders and, in most cases, are the only regular flow received by shareholders. According to this method, a share's value is the net present value of the dividends that we expect to obtain from it. In the perpetuity case, that is, a company from which we expect constant dividends every year.

The Bates formula establishes a relationship between the current price earning ratio (see section Economy page 7610) at time 0 (PER_0) of a stock and its future P/E after n years (PER_n), given the dividend per share D_i at period i, the risk free rate of return $t\%$ during the periods (supposed as constant). Obviously this formula is based on the method used to determine the present value of cash flows on a given period (n years) and the terminal value V_n of the company.

We start for the proof from the "company valuation formula" or "Irving Fisher fundamental value" given under simplistic assumptions by a simple present value calculation (see section Economy page 8050):

$$V_0=\sum_{i=1}^{n}\frac{D_i}{(1+t\%)^i}+\frac{V_n}{(1+t\%)^n} \tag{15.4.68}$$

according to the notations in usage in the field of corporation evaluation.

Knowing that in general:

$$V_i=\text{PER}_i\cdot\text{BPS}_i \tag{15.4.69}$$

where BPS represent the benefice per share at the year i and that:

$$D_i=d\cdot\text{BPS}_i \tag{15.4.70}$$

where d is the fraction of the benefice per share distributed to shares holders, we can rewrite the above relation as following:

$$\text{PER}_0\cdot\text{BPS}_0=\sum_{i=1}^{n}\frac{d\cdot\text{BPS}_i}{(1+t\%)^i}+\frac{\text{PER}_n\cdot\text{BPS}_n}{(1+t\%)^n} \tag{15.4.71}$$

Following the same assumption as the Gordon-Shapiro model (see section Economy page 7613) and using the corresponding usual notation we know that we can write:

$$\text{BPS}_n=\text{BPS}_0(1+g)^n\Rightarrow\text{BPS}_i=\text{BPS}_0(1+g)^i \tag{15.4.72}$$

with BPS_0 being the actual benefice per share.

We get then get:

$$\frac{\text{BPS}_i}{\text{BPS}_0}=(1+g)^i \tag{15.4.73}$$

So rearranging the prior previous relation we get:

$$\begin{aligned}\text{PER}_0 &= \sum_{i=1}^{n}\frac{d\left(\dfrac{\text{BPS}_i}{\text{BPS}_0}\right)}{(1+t\%)^i}+\frac{\text{PER}_n\left(\dfrac{\text{BPS}_n}{\text{BPS}_0}\right)}{(1+t\%)^n}\\ &= \sum_{i=1}^{n} d\frac{(1+g)^i}{(1+t\%)^i}+\text{PER}_n\frac{(1+g)^n}{(1+t\%)^n}\\ &= d\sum_{i=1}^{n}\left(\frac{1+g}{1+t\%}\right)^i+\text{PER}_n\left(\frac{1+g}{1+t\%}\right)^n\end{aligned}\tag{15.4.74}$$

The last equality is the "Bates formula":

$$\boxed{\text{PER}_0 = d\sum_{i=1}^{n}\left(\frac{1+g}{1+t\%}\right)^i+\text{PER}_n\left(\frac{1+g}{1+t\%}\right)^n}\tag{15.4.75}$$

However for more elegance it is convenient to notice that the first sum is a geometric series of common ratio:

$$K=\left(\frac{1+g}{1+k_e}\right)\tag{15.4.76}$$

Which leads us to write (see section Economy page 7563):

$$\begin{aligned}d\sum_{i=1}^{n}\left(\frac{1+g}{1+t\%}\right)^i &= d\sum_{i=1}^{n}K^i=dK\left(\frac{K^n-1}{K-1}\right)=d\frac{\dfrac{1+g}{1+t\%}}{\dfrac{(g-t\%)}{1+t\%}}(K^n-1)\\ &= d\left(\frac{1+g}{g-t\%}\right)(K^n-1)\end{aligned}\tag{15.4.77}$$

So we can rewrite the Bates formula as following:

$$\boxed{\text{PER}_0 = d\left(\frac{1+g}{g-t\%}\right)(K^n-1)+\text{PER}_n K^n}\tag{15.4.78}$$

Empirical evidence shows that the companies that pay more dividends (as a percentage of their earning) do not obtain a growth in their share price as a result. This is because when a company distributes more dividends, normally it reduces its growth because it distributes the money to its shareholders instead of plowing it back into new investments.

Empirical observations also show that shares value increase many times just before dividend pay time and decease just after.

15.4.1.6.2.3 Sales Multiples

This valuation method, which is used in some industries with a certain frequency, consists of calculating a company's value by multiplying its sales by a number. For example, a pharmacy is often valued by multiplying its annual sales (in dollars) by 2 or another number, depending on the market situation. It is also a common practice to value a soft drink bottling play by multiplying its annual sales in litres by 500 or another number, depending on the market situation.

15.4.1.6.3 Goodwill-Based Methods

Generally speaking, goodwill is the value that a company has above its book value or above the adjusted book value, Goodwill seeks to represent the value of the company's intangible assets, which often do not appear on the balance sheet but which, however, contribute an advantage with respect to other companies operating in the industry (quality of the customer portfolio, industry leadership, brands, strategic alliances, etc.). The problem arises when one tries to determine its value, as there is no consensus regarding the methodology used to calculate it. Some of the methods used to value the goodwill rise to the various valuation procedures described below.

These methods apply a mixed approach: on the one hand, they perform a static valuation of the company's assets and, on the other hand, they try to quantify the value that the company will generate in the future. Basically, these methods seek to determine the company's value by estimating the combine value of its assets plus a capital gain resulting from the value of its future earnings: they start by valuing the company's assets and then add a quantity relative with future earnings.

15.4.1.7 Capital Goods

A capital good is a durable good (one that does not quickly wear out) that is used in the production of goods or services. Capital goods are one of the three types of producer inputs, the other two being land and labour, which are also known collectively as primary factors of production. In the study of economic systems and in Marxian economics, the term means of production is often used with the same meaning as capital goods. This classification originated during the classical economic period and has remained the dominant method for classification.

Capital goods are acquired by a society by saving wealth which can be invested in the means of production. In terms of economics one can consider capital goods to be tangible. They are used to produce other goods or services during a certain period of time. Machinery, tools, buildings, computers, or other kind of equipment that is involved in production of other things for sale represent the term of a Capital good. The owners of the Capital good can be individuals, households, corporations or governments. Any material that is used in production of other goods also is considered to be capital good.

Capital goods undergo a gradual depreciation due to wear or obsolescence. This decline in value recorded as an expense in accounting in many countries around the world, is named "book depreciation". The reader must not confuse financial amortization as seen in the section of Economy (page 7570) and corresponding to debt repayment and the accounting depreciation that is a decrease in value of the means of production.

Certain assets have lost value fairly uniform in time unlike others that depreciate quickly the first few years, some are just empirical at defined by governments laws. Here, we discuss some of the accounting methods used in practice that describe either of these phenomena.

15.4.1.7.1 Linear Amortization

Definition (#15.4.718): We speak of a "linear amortization" of a capital good when its asset value is decreased (depreciated) of a periodic constant amount (annually in accounting) during its lifetime.

Thus, if we denote by A_n the amount of the k-th amortization and the initial value of the capital good V_0 and V_n its desired final value (which in most cases will be zero), we have obviously:

$$A=A_k=\frac{V_0-V_n}{m} \tag{15.4.79}$$

It is possible to obtain the depreciation value using the function `SLN( )` of any spreadsheet software like of Microsoft® Excel® 11.8346.

The equivalent constant depreciation rates based on the purchase and residual value is then given of course by:

$$t\%=\frac{\dfrac{V_0-V_n}{n}}{V_0} \tag{15.4.80}$$

Notice that this constant rate and the final value are sometimes imposed by legislation in some countries (as it is the case in Switzerland for example) to a residual value of zero or non-zero as defined by the law!

15.4.1.7.2 Arithmetic Declining Amortization

Definition (#15.4.719): When the asset value (depreciation) of good decreases inversely to the order of periods (accounting years) then we talk of "arithmetic declining depreciation" (there is therefore so no amortization rate that can be required by the government!).

For example, a good of 4 years life, will be depreciated the first year $4/10$, $3/10$ the second years, $2/10$ the third year, $1/10$ the last year. The common base "10" (in this example) is the arithmetic sum of $1+2+3+4$ so that the sum of all are equal to unity. This is a purely American tax rule named "Sum-of-years'-digits" (SYD).

Remark

Do not confuse the "arithmetic declining depreciation" with the "declining balance" that consist to apply a multiplier (enacted by the tax authorities) to the linear amortization and that we will not discuss here (except on explicit request of readers). It can only be used for new goods and does not apply to all types of asset. This declining balance rate will apply each year on the residual accounting value of the good.

Given the k-th amortization and V_0 the initial value of the good and V_n its desired final value (which in most cases will be zero) then we have:

$$\begin{aligned} A_1 &= \frac{4}{10}(V_0 - V_n)\\ A_2 &= \frac{3}{10}(V_0 - V_n)\\ A_3 &= \frac{2}{10}(V_0 - V_n)\\ A_4 &= \frac{1}{10}(V_0 - V_n) \end{aligned} \tag{15.4.81}$$

That can be written in the most general case:

$$A_k = \frac{n-k+1}{1+2+3+4}(V_0 - V_n) = \frac{n-k+1}{S_n}(V_0 - V_n) \tag{15.4.82}$$

and as we have proved it in the section of Sequences and Series (see page 1653):

$$S_n = \frac{n(n+1)}{2} \tag{15.4.83}$$

Which takes us to write:

$$A_k = \frac{2(V_0 - V_n)}{n(n+1)}(n-k+1) \tag{15.4.84}$$

You can get the amortization at a period k with a spreadsheet software using for example the function `SYD( )` of Microsoft® Excel® 11.8346.

15.4.1.7.3 Geometric Declining Amortization (declining balance)

Definition (#15.4.720): When the capital value of good decreases at a constant rate of depreciation based on the residual value of the previous period (that is to say like compound interest with negative rate), then we talk "simple geometric declining amortization".

Thus, the value of the good after n years is given by:

$$V_n = V_0(1-t\%)^n \qquad (15.4.85)$$

with then (elementary algebra):

$$t\% = 1-\sqrt[n]{\frac{V_n}{V_0}} \qquad (15.4.86)$$

Remark

We see that the value $t\%$ is in the range between $[0,1[$. The limit $(1-t\%)^n$ as n tends to big values is never zero. Thus, the residual value never will either!

Knowing by definition of this depreciation that:

$$A_k = V_{k-1}t\% \qquad (15.4.87)$$

we get:

$$A_k = V_0(1-t\%)^{k-1}t\% \qquad (15.4.88)$$

By injecting the expression of the in the above relation, we get:

$$\begin{aligned}A_k &= V_0\left(1-\left(1-\sqrt[n]{\frac{V_n}{V_0}}\right)\right)^{k-1}\left(1-\sqrt[n]{\frac{V_n}{V_0}}\right) = V_0\left(\sqrt[n]{\frac{V_n}{V_0}}\right)^{k-1}\left(1-\sqrt[n]{\frac{V_n}{V_0}}\right)\\ &= V_0\left(\frac{V_n}{V_0}\right)^{\frac{k-1}{n}}\left(1-\sqrt[n]{\frac{V_n}{V_0}}\right) = V_0\left(\left(\frac{V_n}{V_0}\right)^{\frac{k-1}{n}} - \left(\frac{V_n}{V_0}\right)^{\frac{1}{n}}\left(\frac{V_n}{V_0}\right)^{\frac{k-1}{n}}\right)\\ &= V_0\left(\left(\frac{V_n}{V_0}\right)^{\frac{k-1}{n}} - \left(\frac{V_n}{V_0}\right)^{\frac{k}{n}}\right)\end{aligned} \qquad (15.4.89)$$

We notice that the depreciation values do not need to know the depreciation rate explicitly. Just knowing the final and initial value is enough. This is precisely why the `DB( )` function of the spreadsheet software Microsoft® Excel® 11.8346 does not require the depreciation rate.

We notice also that this constant rate and the final value are sometimes imposed by legislation in some countries (as is the case in Switzerland for example) to a residual value of zero or non-zero also defined by the law!

Remark

The declining geometric depreciation is particularly suitable for goods with a very sharp depreciation in the early years.

15.4.2 Project Management

Project management is the discipline of initiating, planning, executing, controlling, and closing the work of a team to achieve specific goals and meet specific success criteria. A project is a temporary endeavour designed to produce a unique product, service or result with a defined beginning and end (usually time-constrained, and often constrained by funding or deliverables) undertaken to meet unique goals and objectives, typically to bring about beneficial change or added value. The temporary nature of projects stands in contrast with business as usual (or operations), which are repetitive, permanent, or semi-permanent functional activities to produce products or services. In practice, the management of these two systems is often quite different, and as such requires the development of distinct technical skills and management strategies.

As many technical Project Management subjects are related to Corporate Finance (empirical index, sensitivity analysis) and hence to Economy (Actuarial, Interests calculations, Loan Amortization/Repayment, Portfolio Theory and Forecasting), Optimization techniques (see section Numerical Methods page 6645) and also Industrial Engineering (see section of the same name page 8673) we will not come back on this subjects that we have already studied previously in details or that we will study in details.

We will focus here only on subjects that are very specific to quantitative project management and are commonly designated under the name of "Project Management Engineering".

Remark

Before reading the undergraduate project management quantitative techniques that will follow below, we strongly recommend the reader to revise high school level techniques related to time management like the harmonic mean of working rates (see section Statistics page 564).

15.4.2.1 Probabilistic PERT (Beta-PERT Distribution)

Always remaining within the framework of statistics and probabilities with respect to mathematical management techniques, there is a project management empirical law (domain we assume known by the reader as trivial) widely used in the context of "probabilistic PERT" (where PERT stands for "Program Evaluation and Review Technique") and included in a lot of specialized softwares to make cost and time predictions for project plannings (see section Graph Theory page 3016). We speak then about "Probabilistic Network Evaluation Technique" (PNET).

This empirical distribution, named "beta distribution" or sometimes "PERT law", or also "Beta-PERT Distribution", is often presented as follows in the books and without proof (...) and applies as well to costs or time estimation:

$$t_{Pr}=\frac{t_O+4t_V+t_P}{6} \tag{15.4.90}$$

and gives the expected mean duration (or cost) t_{Pr} of an elementary task (not downsizable into sub-tasks) where we have t_O, t_V, t_P which are respectively the optimistic, most likely and pessimistic duration (or cost) of the task. We will show below the origin of this relation and why it is partially false when written in a such simple way!

Remark

This classical approach dates from 11962 (holocene calendar) and is due to C.E. Clark. It is said to be based on a project task database analysis. In facts you should always check what kind of law (probabilistic distribution) follow the tasks in your company and not apply just stupidly and simply the beta distribution.

The principles of this approach is based on the idea that the duration (or cost) of each project task is considered random and Beta distribution is systematically used as a more accurate approach than the triangular distribution (see section Statistics page 743). The parameters of this distribution as we will prove it are determined through calculation of a fairly strong assumption, based on extreme values a and b as the execution time (cost) can take, and is modal value.

So we just have to ask ourselves following two questions:

1. What is the minimum physically possible time or cost execution?
2. What is the maximum physically possible time or cost execution?

to obtain the parameters a, b, M_0, which are then used to calculate the average (expected mean), the variance and the shape of the distribution of this random time/cost.

Then we determine the critical path of the project (using the Potential Metra Method supposed to be known by the reader after its study of the section on Graph Theory at page 3017), placing ourselves in some universe and using a given probabilistic duration for each task obtained with the beta distribution, allowing to find afterwards the probabilistic critical paths and thus the total probabilistic duration/cost of the whole project.

This done some practitioners place themselves then in random universe where the project duration is considered as the sum of the durations of critical path tasks previously identified. They use then the central limit theorem that we have proved in section Statistics (recall that this theorem states, under generally respected conditions that the random variable consisting of a sum of n independent random variables identically distributed approximately follows a Normal distribution, whatever are the original distributions as soon as n is large enough) to approximate the density distribution law of the whole project itself. Even if this practice is simple and useful it is in fact dangerous because in reality task are not equally distributed and can takes the practitioners to huge bias error.

Remark

In a rigorous way the practitioner should use Monte Carlo simulations with special softwares like @Risk of Palisade to estimate the probabilistic time/cost of the whole project.

If X_i is the corresponding cost or duration of task i the using the property of linearity of the mean (see section Statistics page 571) we have for the mean cost or duration of the whole project:

$$\mathrm{E}(X)=\mathrm{E}\left(\sum_i X_i\right)=\sum_i \mathrm{E}(X_i) \qquad (15.4.91)$$

and in the strong hypothesis that all tasks of a project are independent we can still write that the global variance (see section Statistics page 596) is:

$$\mathrm{V}(X)=\mathrm{V}\left(\sum_i X_i\right)=\sum_i \mathrm{V}(X_i) \tag{15.4.92}$$

Now let us go a little bit more deeply in technical tools for project duration and cost estimation.

Recall that we saw in the sections of Statistics (see page 761) and of Differential and Integral Calculus (see page 1574) that:

$$B(p,q)=\frac{\Gamma(p)\Gamma(q)}{\Gamma(p+q)}=\int\limits_0^1 t^{p-1}(1-t)^{q-1}\mathrm{d}t \tag{15.4.93}$$

and:

$$\Gamma(x+1)=x\Gamma(x) \tag{15.4.94}$$

In management we notice that often (applying an Anderson-Darling Goodness of fit test as seen in the section of Statistics at page 1130) that tasks durations follow a distribution that we name "beta distribution of the first kind" (see section Statistics page 760) given by:

$$P_{0,1}(x)=\frac{x^\alpha(1-x)^\gamma}{\int\limits_0^1 t^\alpha(1-t)^\gamma\mathrm{d}t}1_{[0,1]} \tag{15.4.95}$$

For an interval $[a,b]$ which includes x, we can obtain the more general form:

$$P_{a,b}(x)=\frac{(x-a)^\alpha(b-x)^\gamma}{(b-a)^{\alpha+\gamma+1}\int\limits_0^1 t^\alpha(1-t)^\gamma\mathrm{d}t}1_{[a,b]} \tag{15.4.96}$$

Theorem 15.8. Let us check that we have well:

$$\int\limits_a^b P_{a,b}(x)\mathrm{d}x=\frac{1}{(b-a)^{\alpha+\gamma+1}\int\limits_0^1 t^\alpha(1-t)^\gamma\mathrm{d}t}\int\limits_a^b(x-a)^\alpha(b-x)^\gamma\mathrm{d}x=1 \tag{15.4.97}$$

Proof 15.8.1. By the change of variable:

$$u=\frac{x-a}{b-a}\Rightarrow\mathrm{d}u=\frac{1}{b-a}\mathrm{d}x \qquad \text{and} \qquad 1-u=1-\frac{x-a}{b-a}=\frac{b-x}{b-a} \tag{15.4.98}$$

we get:

$$\begin{aligned}\int\limits_a^b P_{a,b}(x)\mathrm{d}x&=\frac{\int\limits_0^1((b-a)u)^{\alpha}(b-x)^{\gamma}(b-a)\mathrm{d}u}{(b-a)^{\alpha+\gamma+1}\int\limits_0^1 t^{\alpha}(1-t)^{\gamma}\mathrm{d}t}=\frac{\int\limits_0^1(u^{\alpha}(b-x)^{\gamma}\mathrm{d}u}{(b-a)^{\gamma}\int\limits_0^1 t^{\alpha}(1-t)^{\gamma}\mathrm{d}t}\\&=\frac{\int\limits_0^1(u^{\alpha}\left(\frac{b-x}{b-a}\right)^{\gamma}\mathrm{d}u}{\int\limits_0^1 t^{\alpha}(1-t)^{\gamma}\mathrm{d}t}=\frac{1}{\int\limits_0^1 t^{\alpha}(1-t)^{\gamma}\mathrm{d}t}\int\limits_0^1 u^{\alpha}\,(1-u)^{\gamma}\,\mathrm{d}u=1\end{aligned}\tag{15.4.99}$$

Let us now determine the expected mean:

$$\mu=\int\limits_a^b xP_{a,b}(x)\mathrm{d}x=\frac{1}{(b-a)^{\alpha+\gamma+1}\int\limits_0^1 t^{\alpha}(1-t)^{\gamma}\mathrm{d}t}\int\limits_a^b x(x-a)^{\alpha}(b-x)^{\gamma}\mathrm{d}x\tag{15.4.100}$$

Always with the same change of variable, we get:

$$\begin{aligned}\mu&=\int\limits_a^b xP_{a,b}(x)\mathrm{d}x=\frac{1}{\int\limits_0^1 t^{\alpha}(1-t)^{\gamma}\mathrm{d}t}\int\limits_a^b(a+u(b-a))u^{\alpha}(1-u)^{\gamma}\mathrm{d}u\\&=a+\frac{b-a}{\int\limits_0^1 t^{\alpha}(1-t)^{\gamma}\mathrm{d}t}\int\limits_a^b u^{\alpha+1}(1-u)^{\gamma}\mathrm{d}u=a+(b-a)\frac{B(\alpha+2,\gamma+1)}{B(\alpha+1,\gamma+1)}\end{aligned}\tag{15.4.101}$$

But we know from the study of the section on Differential and Integral Calculus (see page 1574) that:

$$\begin{aligned}\frac{B(\alpha+2,\gamma+1)}{B(\alpha+1,\gamma+1)}&=\frac{\Gamma(\alpha+2)\Gamma(\gamma+1)}{\Gamma(\alpha+\gamma+3)}\frac{\Gamma(\alpha+\gamma+2)}{\Gamma(\alpha+1)\Gamma(\gamma+1)}\\&=\frac{\Gamma(\alpha+2)}{\Gamma(\alpha+\gamma+3)}\frac{\Gamma(\alpha+\gamma+2)}{\Gamma(\alpha+1)}=\frac{(\alpha+1)(\alpha)\Gamma(\alpha)}{\Gamma(\alpha+\gamma+3)}\frac{\Gamma(\alpha+\gamma+2)}{(\alpha)\Gamma(\alpha)}\\&=\frac{(\alpha+1)(\alpha)\Gamma(\alpha)}{(\alpha+\gamma+2)\Gamma(\alpha+\gamma+2)}\frac{\Gamma(\alpha+\gamma+2)}{(\alpha)\Gamma(\alpha)}=\frac{\alpha+1}{\alpha+\gamma+2}\end{aligned}\tag{15.4.102}$$

Thus:

$$\mu=a+(b-a)\frac{\alpha+1}{\alpha+\gamma+2}\tag{15.4.103}$$

Let us calculate now the variance using the Huygens relation that we have proved in the section Statistics (see page 593):

$$\mathrm{V}(X)=\mathrm{E}(X^2)-\mathrm{E}(X)^2 \tag{15.4.104}$$

First we calculate $\mathrm{E}(X^2)$:

$$\mathrm{E}(X^2)=\int\limits_a^b x^2 P_{a,b}(x)\mathrm{d}x=\frac{1}{(b-a)^{\alpha+\gamma+1}\int\limits_0^1 t^{\alpha}(1-t)^{\gamma}\mathrm{d}t}\int\limits_a^b x^2(x-a)^{\alpha}(b-x)^{\gamma}\mathrm{d}x \tag{15.4.105}$$

Always with the same change of variable, we get:

$$\begin{aligned}\mathrm{E}(X^2)&=\int\limits_a^b x^2 P_{a,b}(x)\mathrm{d}x=\frac{1}{\int\limits_0^1 t^{\alpha}(1-t)^{\gamma}\mathrm{d}t}\int\limits_a^b (a^2+u^2(b-a)^2+2au(b-a))u^{\alpha}(1-u)^{\gamma}\mathrm{d}u\\ &=a^2+\frac{(b-a)^2}{B(\alpha+1,\gamma+1)}B(\alpha+3,\gamma+1)+\underbrace{\frac{2a(b-a)}{\int\limits_0^1 t^{\alpha}(1-t)^{\gamma}\mathrm{d}t}\int\limits_0^1 u^(\alpha+1)(1-u)^{\gamma}du}_{=2a(b-a)\frac{\alpha+1}{\alpha+\gamma+2}\text{ (see previous dev.)}}\\ &=a^2+2a(b-a)\frac{\alpha+1}{\alpha+\gamma+2}+(b-a)^2\frac{B(\alpha+3,\gamma+1))}{B(\alpha+1,\gamma+1)}\end{aligned} \tag{15.4.106}$$

But we have:

$$\frac{B(\alpha+3,\gamma+1))}{B(\alpha+1,\gamma+1)}=\frac{\Gamma(\alpha+3)\Gamma(\gamma+1)}{\Gamma(\alpha+\gamma+4)}\frac{\Gamma(\alpha+\gamma+2)}{\Gamma(\alpha+1)\Gamma(\gamma+1)}=\frac{(\alpha+2)(\alpha+1)}{(\alpha+\gamma+3)(\alpha+\gamma+2)} \tag{15.4.107}$$

Thus:

$$\mathrm{E}(X^2)=a^2+2a(b-a)\frac{\alpha+1}{\alpha+\gamma+2}+(b-a)^2\frac{(\alpha+2)(\alpha+1)}{(\alpha+\gamma+3)(\alpha+\gamma+2)} \tag{15.4.108}$$

To finish:

$$\begin{aligned}\mathrm{V}(X)&=\sigma^2=\mathrm{E}(X^2)-\mathrm{E}(X)^2=\mathrm{E}(X^2)-\mu^2\\ &=a^2+2a(b-a)\frac{\alpha+1}{\alpha+\gamma+2}+(b-a)^2\frac{\alpha+2}{\alpha+\gamma+3}\frac{\alpha+1}{\alpha+\gamma+2}-\left(a+(b-a)\frac{\alpha+1}{\alpha+\gamma+2}\right)^2\\ &=(b-a)^2\frac{\alpha+1}{\alpha+\gamma+2}\left(\frac{\alpha+2}{\alpha+\gamma+3}-\frac{\alpha+1}{\alpha+\gamma+2}\right)=\frac{(b-a)^2(\alpha+1)(\gamma+1)}{(\alpha+\gamma+2)^2(\alpha+\gamma+3)}\end{aligned} \tag{15.4.109}$$

Let us now calculate the modal M_0 value of this distribution (for recall of the section Statistics the modal value is by definition the overall maximum of the distribution function):

$$P_{a,b}(x)=\frac{(x-a)^{\alpha}(b-x)^{\gamma}}{(b-a)^{\alpha+\gamma+1}\int\limits_{0}^{1}t^{\alpha}(1-t)^{\gamma}\mathrm{d}t}1_{[a,b]} \tag{15.4.110}$$

To get the expression of the modal value we just need to solve the equation:

$$\frac{\mathrm{d}P_{a,b}(x)}{\mathrm{d}x}=0 \tag{15.4.111}$$

After derivation, we get:

$$\alpha(x-a)^{\alpha-1}(b-x)^{\gamma}-\gamma(x-a)^{\alpha}(b-x)^{\gamma-1}=0 \tag{15.4.112}$$

dividing by $(x-a)^{\alpha-1}(b-x)^{\gamma-1}$ we get:

$$\alpha(b-x)-\gamma(x-a)=0 \tag{15.4.113}$$

that is to say:

$$x=M_0=\frac{\alpha b+\gamma a}{\alpha+\gamma} \tag{15.4.114}$$

Now the reader will have noticed that the value a is the smallest value and the greatest is b. In between there is therefore the modal value M.

In project management a corresponds to the optimistic duration (or cost) t_O and b the duration t_P duration (or cost) of a task.

$$\alpha=2+\sqrt{2},\gamma=2-\sqrt{2} \tag{15.4.115}$$

or:

$$\alpha=2-\sqrt{2},\gamma=2+\sqrt{2} \tag{15.4.116}$$

This means that we have:

$$M_0=\frac{\alpha b+\gamma a}{\alpha+\gamma}=\frac{(2+\sqrt{2})b+(2-\sqrt{2})a}{2+\sqrt{2}+2-\sqrt{2}}=\frac{2(a+b)+\sqrt{2}(b-a)}{4} \tag{15.4.117}$$

as well as:

$$\begin{aligned}\mathrm{V}(X)&=\frac{(b-a)^2(\alpha+1)(\gamma+1)}{(\alpha+\gamma+2)^2(\alpha+\gamma+3)}=\frac{(b-a)^2(2+\sqrt{2}+1)(2-\sqrt{2}+1)}{(2+\sqrt{2}+2-\sqrt{2}+2)^2(2+\sqrt{2}+2-\sqrt{2}+3)}\\&=\frac{(b-a)^2(3+\sqrt{2})(3-\sqrt{2})}{6^27}=\frac{(b-a)^2(9-2)}{36\cdot 7}=\frac{(b-a)^2(3+\sqrt{2})(3-\sqrt{2})}{6^27}\\&=\frac{(b-a)^2(9-2)}{6^2}\end{aligned} \tag{15.4.118}$$

And finally:

$$\begin{aligned}\mathrm{E}(X)&=a+(b-a)\dfrac{\alpha+1}{\alpha+\gamma+2}=\dfrac{6a+(b-a)(2+\sqrt{2}+1)}{6}\\&=\dfrac{6a+2b+\sqrt{2}b+b-2a-\sqrt{2}a-a}{6}=\dfrac{5a+a+b+b+\sqrt{2}b+b-2a-\sqrt{2}a-a}{6}\\&=\dfrac{a+b}{6}+\dfrac{2a+2b+(b-a)\sqrt{2}}{6}=\dfrac{a+b}{6}+\dfrac{4M_0}{6}=\dfrac{a+4M_0+b}{6}\end{aligned} \tag{15.4.119}$$

This gives us to resume the following relations:

$$\boxed{\begin{aligned}M_0&=\dfrac{2(a+b)+\sqrt{2}(b-a)}{4}\\\mathrm{V}(X)&=\dfrac{(b-a)^2}{6^2}\\\mathrm{E}(X)&=\dfrac{a+4M_0+b}{6}\end{aligned}} \tag{15.4.120}$$

that is assimilated in some textbooks to the Beta-PERT distribution with a scale parameter λ equal to 4 as a more general derivation (that we will not present here) gives :

$$\mathrm{E}(X)=\dfrac{a+\lambda M_0+b}{\lambda+2} \tag{15.4.121}$$

Remark

The last two expressions of the variance and expected mean are the ones you can find in any project management book (of course without proof...) such as the famous PMBOK (Project Management Body of Knowledge). Unfortunately, there are two errors in this project management reference book as far as we know (the first error was corrected at the beginning of the years 12010 according to holocene calendar). Indeed, the first error is that the modal value is said to be imposed by the project manager but as we know, in fact it should be calculated with the first of the three above relations using the pessimistic and optimistic task duration (or cost)!!! The second mistake is that the PMBOK says that the modal value is always smaller than the expected mean. Which is obviously wrong! To check this we can put for example $a=0$:

$$\begin{aligned}M_0&=\dfrac{2(a+b)+\sqrt{2}(b-a)}{4}=\dfrac{2b+\sqrt{2}b}{4}\\\mathrm{E}(X)&=\dfrac{a+4M_0+b}{6}=\dfrac{4\dfrac{2(a+b)+\sqrt{2}(b-a)}{4}=\dfrac{2b+\sqrt{2}b}{4}+b}{6}=\dfrac{3b+\sqrt{2}b}{6}\end{aligned} \tag{15.4.122}$$

and simplifying by b we immediately see that:

$$\dfrac{2+\sqrt{2}}{4}\geq\dfrac{3+\sqrt{2}}{6}\Leftrightarrow 0.853\geq 0.753\Rightarrow M_0>\mathrm{E}(X) \tag{15.4.123}$$

It is important to know that exactly the same developments made so far are valid with the following formulation of the 4-parameter beta distribution (which will also be very useful in the section of Industrial Engineering for reliability calculations):

$$\boxed{P_{a,b}(x)=\frac{(x-a)^{\alpha-1}(x-a)^{\gamma-1}}{(b-a)^{\alpha+\gamma+1}\int\limits_0^1 t^{\alpha-1}(1-t)^{\gamma-1}\mathrm{d}t}=\frac{(x-a)^{\alpha-1}(x-a)^{\gamma-1}}{(b-a)^{\alpha+\gamma+1}B(\alpha,\gamma)}} \tag{15.4.124}$$

The latter formulation is that available in spreadsheets softwares such as Microsoft® Excel® version of 11.8346 for example using the `BETADIST()` function or its inverse using the `BETAINV()` function.

We then get for the modal value, the variance and expected mean (we can detail again all calculations if some readers want to...):

$$\begin{aligned}M_0&=\frac{\alpha a-b+\gamma a-a}{\alpha+\gamma-2}\\ \mathrm{V}(X)&=\frac{(b-a)^2\alpha\gamma}{(\alpha+\gamma)^2(\alpha+\gamma-1)}\\ \mathrm{E}(X)&=a+(b-a)\frac{\alpha}{\alpha+\gamma}\end{aligned} \tag{15.4.125}$$

But to get the P.M.I. result you must use in spreadsheet softwares (if you put this two values in the latter relations you can quickly check that you find back the classic modal value, variance and expected mean of the P.M.I.):

$$\alpha=3+\sqrt{2},\gamma=3-\sqrt{2} \tag{15.4.126}$$

To calculate the probability or quantile in the English version of Microsoft® Excel® 14.0.7153:

- `BETA.DIST(quantile,`$3+\sqrt{2}$`,`$3-\sqrt{2}$`,TRUE,optimistic value,pessimistic value)`
- `BETA.INV(probability,`$3+\sqrt{2}$`,`$3-\sqrt{2}$`,optimistic value,pessimistic value)`

✍**Example:**

Plot of the distribution and cumulative function for the beta law of parameters $(t_o, t_v, t_p) = (0, 1, 3)$:

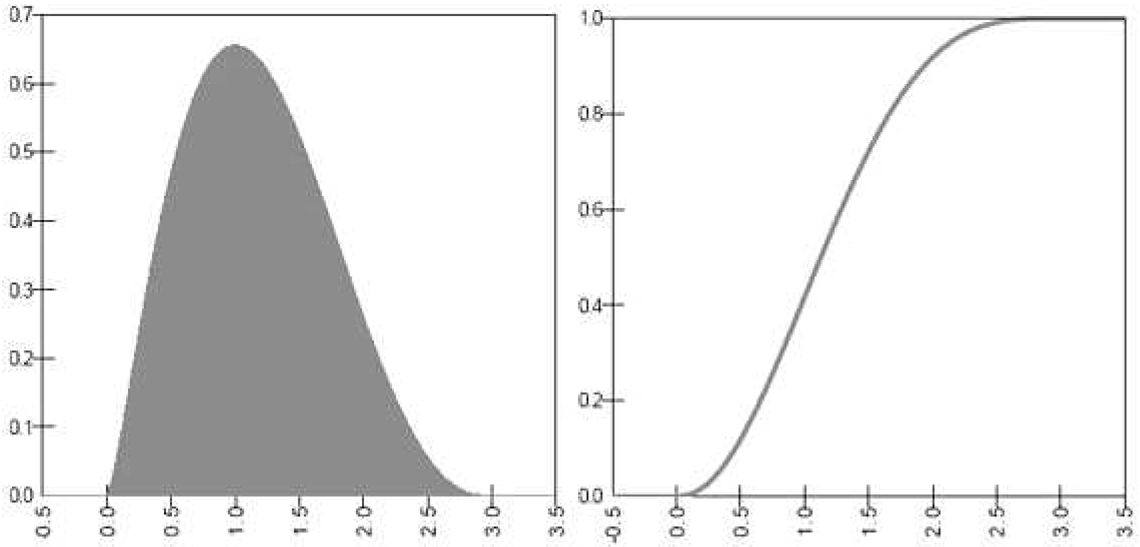

Figure 15.288: Distribution and cumulative function of the beta law

We also define the "action risk" by the ratio (whose interpretation is left to the project managers and customers...):

$$R(T_i) = \frac{t_p - t_o}{t_p} \tag{15.4.127}$$

By the NASA Probabilistic analysis of cost and/or schedule estimates is required (in 12014 according to holocene calendar) for tightly coupled programs and single-project programs (regardless of life-cycle cost), and projects with a LCCE (Life-Cycle Cost Estimate) greater than \$ 250 million. When the probabilistic analysis is developed for only one parameter (i.e., cost or schedule) or when generally referring to a probabilistic assessment of the level of confidence of achieving a specific goal, the analysis is referred to merely as a "confidence level". When the probabilistic analysis is developed to measure the likelihood of meeting both cost and schedule, the analysis is referred to as a "joint cost and schedule confidence level" (JCL). A JCL is defined as the probability that actual cost and schedule will be equal to or less than the targeted cost and schedule. For example, a 70% JCL is the point on the joint cost and schedule probability distribution curve where there is a 70% percent probability that the project or program will be completed at or lower than the estimated cost and on or before the estimated schedule.

15.4.2.2 Project planning variance reduction

As we know a lot of projects budgeting and time planning lack in accuracy because there is always an implicit variance to each task on the critical path and most project manager don't have the time to do detailed planning as for most board committee (and even most project managers!!!) there is no reason that the total variance of a project decrease if we increase the details of the planification (that is to say: we detail a maximum of tasks).

We suppose here that we will work in the framework of softwares used by project management engineers and able to display for each task and early finish (t_o), expected finish (t_V) and late finish (t_p). Even if there are advanced risk modelization softwares doing this work in cutting edge companies (softwares like @Risk, Crystal Ball, Risky Project, etc), most project managers calculate these three point estimates based on a rule of thumb that is most of time of the type:

$$t_V=\mu \qquad t_o=\mu-b\mu \qquad t_p=\mu+b\mu \tag{15.4.128}$$

where b is a security factor that we will here name the "bias" of estimation.

Theorem 15.9. Under some assumptions relevant in real projects variance will decrease if the planning is detailed and that this variance tends to zero when the number of detailed tasks tends to infinity (I always try to explain without maths that this is obvious since if we do a task for every gesture and action in the project we forget less stuff than doing just a macroscopic planning).

For the proof let we have only 3 known assumptions (perhaps they are other hidden one but not identified so far...):

H1. When a project manager estimates a task duration their brain use a non-robust estimator that is the mean μ.

H2. Tasks duration are independent and therefore their covariance is zero.

H3. The project managers always have the same biased b (percentage) for all tasks [57].

Proof 15.9.1. Let us consider the case (that can be easily generalized with high-school maths) of a task of duration T of mean μ and standard-deviation:

$$\sigma_T=b\mu_T=bT \tag{15.4.129}$$

We take the special case where we detail this task of duration T into two critical (i.e. consecutive) sub tasks (still with same bias) of non-zero duration such that:

$$T=T_1+T_2=w_1T+w_2T \tag{15.4.130}$$

where obviously $w_1+w_2=1$. This is quite a natural process for most project managers until now so nothing new...

---

[57] In practice I see that most project managers have a significant bias much greater than 20% in task duration and budget estimation

But now let us calculate the standard deviation of the sum under the assumption of independence and stability:

$$\begin{aligned}\sigma_{T_1+T_2} &= \sqrt{\sigma_{T_1}^2+\sigma_{T_2}^2}=\sqrt{(b\mu_{T_1})^2+(b\mu_{T_1})^2}=b\sqrt{mu_{T_1}^2+mu_{T_2}^2}\\ &= b\sqrt{(w_1T)^2+(w_2T)^2}=bT\sqrt{w_1^2+w_2^2}\end{aligned}\tag{15.4.131}$$

So we see that as if $0<w_i<1$ then we have:

$$\sigma_T<\sigma_{T_1+T_2}\tag{15.4.132}$$

as:

$$bT<bT\sqrt{w_1^2+w_2^2}\tag{15.4.133}$$

Because:

$$\sqrt{w_1^2+w_2^2}<1\tag{15.4.134}$$

So as we see, the deeper the granularity of a project planning is, the lower is the variation the latter. That is:

$$i\rightarrow+\infty:\quad \sigma_{\sum T_i}=bt\sqrt{\sum_{i=1}^{+\infty}w_i^2}\rightarrow 0\tag{15.4.135}$$

This result then is like the "Hofstadter's law", that is a self-referential time-related adage, coined by Douglas Hofstadter and named after him that states: «*It always takes a project longer than you expect, even when you take into account Hofstadter's Law*».

■ Q.E.D.

It is quite easy to notice that in the best case, for every $i>1$ we minimize $\sigma_{\sum T_i}$ if all w_i are equal to:

$$w_i=\frac{1}{i}\tag{15.4.136}$$

For example with $i=2$ in the best case we can reduce the initial variance of almost 30%, if $i=3$ of almost 42%, if $i=4$ of exactly 50%, if $i=5$ of almost 55% and so on. The variance reduction relation is simple given in the general best case by:

$$\boxed{\text{VR}=1-\sqrt{\sum_i\left(\frac{1}{i}\right)^2}=1-\sqrt{\frac{1}{i}}}\tag{15.4.137}$$

This result corroborates the fact the division of labour increases production. In other words, when the tasks involved with producing a good or service are divided and subdivided, workers and businesses can produce a greater quantity of output. In his observations of pin factories, Adam Smith observed that one worker alone might make 20 pins in a day, but that a small business of 10 workers (some of whom would need to do two or three of the 18 tasks involved with pin-making), could make $48,000$ pins in a day. How can a group of workers, each specializing in certain tasks, produce so much more than the same number of workers who try to produce the entire good or service by themselves? Smith offered three reasons:

1. First, specialization in a particular small job allows workers to focus on the parts of the production process where they have an advantage (in later chapters, we will develop this idea by discussing comparative advantage). People have different skills, talents, and interests, so they will be better at some jobs than at others. The particular advantages may be based on educational choices, which are in turn shaped by interests and talents. Only those with medical degrees qualify to become doctors, for instance. For some goods, specialization will be affected by geography - it is easier to be a wheat farmer in North Dakota than in Florida, but easier to run a tourist hotel in Florida than in North Dakota. If you live in or near a big city, it is easier to attract enough customers to operate a successful dry cleaning business or movie theatre than if you live in a sparsely populated rural area. Whatever the reason, if people specialize in the production of what they do best, they will be more productive than if they produce a combination of things, some of which they are good at and some of which they are not.

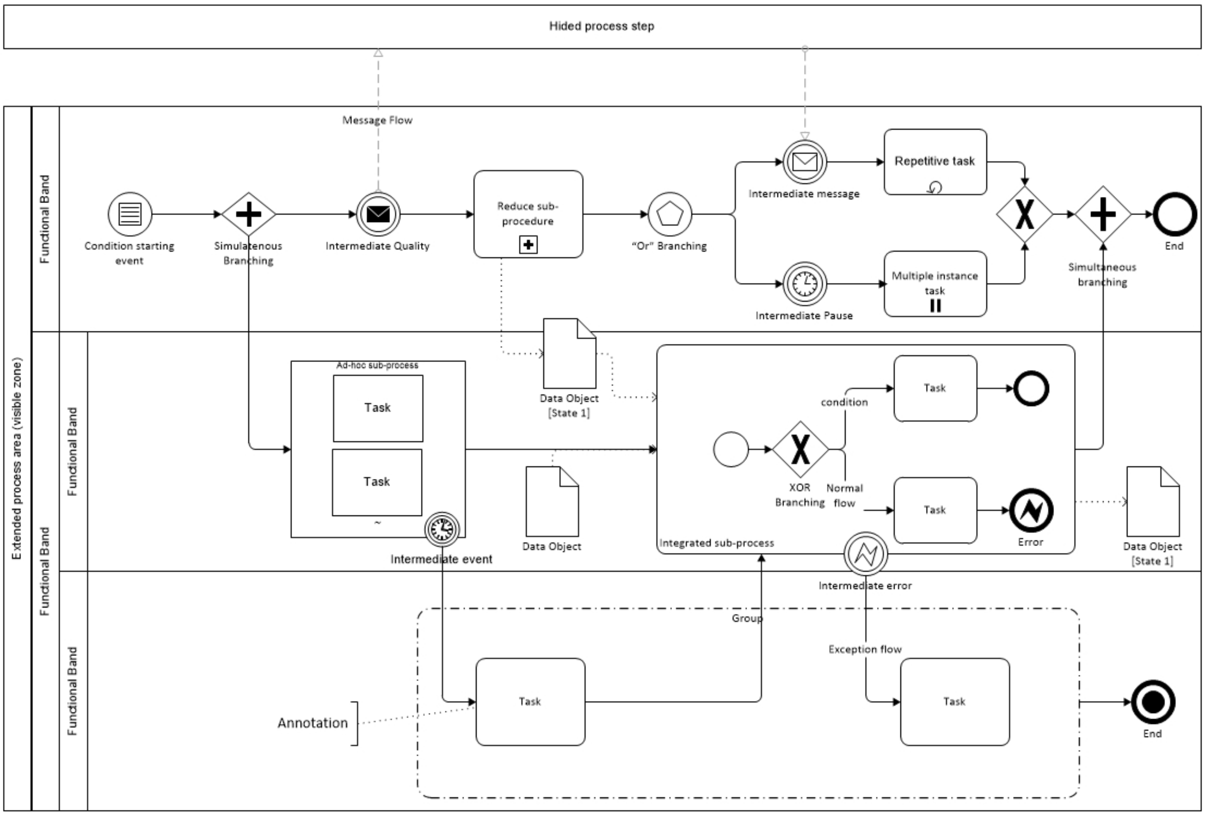
2. Second, workers who specialize in certain tasks often learn to produce more quickly and with higher quality. This pattern holds true for many workers, including assembly line labourers who build cars, stylists who cut hair, and doctors who perform heart surgery. In fact, specialized workers often know their jobs well enough to suggest innovative ways to do their work faster and better.

   A similar pattern often operates within businesses. In many cases, a business that focuses on one or a few products (sometimes named its "core competency") is more successful than firms that tries to make a wide range of products.

3. Third, specialization allows businesses to take advantage of economies of scale, which means that for many goods, as the level of production increases, the average cost of producing each individual unit declines. For example, if a factory produces only 100 cars per year, each car will be quite expensive to make on average. However, if a factory produces $50,000$ cars each year, then it can set up an assembly line with huge machines and workers performing specialized tasks, and the average cost of production per car will be lower. The ultimate result of workers who can focus on their preferences and talents, learn to do their specialized jobs better, and work in larger organizations is that society as a whole can produce and consume far more than if each person tried to produce all of their own goods and services. The division and specialization of labour has been a force against the problem of scarcity.

15.4.2.3 Process Reliability

Almost every people and even child know what why process are important and how to draw them using various normalized symbols (like the most famous one that are ISO 5807:85 or BPMN/ISO 19510:2013) as shown the figure below:



Hided process step
Message Flow
Extended process area (visible zone)
Functional Band
Condition starting event
Simultaneous Branching
Intermediate Quality

Exception flow
Task
Task
Annotation
End

Figure 15.289: BPMN process representative diagram with Microsoft Visio 2010

But in some high level and cutting edge industries just drawing processes is not enough. We consider mainly three situations about processes:

- An organization has processes, people respect them or not and there is not statistical analysis about their usage.

  There is nothing to say about this as it is what the huge majority of undergraduate project managers and business analysts do!

- An organization has processes, people respect them or not and there is a Six Sigma statistical analysis about the capability of the processes or their subparts (see section Industrial Engineering page 8683).

  For the capability analysis we will study and prove in details in the section of Industrial Engineering that we can (or have to) calculate the following indicators:

$$\boxed{C_p=\frac{\text{USL}-\text{LSL}}{\sigma_{\text{ST}}}\qquad C_{pk}=\left\{\frac{\text{USL}-\mu}{3\sigma_{\text{ST}}},\frac{\mu-\text{LSL}}{3\sigma_{\text{ST}}}\right\}\qquad C_{pm}\cong\frac{\text{USL}-\text{LSL}}{6\sqrt{\sigma_{\text{ST}}^2+(m-T)^2}}} \tag{15.4.138}$$

and:

$$\boxed{P_p = \frac{\text{USL}-\text{LSL}}{\sigma_{\text{LT}}} \qquad P_{pk} = \left\{\frac{\text{USL}-\mu}{3\sigma_{\text{LT}}}, \frac{\mu-\text{LSL}}{3\sigma_{\text{LT}}}\right\} \qquad P_{pm} \cong \frac{\text{USL}-\text{LSL}}{6\sqrt{\sigma_{\text{LT}}^2+(m-T)^2}}} \tag{15.4.139}$$

associated with various run charts (see section Industrial Engineering page 8935) to do real scientific robust process management analysis.

- An organization has processes, people respect them or not and there is a reliability analysis of the processes or their subparts (see section Industrial Engineering page 8683).

  This is typically used in Nuclear Engineering or high level Pharmaceutical products quality tracking.

  The mathematical relations used in this case are those proven in the section of Industrial Engineering during our study of Topological Systems in Preventive Maintenance (see section Industrial Engineering page 8716) also associated with Monte Carlo simulations (see section Numerical Methods page 6708). That is to say:

  - The reliability (probability of operation) of a pure series topology:

$$\boxed{R_S = 1 - F_S = \prod_{i=1}^{n} R_i} \tag{15.4.140}$$

  - The reliability (probability of operation) of a pure parallel topology:

$$\boxed{R_P = 1 - \prod_{i=1}^{n} F_i = 1 - \prod_{i=1}^{n}(1-R_i)} \tag{15.4.141}$$

  - The reliability of a k/n topology:

$$\boxed{R_{k/n} = \sum_{x=k}^{n} C_x^n R^x (1-R)^{n-x}} \tag{15.4.142}$$

  - The reliability of a series topologies in parallels:

$$\boxed{R_{S/P} = 1 - \prod_{j=1}^{m}(1-R_j) = \prod_{j=1}^{m}\left(1 - \prod_{i=1}^{n} R_{ij}\right)} \tag{15.4.143}$$

  - The reliability of parallel topologies in series:

$$\boxed{R_{P/S} = \prod_{i=1}^{n} R_i = \prod_{i=1}^{n}\left(1 - \prod_{j=1}^{m}(1-R_{ij})\right)} \tag{15.4.144}$$

  - The reliability of bridged topology in series:

$$\boxed{\begin{aligned} R_B = &(1-R_5)(1-(1-R_1R_2)(1-R_3R_4)) \\ &+ R_5((1-(1-R_1)(1-R_3))(1-(1-R_2)(1-R_4))) \end{aligned}} \tag{15.4.145}$$

Do these calculations is quite easy even with a spreadsheet software. But obviously it is strongly recommended to use specialized softwares like the add-in Process Simulator of ProModel® for Microsoft Visio.

15.4.2.4 Divide and rule?

Divide and rule (or divide and conquer) in management is gaining and maintaining a better control by breaking up groups into pieces that individually have less incompatibilities. The concept refers to a strategy that breaks up existing structures, and especially prevents individuals in group to disagree, fight together or and generate issues and poor efficiency.

We have proved in the sectionof Statistics (see page 644) that for a group of items (individuals) having a unique common property[58] (characteristic) its entropy was given by:

$$S_j(x)=\frac{N\log_{10}(N)-\sum_{i=1}^{n} f_i\log_{10}(f_i)}{N} \tag{15.4.146}$$

Now let us consider the case of a population of size P with only one property (so that we can split the population in two distinct groups) in proportion:

$$w_1+w_2=1=100\% \tag{15.4.147}$$

and therefore $w_2=1-w_1$ and $w_1P+w_2P=P$. So the total entropy if we consider the two possible groups the first having a proportion p_1^1 of w_1 and p_1^2 of w_2 (and therefore the second group has $p_2^1 = 1 - p_1^1$ and $p_2^2 = 1 - p_1^2$):

---

[58] For example a property: Technical skill with a binary value of the type "Yes"/"No"

$$\begin{aligned}
S_{\text{tot}} = S_1 + S_2 &= \frac{N_1 \log_{10}(N_1) - \displaystyle\sum_{i=1}^{2} f_i \log_{10}(f_i)}{N_1} + \frac{N_2 \log_{10}(N_2) - \displaystyle\sum_{i=1}^{2} f_i \log_{10}(f_i)}{N_2} \\
&= \frac{(p_1^1 w_1 + p_1^2 w_2) P \log_{10}((p_1^1 w_1 + p_1^2 w_2)P) - \displaystyle\sum_{i=1}^{2} f_i \log_{10}(f_i)}{(p_1^1 w_1 + p_1^2 w_2)P} \\
&+ \frac{(p_2^1 w_1 + p_2^2 w_2) P \log_{10}((p_1^1 w_1 + p_1^2 w_2)P) - \displaystyle\sum_{i=1}^{2} f_i \log_{10}(f_i)}{(p_2^1 w_1 + p_2^2 w_2)P} \\
&= \frac{(p_1^1 w_1 + p_1^2 w_2) P \log_{10}((p_1^1 w_1 + p_1^2 w_2)P) - \left[p_1^1 w_1 P \log(p_1^1 w_1 P) + p_1^2 w_2 P \log(p_1^2 w_2 P)\right]}{(p_1^1 w_1 + p_1^2 w_2)P} \\
&+ \frac{(p_2^1 w_1 + p_2^2 w_2) P \log_{10}((p_2^1 w_1 + p_2^2 w_2)P) - \left[p_2^1 w_1 P \log(p_2^1 w_1 P) + p_2^2 w_2 P \log(p_2^2 w_2 P)\right]}{(p_2^1 w_1 + p_2^2 w_2)P}
\end{aligned} \tag{15.4.148}$$

A first simplification by P gives:

$$\begin{aligned}
S_{\text{tot}} = S_1 + S_2 = &\frac{(p_1^1 w_1 + p_1^2 w_2) \log_{10}((p_1^1 w_1 + p_1^2 w_2)P) - \left[p_1^1 w_1 \log(p_1^1 w_1 P) + p_1^2 w_2 \log(p_1^2 w_2 P)\right]}{p_1^1 w_1 + p_1^2 w_2} \\
&+ \frac{(p_2^1 w_1 + p_2^2 w_2) \log_{10}((p_2^1 w_1 + p_2^2 w_2)P) - \left[p_2^1 w_1 \log(p_2^1 w_1 P) + p_2^2 w_2 \log(p_2^2 w_2 P)\right]}{p_2^1 w_1 + p_2^2 w_2}
\end{aligned} \tag{15.4.149}$$

We can work in percentage of the population P. So if we put $P = 100\% = 1$, we get:

$$\begin{aligned}
S_{\text{tot}} = S_1 + S_2 = &\frac{(p_1^1 w_1 + p_1^2 w_2) \log_{10}(p_1^1 w_1 + p_1^2 w_2) - \left[p_1^1 w_1 \log(p_1^1 w_1) + p_1^2 w_2 \log(p_1^2 w_2)\right]}{p_1^1 w_1 + p_1^2 w_2} \\
&+ \frac{(p_2^1 w_1 + p_2^2 w_2) \log_{10}(p_2^1 w_1 + p_2^2 w_2) - \left[p_2^1 w_1 \log(p_2^1 w_1) + p_2^2 w_2 \log(p_2^2 w_2)\right]}{p_2^1 w_1 + p_2^2 w_2}
\end{aligned} \tag{15.4.150}$$

So we have a function of three variables $S_{\text{tot}}(w_1, p_1^1, p_1^2)$ as for recall:

$$\begin{aligned}
w_2 &= 1 - w_1 \\
p_2^1 &= 1 - p_1^1 \\
p_2^2 &= 1 - p_1^2
\end{aligned} \tag{15.4.151}$$

If we fix one of them we have a function of two variable that we can easily plot and study. So let us fix w_1.

First case we fix $w_1 = 0.5$ and we use the following Maple™ 4.00b command lines:

```
>w_1:=0.5;w_2:=1-w_1;
>p_21:=1-p_11;p_22:=1-p_12;
```

```
>S_tot:=((p_11*w_1+p_12*w_2)*log10(p_11*w_1+p_12*w_2)-(p_11*w_1*log10(p_11*w_1)
+p_12*w_2*log10(p_12*w_2)))/(p_11*w_1+p_12*w_2)+((p_21*w_1+p_22*w_2)*
log10(p_21*w_1+p_22*w_2)-(p_21*w_1*log10(p_21*w_1)+p_22*w_2*log10(p_22*w_2)))/
(p_21*w_1+p_22*w_2);
>plot3d(S_tot,p_11=0.1..0.9,p_12=0.1..0.9,filled=true,axes=boxed);
```

That gives:

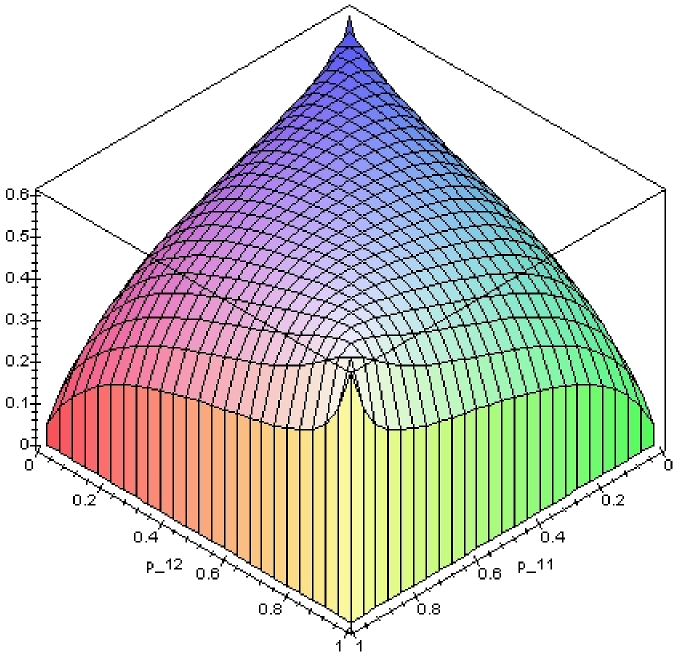

Figure 15.290: S_{tot} **Maple™ 4.00b with** $w_1 = 0.5$

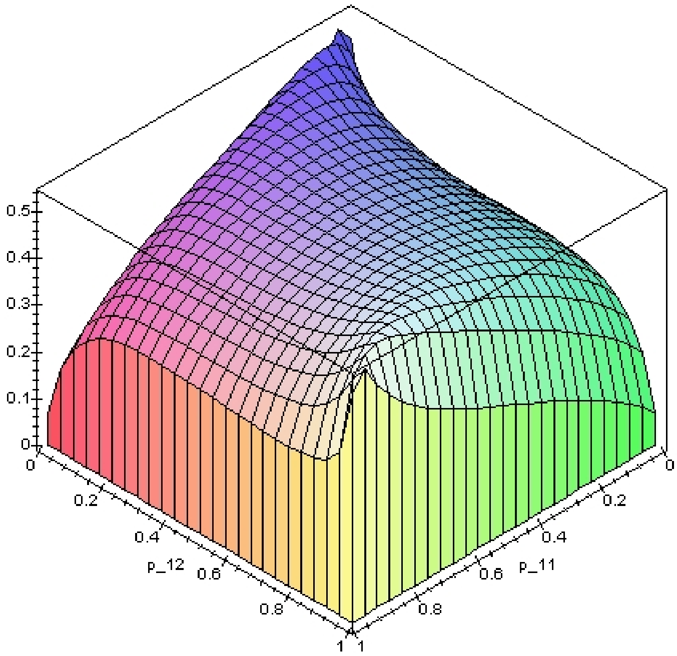

Figure 15.291: S_{tot} **Maple™ 4.00b with** $w_1 = 0.25$

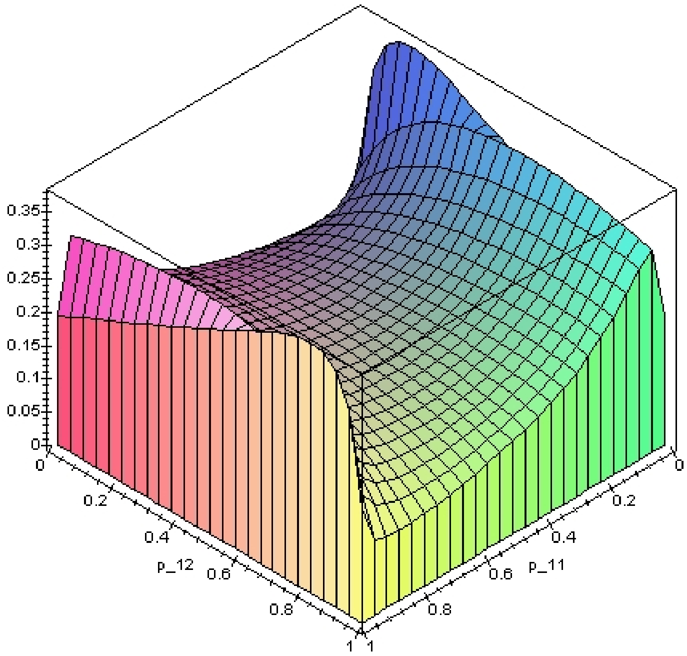

Figure 15.292: S_{tot} **Maple™ 4.00b with** $w_1 = 0.95$

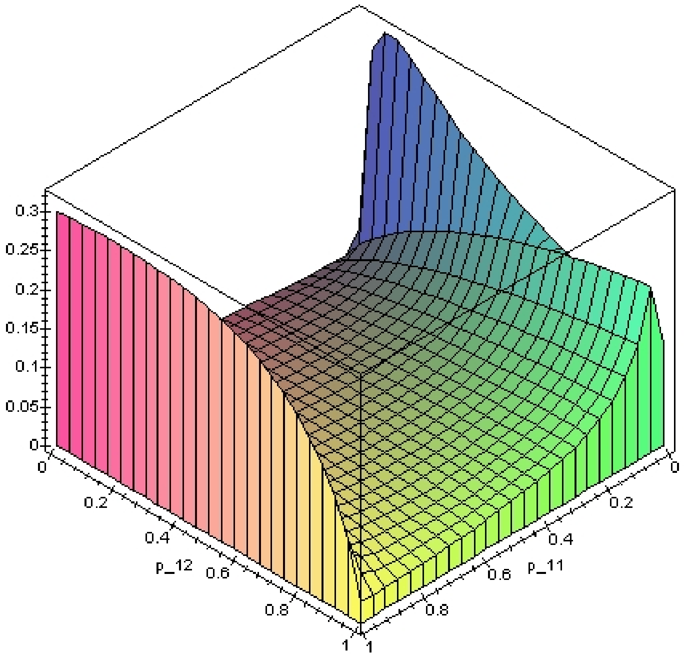

Figure 15.293: S_{tot} **Maple™ 4.00b with** $w_1 = 0.99$

With the above plots we can conclude that:

- If the both groups or individuals are almost in the same proportions, it is a better strategy to divide them in two groups as it minimize entropy. Divide and rule is better!
- If one of the group is in huge majority, it is better to put everybody together to minimize the entropy. Merge and rule is better!

15.4.3 Lean Management (Six Sigma Process)

As we saw it in the section Statistics (see page 692), the Normal distribution is a function whose shapes looks like a "bell" curve given by:

$$\boxed{P(k,\mu,\sigma)=\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{(k-\mu)^2}{2\sigma^2}}} \tag{15.4.152}$$

whose standard deviations are used to give the cumulative probability interval to lie within these limits centered on the average as shown below:

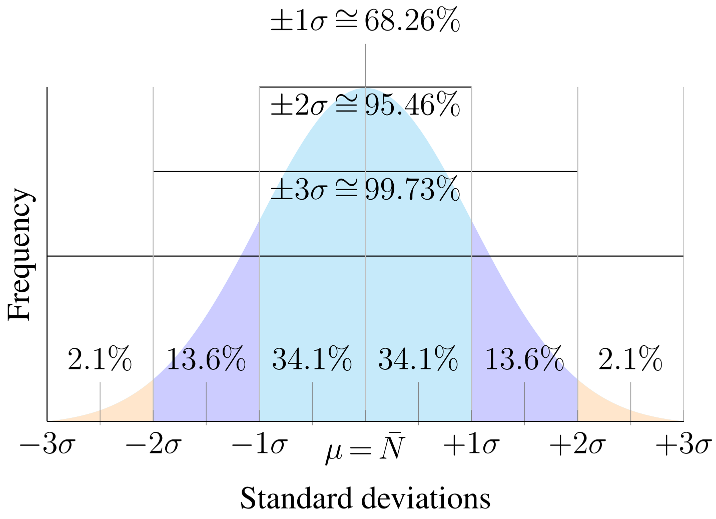

Figure 15.294: Sigma intervals for the Normal distribution

This being recalled, we also presented in the section of Industrial Engineering the joint probabilities as part of Six Sigma analysis tools for a serial process/workflow chain.

In fact the mentioned processes/workflow are not necessarily industrial processes but can be treated under identical assumptions to arbitrary processes (administrative, procedures, checklists, etc.).

We had seen that the joint probability of such a process/workflow is named in Six Sigma "rolled throughput yield" (R.T.Y.) and was given by (see section Probabilities page 480):

$$\boxed{\text{RTY}=P\left(\bigcap_i P_i\right)=\prod_i P_i} \tag{15.4.153}$$

For example, applying the above relation gives for a 4-step serial process ($i=4$) whose reliability is $P_i=90\%$ at each step (for more complex structures, remember that we sometimes talk about "weighted probability trees" or "topological systems"):

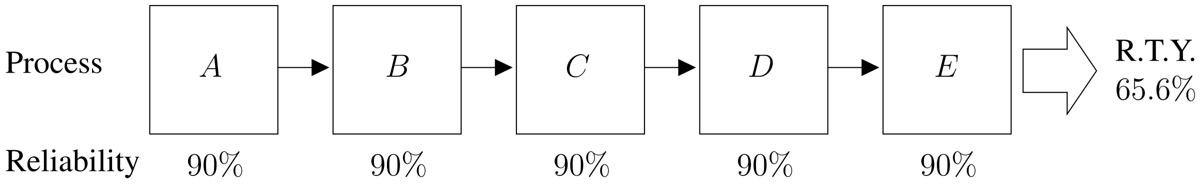

Figure 15.295: Serial/Process Workflow

We find ourselves in the final step with a 65.6% reliability that is to say a cumulative probability of default of 34.4% for the entire process (you can also imagine that these are sequential tasks in a project!).

Remark

The reader that is attentive will have noticed that the serial system is always less reliable than its least reliable component!!

Let us communicate again the Six Sigma table according to the worst situation of a not centered process with an average deviation of (thus to the right but we might take left and the results will be the same) relative to the target and with a unit standard-deviation and also with symmetrical USL and LSL (which restricts the scope):

C_p	C_{pk}	**Defectives (PPM)**	**Sigma Quality Level**	**Criteria**
0.5	0	501,350	1.5	Bad
0.6	0.1	382,572	1.8	
0.7	0.2	274,412	2.1	
0.8	0.3	184,108	2.4	
0.9	0.4	115,083	2.7	
1	0.5	66,810	3	
1.1	0.6	35,931	3.3	
1.2	0.7	17,865	3.6	
1.3	0.8	8,198	3.9	Limit
1.4	0.9	3,467	4.2	
1.5	1	1,350	4.5	
1.6	1.1	483	4.8	
1.7	1.2	159	5.1	
1.8	1.3	48	5.4	
1.9	1.4	13	5.7	
2	1.5	13.4	6	Excellent

Table 15.71: Defectives and Sigma quality level of a non-center process

where we proved in the section of Industrial Engineering (see page 8697) that the PPM values were given by:

$$\begin{aligned}\text{PPM}_{\text{tot}} &= \left(1-\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{\text{USL}} e^{-\frac{(x-\mu)^2}{2}}\mathrm{d}x\right)10^6+\left(\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{\text{LSL}} e^{-\frac{(x-\mu)^2}{2}}\mathrm{d}x\right)10^6\\ &= \left(1-\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{3C_p} e^{-\frac{(x-1.5\sigma)^2}{2}}\mathrm{d}x\right)10^6+\left(\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{-3(C_p+1)} e^{-\frac{(x-1.5\sigma)^2}{2}}\mathrm{d}x\right)10^6\\ &= \left(1-\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{3C_p} e^{-\frac{(x-1.5)^2}{2}}\mathrm{d}x\right)10^6+\left(\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{-3(C_p+1)} e^{-\frac{(x-1.5)^2}{2}}\mathrm{d}x\right)10^6\end{aligned} \tag{15.4.154}$$

Which gives for a level of quality of 3 sigma with Maple™ 4.00b:

```
>evalf((1-1/sqrt(2*Pi)*int(exp(-(x-1.5)^ 2/2),x=-infinity..(1*3))))
*1E6+evalf((1/sqrt(2*Pi)*int(exp(-(x-1.5)^ 2/2),x=-infinity..-(3*(1+1)))))*1E6;
```

This gives a value of $\sim 66,810$ that is to say the value of the 6th line in the above table. This corresponds to $\sim 6.68\%$ in terms of cumulative probability of non-quality ($66,810$ divided by 1 million and in percent) and thus respectively to a cumulative probability of 93.32% of quality.

We have the following table that can summarize some important values of the above table by using the Maple™ 4.00b command given above:

	$\pm 3\sigma$	$\pm 4\sigma$	$\pm 5\sigma$	$\pm 6\sigma$
Quality %	93.32	99.38	99.98	99.996
C_p	1	1.33	1.68	2
Judgement	Bad	Limit	Good	Excellent

Table 15.72: **Important values of the process control**

Under the assumption that each step in a process series follows the same law with the same moment and the same deviations from the target then we have for the R.T.Y.:

Step/Quality %	$\pm 3\sigma$	$\pm 4\sigma$	$\pm 5\sigma$	$\pm 5\sigma$
1	93.32	99.38	99.98	99.9996
7	61.63	95.73	99.84	99.9976
10	50.08	93.96	99.77	99.9966
20	25.08	88.29	99.54	99.9932
40	6.29	77.94	99.07	99.9864
60	1.58	68.81	98.61	99.9796
80	0.40	60.75	98.16	99.9728
100	0.10	53.64	97.70	99.966
...	...	...	...	...

Table 15.73: **Defectives and Sigma quality level of a non-center process**

where each line represents the throughput Rolled Yield (TRY) thus calculated:

$$\text{RTY} = P\left(\bigcap_i P_i\right) = \prod_i P_i \qquad (15.4.155)$$

where i is the number of process steps $(1,7,10,20,40)$ and where the probabilities are given by the first line of the before last table. Thus, with a quality level of $\pm 3\sigma$ and a deviation to the target of $\pm 1.5\sigma$ for a process of 20 steps identically distributed:

$$\text{RTY} = \prod_i P_i = \prod_{i=1}^{20} 93.32\% = 0.9332^{20} \cong 25.08\% \qquad (15.4.156)$$

This is lamentable! An industrial process in 20 steps of a complete product should have a minimum level of 4σ quality to be acceptable in terms of yield and quality.

Thus, the objective of Lean Six Sigma in a company is to increase the level of quality with maximum R.T.Y. for a given number of steps in a process.

Remark

In the case of parallel or mixed serial/parallel process, the reader is invited to read the section of Industrial Engineering at page 8743.

15.4.3.1 Pareto Analysis

The Pareto chart, as we shall see, is an easy technique (among others) to classify phenomena in order of importance. But the Pareto distribution is often used in business as a basis for stochastic simulation of random variables representing projects investment (about as often used as the triangular distribution, Beta distribution or log-normal distribution in modern industry).

Remember that a random variable is said by definition follow a Pareto distribution if its cumulative probability function is given by (see section Statistics page 746):

$$P(X \leq x) = 1 - \left(\frac{x_m}{x}\right)^k \qquad (15.4.157)$$

with $k \in \mathbb{R}_+$ and $x \geq x_m \geq 0$ (thus $x > 0$) and for the mean (average):

$$\mu = \frac{kx_m}{k-1} \qquad (15.4.158)$$

and for variance:

$$\sigma^2 = V(X) = \frac{kx_m^2}{k-2} - \left(\frac{kx_m}{k-1}\right)^2 = \frac{kx_m^2}{(k-1)^2(k-2)} \qquad (15.4.159)$$

To illustrate this type of representation (Pareto Diagram), we assume that a study to reorganize the LAMBDA company's sales network will lead the sales manager to be interested in the distribution of purchase of $55,074$ orders (bottom right value in the table below) received during a given year depending on the city where customers are domiciled (we used here the first 200 cities in the imaginary country this is why we have 200 rows in the table below).

To calculate the parameters of the Pareto distribution, the reader should refer to the section of Industrial Engineering (see page 8736) because in the present section we will have a qualitative approach as do managers, quantitative analysis being reserved mainly for engineers.

n_i	N_i	n_i	N_i	n_i	N_i	n_i	N_i	n_i	N_i

Table 15.74: **Dataset for Pareto Analysis**

where the 200 n_i values (number of orders from a city i) have been classified by decreasing values and cumulated in a column N_i.

The first city is characterized by $8,965$ purchase orders (which corresponds to 16.28% of the total orders), the second by $4,555$, so that the first two cities made $13,520$ purchase orders (that corresponds to 24.55% of the total orders), the first three cities, spent $16,589$ purchase orders (which corresponds to 30.12% of the total orders), etc. Another way to describe this phenomenon is to say: 0.5% of cities (ranked by decreasing value of the chosen criterion) made 16.28% of the total orders, 1% of cities have passed 24.55% of the total orders, etc.

These calculations are partly shown in the table below:

$i\%$	$N_i\%$	$i\%$	$N_i\%$	$i\%$	$N_i\%$	$i\%$	$N_i\%$	$i\%$	$N_i\%$
0.5	16.28	20.5	72.68	40.5	84.86	60.6	92.45	80.5	97.6
1	24.55	21	73.11	41	85.09	61	92.61	81	97.7
1.5	30.12	21.5	73.51	41.5	85.32	61.5	92.77	81.5	97.8
2	34.36	22	73.92	42	85.54	62	92.92	82	97.89
...	...	...	...	...	...	...	...	...	...
19	71.33	39	84.18	59	91.97	79	97.3	99	99.7
19.5	71.79	39.5	84.41	59.5	92.13	79.5	97.4	99.5	99.99
20	72.24	40	84.64	60	92.29	80	97.5	100	100

Table 15.75: **Aggregated and normalized data for Pareto analysis**

translated graphically (according to the traditions of use) below as a Pareto chart with any modern spreadsheet software:

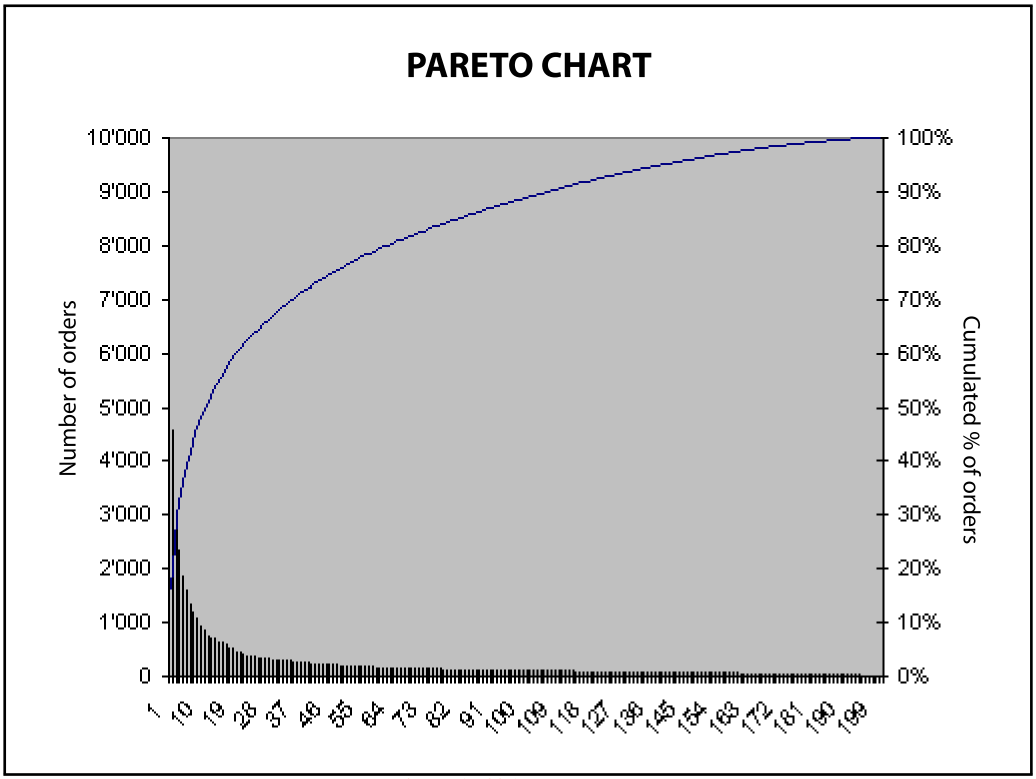

Figure 15.296: **Pareto chart**

or in a more relevant way using a "Lorenz diagram" also named sometimes "gain chart" (the horizontal axes with the numbers of cities is replaced by the cumulative% of towns as in the data table above):

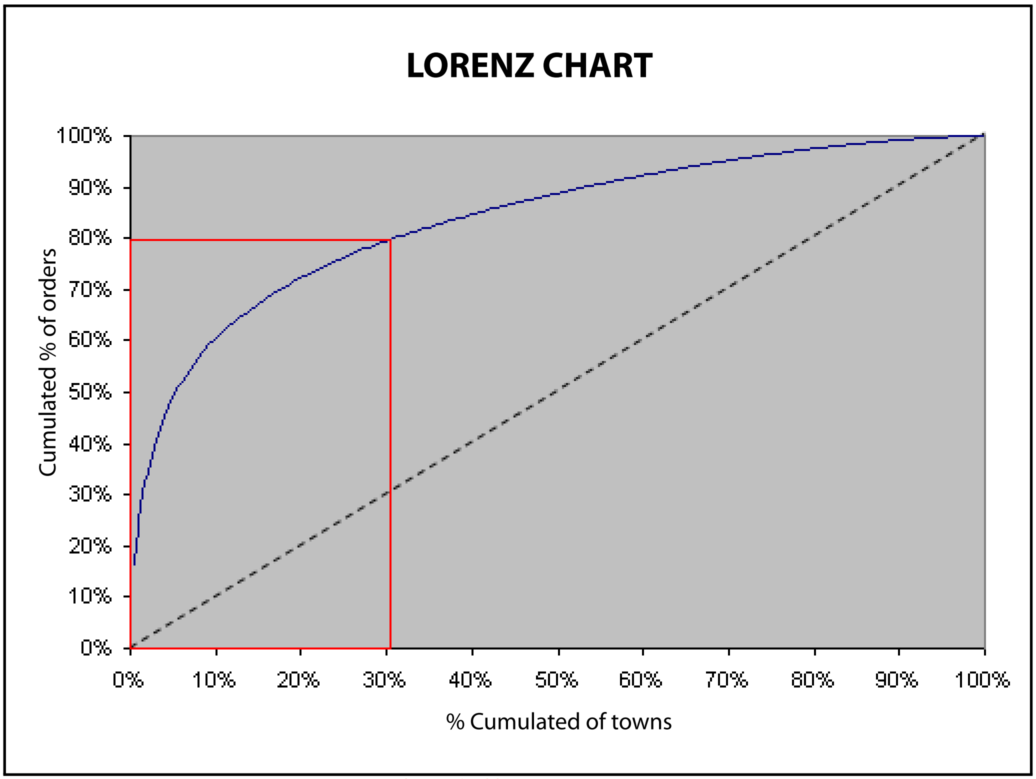

Figure 15.297: Lorenz chart

This analysis shows that a small number of elements is the root of most of the studied phenomenon (e.g. here 31% of cities generate 80% of purchase orders). This explains why it is one of the major techniques used in the field of "Total Quality Management" and in the analysis of the importance of the roots of a quality problem. It is also used by managers to structure the organization, especially to differentiate processes based on characteristic of demand (differentiated customer tracking according to its importance, for example) and when it is used to define 3 classes, this technique often takes the name "ABC method".

The dotted line in the Lorenz graph represents what we would have observed if the case of equal distribution of the studied phenomenon, that is to say if each city was characterized by the same number of purchase orders.

In general, the more a Lorenz curve is close to the perfect equality of the straight line and more the distribution of mass seen in the population is equal. Indeed, in this case, the majority (wages, wealth, income, etc.) is not concentrated only on a few items.

Remark

The presentation of this analysis was conducted by classifying the observations by decreasing values, but we could just as well from a ranking by increasing values and, in the latter case, the resulting curve would have been symmetric, the center of symmetry being the coordinate point $(0.5, 0.5)$.

In an industrial environment, potential improvement points are obviously almost innumerable. It could even improve indefinitely, everything and anything. It should however not be forgotten that the improvement also costs and in return should provide added value, or at least offset losses!

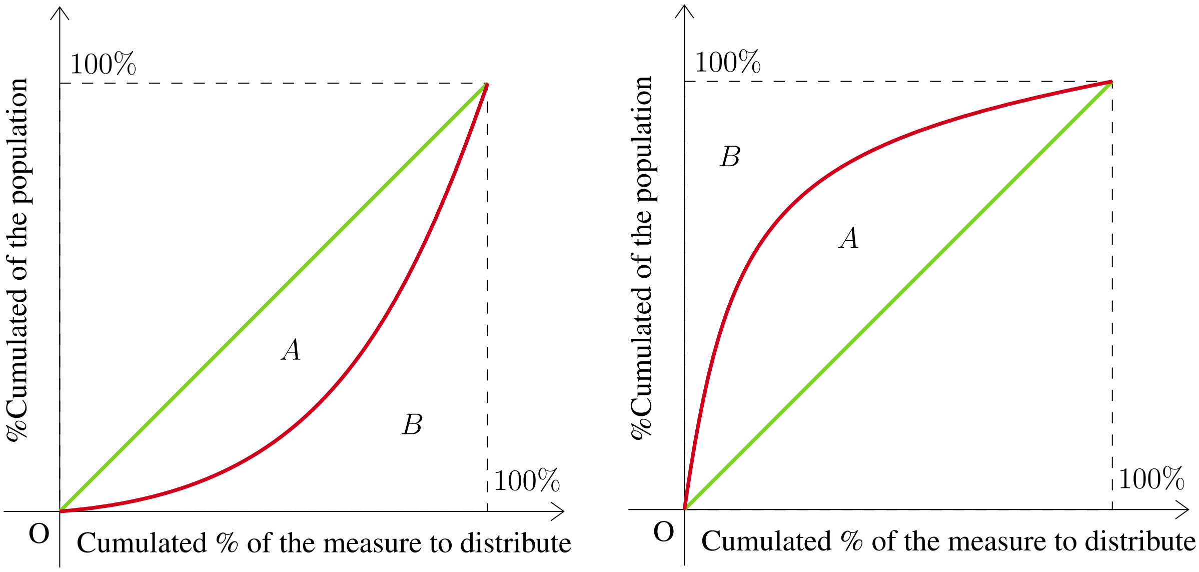
15.4.3.1.1 Gini Index

The studied phenomenon is even less equally distributed as the curve moves away from the straight line of equal distribution. Economists, managers or corporate departments responsible sometimes use (for their performance dashboard) a synthetic indicator to measure this phenomenon and its evolution: the "Gini index" (also named "Gini coefficient").

This coefficient is defined by the ratio:

$$G=\frac{A}{A+B} \tag{15.4.160}$$

where the surfaces A and B relate to the following figures:



100%
%Cumulated of the population
A
B
100%
O
Cumulated % of the measure to distribute
100%
%Cumulated of the population
B
A
100%
O
Cumulated % of the measure to distribute

Figure 15.298: **The two most common situations of the Gini index**

The Gini coefficient is thus a real number between 0 and 1. In case of perfect equality, it is equal to zero (since $A=0$). In case of total inequality is equal to 1, since $B=0$. Therefore, as G increases from 0 to 1, inequality of the distribution increases.

Knowing that the Lorenz curve 1×1 is seen that the area $A+B$ is equal to half of this surface. So we have:

$$A+B=\frac{1}{2} \tag{15.4.161}$$

We can thereby write:

$$G=\frac{A}{A+B}=\frac{A}{\frac{1}{2}}=2A \tag{15.4.162}$$

Also as:

$$A+B=\frac{1}{2}\Leftrightarrow A=\frac{1}{2}-B \tag{15.4.163}$$

Finally, we can write that:

$$G=\frac{A}{A+B}=2A=1-2B \tag{15.4.164}$$

Using the trapezoidal numerical integration (see section Numerical Methods page 6624) we get that the area B which is given by:

$$\begin{aligned}G&=1-2\left(\frac{A_G+A_D}{2}\right)=1-(A_G+A_D)=1-h\left(\sum_{i=0}^{n-1}f\left(x_{i+1}\right)+\sum_{i=0}^{n-1}f\left(x_i\right)\right)\\&=1-h\sum_{i=0}^{n-1}\left(f\left(x_{i+1}\right)+f\left(x_i\right)\right)=1-h\sum_{i=0}^{n-1}\left(y_{i+1}+y_i\right)\end{aligned} \tag{15.4.165}$$

where as reminder h is the length of the intervals all assumed equals (which is always the case in the context of Lorenz analysis). This relation is correct if and only if the data table configuration is such that we get the following type of chart (which is rare...):

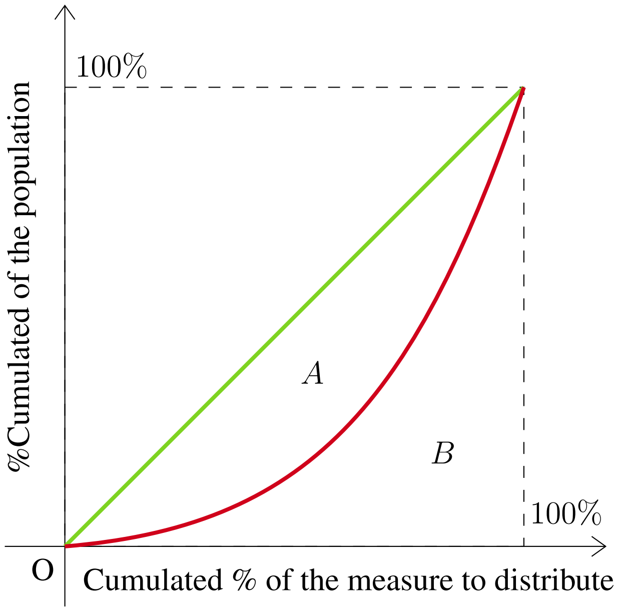


Figure 15.299: **Gini Index first case calculation**

Traditionally we find the last relation in the form:

$$G=1-\frac{1}{n}\sum_{i=1}^{n}\left(y_{i+1}+y_i\right) \tag{15.4.166}$$

where n is the number of statistical units (the size of the population).

In the situation where the chart looks as (this case is significantly more common in the business and this also corresponds to our data table above!!):

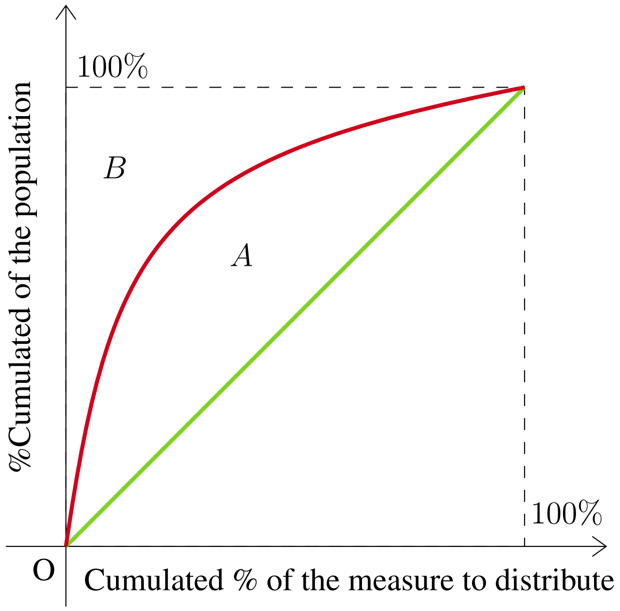

Figure 15.300: **Gini Index second case calculation**

The trapezoidal numerical integration method brings us then to write:

$$\begin{aligned} G &= 1-2\left(1\cdot\frac{-A_G+A_D}{2}\right)=1-2+(A_G+A_D)\\ &=-1+h\left(\sum_{i=0}^{n-1}f(x_{i+1})+\sum_{i=0}^{n-1}f(x_i)\right)=-1+h\sum_{i=0}^{n-1}\left(f(x_{i+1})+f(x_i)\right)\\ &=-1+h\sum_{i=0}^{n-1}(y_{i+1}+y_i) \end{aligned} \tag{15.4.167}$$

Traditionally we find this last relation in the form:

$$G=-1+\frac{1}{n}\sum_{i=1}^{n}(y_{i+1}+y_i) \tag{15.4.168}$$

In the case that serves us as an example from the beginning with the table:

$i\%$	$N_i\%$	$i\%$	$N_i\%$	$i\%$	$N_i\%$	$i\%$	$N_i\%$	$i\%$	$N_i\%$
0.5	16.28	20.5	72.68	40.5	84.86	60.6	92.45	80.5	97.6
1	24.55	21	73.11	41	85.09	61	92.61	81	97.7
1.5	30.12	21.5	73.51	41.5	85.32	61.5	92.77	81.5	97.8
2	34.36	22	73.92	42	85.54	62	92.92	82	97.89
...	...	...	...	...	...	...	...	...	...
19	71.33	39	84.18	59	91.97	79	97.3	99	99.7
19.5	71.79	39.5	84.41	59.5	92.13	79.5	97.4	99.5	99.99
20	72.24	40	84.64	60	92.29	80	97.5	100	100

and adopting the notations accordingly, this gives:

$$G = -1 + \frac{1}{n}\sum_{i=1}^{n}(y_{i+1} + y_i) = -1 + \frac{1}{200}\sum_{i=1}^{200}(N_{i+1}\% + N_i\%) = -1 + \frac{335.10}{200} \cong 0.675 \tag{15.4.169}$$

15.4.3.2 Weighted Ishikawa Diagram

The traditional "Ishikawa diagram", or "fishbone diagram", is a qualitative tool of management. Using this tool one can show the relations between causes and the analysed effect. The most often used is the Ishikawa diagram in a form named the "6M+E model". The symbol 6M+E describes next general causes: man, machine, material, method, management, measurement and environment.

This diagram is presented in the figure below:

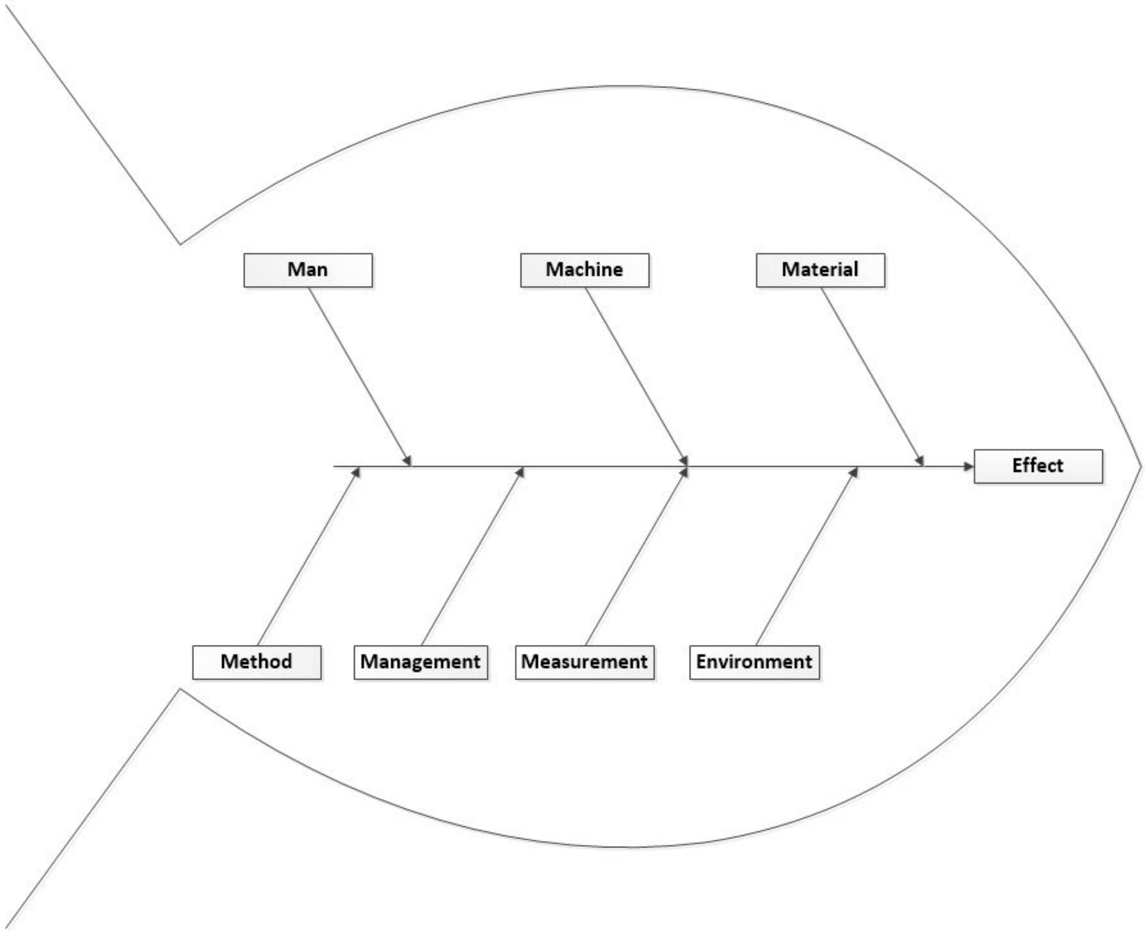

Figure 15.301: **6M+E Ishikawa diagram**

But the model of the classical Ishikawa diagram is not complete. There is no quantitative information to obtain from this diagram and as we know in management: *can be improved only what can be quantified*! We own in 12005 (holocene calendar) to Aleksander Gwiazad a first approach to quantify this diagram! This approach is in my point of view an "a priori" analysis as in don't make usage of the frequency of events. But obviously it is quite easy to improve this model by including a frequency data or also with Bayesian point of view or even with Monte Carlo simulations.

Below is presented the method of preparing the weighted Ishikawa diagram:

1. Determination of a set of main causes
2. Determination of subcauses
3. Determination of weights of main causes
4. Preparing the weighted Ishikawa diagram
5. Conducting the stratification analysis
6. Determination the set of important causes and subcauses

To determine the weights of connections (causes) it is proposed to use a form of the Saaty matrix (from the name of the creator of the AHP decision tool that we have studied in the section of Game and Decision Theory at page 7462). As we know this matrix is a non-symmetric influence matrix which influential elements are in the rows, this is why the summations are done for each row and not for each column:

Input **Input**	**Man**	**Machine**	**Material**	**Method**	**Management**	**Measurement**	**Environment**	**Sum**	**Normalised Sum**
Man	X	0.5	1	0.5	1	1	0.5	4.5	0.214
Machine	0.5	X	1	0.5	0.5	1	0	3.5	0.167
Material	0	0	X	0	0.5	0.5	0	1	0.048
Method	0.5	0.5	1	*X*	0.5	1	0.5	4	0.19
Management	0	0.5	0.5	0.5	X	1	0	2.5	0.119
Measurement	0	0	0.5	0	0	X	0	0.5	0.024
Environment	0.5	1	1	0.5	1	1	X	5	0.238

Table 15.76: **Ishikawa Satty matrix**

Using this matrix one can compare in pairs every cause on the same level of analysis. The scale of notes is as presented: $0, 0.25, 0.5, 0.75, 1$. Where 0 means that analysed cause is of no importance. The note 0.25 is for causes of small importance. If the importance of causes is equal one gives them the note 0.5. The notes 0.75 and 1 are for cause that are more important and very important. Next, in the column $\sum$ there is calculated the sum of all component notes. This sum is the weight of each cause. In the next column the normalized weight is computed. The normalized weights are inscribed to the Ishikawa diagram.

In the same manner the weights of subcauses, for each main cause separately, are determined. Next are computed the absolute weights by comparing the weights of subcauses with the weight of the main cause.

For example consider that for Man branch we have three causes Subcause1, Subcause2, Subcause3 with respective weights $\{0.17, 0.33, 0.5\}$ that obviously sum up to 1.

After each influence is given by:

$$\begin{aligned} 0.17 \cdot 0.214 &= 0.036 \\ 0.33 \cdot 0.214 &= 0.071 \\ 0.50 \cdot 0.214 &= 0.107 \end{aligned} \tag{15.4.170}$$

A complete example is given in the figure below:

Figure 15.302: **Weighted Ishikawa diagram (source: Aleksander Gwiazad/Industrial Management and Organisation)**

The next step is the stratification analysis. This analysis is based on the Pareto rule. The first step in this analysis is to prepare a table of weights of all subcauses:

N°	Subcause	Weight	Cumulated Weight
1	environment 1	0.159	0.159
2	machine 1	0.112	0.271
3	man 3	0.107	0.378
4	method 1	0.095	0.473
5	method 2	0.095	0.0.568
6	environment 2	0.079	0.647
7	man 2	0.071	0.718
8	machine 2	0.055	0.773
9	management 1	0.050	0.823
10	man 1	0.036	0.859
11	management 2	0.030	0.889
12	management 3	0.030	0.919
13	material 1	0.018	0.937
14	material 3	0.018	0.955
15	material 2	0.012	0.967
16	measurement 1	0.012	0.979
17	management 4	0.009	0.988
18	measurement 2	0.008	0.996
19	measurement 3	0.002	0.998

In the presented case the first eight subcauses constitute the group of important causes.

15.4.4 Supply Chain Management

The challenge of inventory management and supply chain is something critical for all big companies worldwide. The goal is to implement processes that optimize the economic function under the constrained of in theory a flawless availability. These are the objectives of the stocks manager. This entails having a visibility on the inventory and appropriate methodologies to different situations.

A production without stock is almost inconceivable (even if it is the final goal!) given the many functions performed by stocks. Indeed, stockpiling is required if:

1. There is non-coincidence in time or space of production and consumption: the stock is essential in this case because it is hard or costly to produce where and when the demand arises (this is typically the purpose of the Lean Six Sigma). Classic examples are the manufacture of toys or confectionery for non-coincidence in time, and supermarkets for the non-coincidence in space.
2. There is uncertainty about the level of demand or on the price: if there is uncertainty about the quantity requested, we will provide a safety stock allowing to face to a peak demand (taking care to avoid the "bullwhip effect" that is to say a to big difference between demand and supply). If there is uncertainty about the price, we will build a speculative stock. For example, oil companies buy much needed crude oil when its price is relatively low on the market.
3. There are risk of issues in chain: this is to avoid that a failure on a machine affects the whole supply chain. A delay in performance on the previous post (manufacturing step) or a transport strike will not immediately stop the entire production process if there are stocks buffers.
4. There is presence of launch costs: in this case, working in batches allows an economy of scale on the cost of production launch but, in contrast, causes an increase in cost of ownership of the stock.

The control of stocks and supply chain of a company is as fundamental in the life of it. To reduce (or optimize it depends...) the various costs that surround everything that has to do with storage, we must use our knowledge in mathematical statistics and differential and integral calculus as we shall see later.

Remarks

R1. The application of the tools we will see now does not really apply to SMEs with fewer than 50 employees producing small pieces irregularly but rather to multinationals producing in enormous quantities of small objects or small quantities of significant size objects and this regularly. In the facts almost nobody use the models we will see below because the assumptions are very difficulty to satisfy but it is still a very good study to be able to build more complicated heuristic models.

R2. In facts we use a combination of Monte Carlo simulations and Data Mining (Machine Learning) techniques to improve supply chain management in a very efficient ways (application of Data Mining to spare millions of dollars per year are numerous in the specialized literature).

First, we will establish how to determine the required initial stock for a company based on statistical data using very simple naive models afterwhat we will do the same with replenishment models whose the approach is somewhat different and allows like for the first one to achieve satisfactory results for large scale stable markets.

The models we will build will therefore give the opportunity under the constraints of stable market (stable in time or "quasi-static" as will say thermodynamics specialists...) to:

1. To regulate the flow of supplies
2. Allow batch production (reduced production costs)
3. To meet seasonal demands

As we can guess, additional stocks can generate "interest costs" (fixed capital), "obsolescence costs" (between the products become obsolete time), "storage costs", "insurance costs" (protection against accidents that can provide on the products) and many others...

We distinguish in the field of supply chain at least three types of stocks:

1. The "safety stock" that responds to the most common issues associated with the consumption and delivery.
2. The "alert stock" or "critical stock" is the stock level for which an order is triggered at risk to be out of stock.
3. The "minimum stock", also named "buffer stock" or "order point" or "reorder point" is by definition the sum of the safety stock and minimum stock.

We often consider at least three stocks management strategies:

1. The "supply chain management by control point": the supply of the stock is raised when it is observed that the stock falls below the reorder point.
2. The "supply chain calendar management": the supply of the stock is triggered at regular intervals T, for example, daily or weekly.
3. The "supply chain conditional calendar management": the supply of the stock is triggered at regular intervals T, but only when it is observed that the stock falls below the control point.

A stock is formed to meet future demand. In case of random demand, there may be no coincidence between the application and the stock. Two cases are of course possible:

1. A demand higher than the available stock: we speak then of "out of stock" or "inventory shortages".
2. A demand lower than the stock: we speak then of "residual stock".

The criteria commonly adopted in inventory management is that of cost minimization (...). We denote this function by the letter C followed in brackets (or as index) of the system control variables.

15.4.4.1 Supply Chain Management in uncertain future

Let's begin our study with the simplest case which requires that consumption is statistically steady in time and under statistical control. It follows (see sections Statistics page 938 and Industrial Engineering page 8692) that the instantaneous consumption then follows a Normal law $\mathcal{N}(\mu,\sigma)$ or more technically: a Gaussian stochastic process where for reminder each day is independent of the previous one (see section Economy page 7899).

Let us take a concrete example, since the theory has already been studied extensively in the section of Statistics and Economy.

Remark

The case where we want to forecast sales using different mathematical assumptions is presented in the section of Economy when we study Time Series Analysis (Forecasting Techniques) at page 7896.

✍**Example:**

Consider an article whose instantaneous demand X follows approximately a Normal law of parameters:

$$\mathcal{N}(\mu,\sigma)=\mathcal{N}(90,20) \tag{15.4.171}$$

Suppose that stock available at the time of restock order is 500 units and that the restock delay is 5 days. We would like to know the cumulative probability of being above or equal to the out of stock 5 days after the last restock and the cumulative probability of being below the assumed consumption?

By using the property of stability of the Normal distribution (see section Statistics page 710) the statistical cumulative consumption after 5 days give us:

$$\begin{aligned}\mu_{5d}&=5\cdot 90=450\\ \sigma_{5d}&=\sqrt{20^2+20^2+20^2+20^2+20^2}=20\sqrt{5}\cong 44.72\end{aligned} \tag{15.4.172}$$

Therefore we have after 5 days the consumption that follows a Normal law of characteristics:

$$\mathcal{N}(\mu_{5d},\sigma_{5d})=\mathcal{N}(\mu_{450},44.72) \tag{15.4.173}$$

Using a spreadsheet software like Microsoft® Excel® 11.8346 we get the cumulative probability $P(X \geq 500)$ to be out of stock at the fifth day:

`=1-NORM.DIST(500,450,44.72,1)=13.17%`

And we can also easily calculate the cumulative probability of being below the assumed consumption each day:

`=1-NORM.DIST(500/5,90,20,1)=30.85%`

Obviously, in practice the reality is far less simple and more..., the Normal law has in fact a probability of negative sales, which is unrealistic... But it is a first model that can be confronted with the reality to see its predictive power and afterwards adapted with more complicated distributions.

Imagine now that the only variability we need to protect against is demand variability, and good historical data are available. The safety stock needed to give a certain level of protection simply is the standard deviation of demand variability multiplied by the Z-score. For example, to satisfy demand with a 95% confidence level, according to statistical analysis, it's necessary to carry extra inventory equal to 1.65 standard deviations of demand variability. This is equivalent to a Z-score of 1.65.

The table below shows the relationship of desired cycle service levels to Z-score:

Desired cycle service level	**Z-score**
84	1
85	1.04
90	1.28
95	1.65
97	1.88
98	2.05
99	2.33
99.9	3.09

Table 15.77: **Cycle service level**

We have seen just earlier that the standard deviation of demand σ_D is the weekly standard deviation times the square root of the ratio of the time units. This is:

$$\text{Safety Stock} = Z_{\alpha/2}\sigma_D\sqrt{\frac{\text{PC}}{T_i}} \tag{15.4.174}$$

where PC is the performance cycle (another term for "total lead time") and T_i is the time increment used for calculating standard deviation of demand.

The performance cycle includes the time needed to perform functions such as deciding what to order or produce, communicating orders to the supplier, manufacturing and processing, and delivery and storage, as well as any additional time required to return to the start of the next cycle.

Caution!!! Safety stock determinations are not intended to eliminate all stockouts - just the majority of them! It's a statistical tool, not a deterministic one!

✍**Example:**

Let us consider an average daily demand (normally distributed) of 15 units, a lead time (LT) in days (constant) of 2 days and a standard deviation of daily demand equal to 5 units and we want a service level of 90%.

Then the Reorder Point (ROP) and Safety stock (SS) is given by:

$$\text{ROP} = \mu_D \cdot \text{LT} + \text{SS} = \mu_D \cdot \text{LT} + Z_{\alpha/2}\sigma_D\sqrt{\frac{\text{PC}}{T_i}} = 15 \cdot 2 + 1.28 \cdot 5 \cdot \sqrt{2} \tag{15.4.175}$$

So the safety stock is about 9 units.

15.4.4.1.1 Safety Stock formula

Now let us prove the famous "safety stock formula" or also named "King's safety formula":

$$\boxed{\text{SS} = Z_{\alpha/2}\sqrt{\mu_L\sigma_D^2 + \mu_D^2\sigma_L^2}} \tag{15.4.176}$$

where μ_L, σ_L are the mean and standard deviations of the time between deliveries and μ_D, σ_D are the mean and standard deviation rates for the demand.

Obviously therefore $\sqrt{\mu_L\sigma_D^2 + \mu_D^2\sigma_L^2}$ is the standard deviation of the item quantity consumed between deliveries, considering that the time between deliveries varies.

As we already know μ_D and σ_D^2 are the mean and variance of the demand per unit time, so that the demand for a period of length T has a mean of $\mu_D T$, a variance of $\sigma_D^2 T$, and therefore a standard deviation of $\sigma_D\sqrt{T}$.

Note that the assumptions are only that these means and variances exist. At this stage, we don't have to assume more, and particularly not that times between deliveries and demand follow a particular distribution. If $D(T)$ is the demand during an interval of duration T, since:

$$\begin{aligned}\text{E}(T) &= \mu_D T\\ \text{V}(D(T)) &= \sigma_D^2 T\end{aligned} \tag{15.4.177}$$

we have using the Huygens relation proved in the section Statistics (see page 593):

$$\text{E}(D(T)^2) = \text{V}(D(T)) + (\text{E}[D(T)])^2 = \sigma_D^2 T + \mu_D^2 T^2 \tag{15.4.178}$$

If we now allow T to vary, around mean μ_L with, standard deviation σ_L, we have:

$$\text{E}(D(T)) = \mu_D \text{E}(T) = \mu_D\mu_L \tag{15.4.179}$$

and therefore:

$$\mathrm{E}(D(T)^2) = \mathrm{E}\left(\mathrm{E}(D(T)^2)\right) = \mathrm{E}\left(\sigma_D^2 T + \mu_D^2 T^2\right) = \sigma_D^2 \mathrm{E}(T) + \mu_D^2 \mathrm{E}(T^2) \quad (15.4.180)$$

Hence:

$$\mathrm{E}(D(T)^2) = \sigma_D^2 \mu_L + \mu_D^2 \left(\sigma_L^2 + \mu_L^2\right) \quad (15.4.181)$$

And the last equality follows because using Huygens relation again:

$$\mathrm{V}(T) = \mathrm{E}(T^2) - (\mathrm{E}(T))^2 \quad (15.4.182)$$

which gives us:

$$\mathrm{E}(T^2) = \sigma_L^2 + \mu_L^2 \quad (15.4.183)$$

Finally:

$$\mathrm{V}(D(T)) = \mathrm{E}(D(T)^2) - (\mathrm{E}(D(T)))^2 = \sigma_D^2 \mu_L + \mu_D^2 (\sigma_L^2 + \mu_L^2) - (\mu_D \mu_L)^2 = \mu_L \sigma_D^2 + \mu_D^2 \sigma_L^2 \quad (15.4.184)$$

And one standard deviation of $D(T)$ is:

$$\sigma_{D(T)} = \sqrt{\mathrm{V}(D(T))} = \sqrt{\mu_L \sigma_D^2 + \mu_D^2 \sigma_L^2} \quad (15.4.185)$$

This finish our proof!

These result demonstrate that we can identify what variability is the dominant influence on safety stock requirements. With the recognition of what factors dominate an equation, it becomes easier to focus improvement efforts. In the case where a reduction in safety stock is desired, we can then know if it's more productive to reduce demand variability or lead time variability. Conversely, if a high level of customer service is not required, safety stock can be lowered to a more appropriate level.

Note that all of the above arguments only require the means and standard deviations to exist and that the variance in a period of time implies it is additive (i.e. if two times periods are uncorrelated). There is no assumption at this point that the demand or the lead time follow a Normal distribution. However, the calculation of the multiplier $Z_{\alpha/2}$ used to set an upper bound for the demand in a period, is based on the assumption that the demand between deliveries is Normally distributed.

15.4.4.2 Optimal initial stock management with zero rotation

Imagine a scenario to develop another statistical model but a little more elaborated than the previous one (strongly inspired by the book *Gestion de la Production* [202] of Vincent Giard). We will limit ourselves however here to a discrete statistical law and we will do later again an another example with a continuous law.

Consider for this purpose that the company MAC is the specialist of a given product whose direct manufacturing cost per unit is 25.- and the sales price is 60.- selling per unit (assumed constant prices and thus independent of the quantity and without discount).

The daily sales of this product is daily from 2.5 units on average and an analysis during three months suggests that it follows a discrete distribution like the Poisson law (this time the domain of definition is at least positive in contrast to the previous example...), that is to say that we have a probability distribution of the number X of these products sold during a day. We will truncate to $x=10$ the realization of this random variable as the likelihood of sales above 10 units will be assumed to be zero.

Tabulating this Poisson law for X from 0 to 10 we get:

X	$P(X)$	**Cumulated Probability**
0	0.0821	0.0821
1	0.2052	0.2873
2	0.2565	0.5438
3	0.2138	0.7576
4	0.1336	0.8912
5	0.0668	0.958
6	0.0278	0.9858
7	0.0099	0.9957
8	0.0031	0.9988
9	0.0009	0.9997
10	0.0003	1

Table 15.78: **Cumulated probability of sales**

We then have the above table that shows us that the most commonly sold quantity to an economic agent is approximately 2 (modal value) and calculation of the expected mean gives us for this table:

$$\bar{x}=\mathrm{E}(X)=\frac{1}{n}\sum_i p_i x_i=2.5 \qquad (15.4.186)$$

result which can also be interpreted as the average daily sales than the average level of stock shortages.

We will assume that the stock is lean. In other words, from one day to the next, no unit is reported for sales of the day after because it is not supposed to have anymore available (what we name "inventory management by zero rotation"). The question therefore is to know, given the table above, how many products we have to manufacture (or to order) every day to maximize profit and minimize losses[59].

From the perspective that we want a minimization of cost of ownership C_p (often named "unit cost of ownership" or "unit cost of possession") and that we know the associated cost for unsold is 25.- per unit, while the cost of shortage (often named "unit cost of shortage") is equal to the loss of profit following the failed sales, that is to say the selling price 60.- subtracted by the 25.- of manufacturing cost, gives a shortage cost of 35.- per unit!

Remark

The cost of shortage is not treated only as the loss caused by a failed sales in practice but also include the cost of a temporary replacement solution proposed by the seller to the customer on hold to provide the right product. Internally in companies, the cost of shortage often leads to layoffs of downstream positions when a piece necessary for the manufacturing is no longer available to the production line.

A rational management must consist to calculate the initial stock S (i.e. the number of products to order or to manufactured for the next day) that minimizes the indicator of "management cost" $C(S)$ defined as the sum of the cost of possession associated with average unsold stock $I_P(S)$ (often named "average stock owned" or "average stock possessed") and the shortage cost associated with average stock sales missed $I_R(S)$ (often name the "average stock of unsold"):

$$\boxed{C(S)=C_pI_p(S)+C_RI_R(S)} \tag{15.4.187}$$

This last relation is, however, a simplification of the relation:

$$C(S)=C_pI_p(S)+C_RI_R(S)+C_CI_C(S) \tag{15.4.188}$$

where the last term is the order cost.

Minimizing the cost function $C(S)$ consist in the mathematical point of view to look for an extreme (minimum) of the management cost function such that for the optimal value of the initial procurement S^* the cost $C(S^*)$ is immediately below $C(S^*\mp 1)$ that is to say less by the right and by the left. In other words:

$$\begin{gathered}C(S^*)<C(S^*+1)\\C(S^*)<C(S^*-1)\end{gathered} \tag{15.4.189}$$

That is to say the function is convex. Or after rearrangement:

$$\begin{gathered}C(S^*)-C(S^*+1)<0\\C(S^*)-C(S^*-1)<0\end{gathered} \tag{15.4.190}$$

inequalities that the diagram below may help to better understand:

---

[59] In many corporations there exist a report commonly used by analysts and produced by the "product control" department that attributes or explains the daily fluctuation of a tracked variable to the root causes of the changes and named "PnL report" used a lot in manufacturing, supply chain and portfolio management.

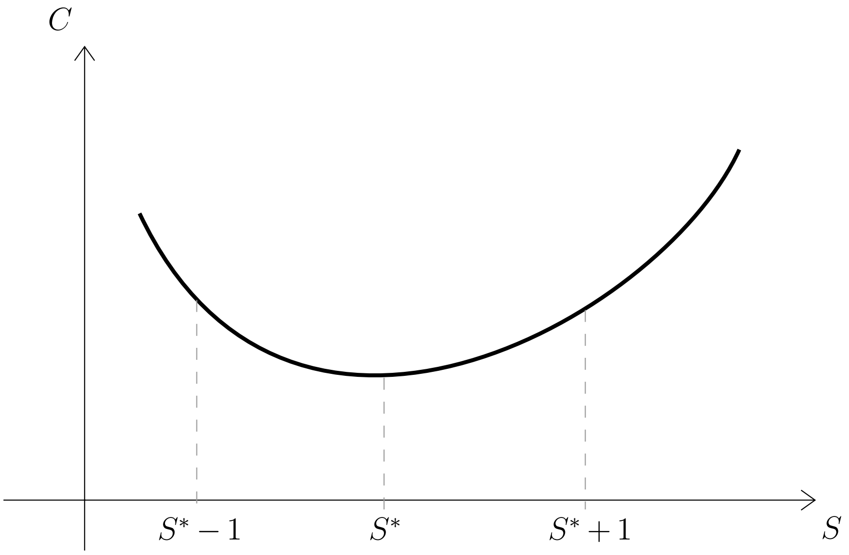

Figure 15.303: **Arbitrary example of the extremum of the function** $C(S)$

From now the question is how to determine S^*. In fact the idea is subtle but simple as it is clearly and thoughtfully exposed.

Let us take the probability distribution of the daily demand law and suppose we want to calculate the average shortage (i.e. expected mean) for a given level of initial stock S for example:

$$I_R(S=4)=\mathrm{E}(x-4) \tag{15.4.191}$$

Or:

$$I_R(S=5)=\mathrm{E}(x-5) \tag{15.4.192}$$

associated with the respective initial stocks with respect to the given distribution (obviously x should be taken to be greater than S). Either in full generality:

$$\boxed{I_R(S)=\sum_{x=S+1}^{n}(x-S)P(x)} \tag{15.4.193}$$

Obviously, if the probability distribution is continuous (or at least approximated as such), the latter relation will be written:

$$I_R(S)=\int\limits_{S+1}^{+\infty}(x-S)f(x)\mathrm{d}x \tag{15.4.194}$$

The idea is then to write the probability density distribution over the missing quantity of stock and not the sold one:

x	$P(x)$	$x-4$	$(x-4)P(x)$	$x-5$	$(x-5)P(x)$
0	0.0821	-	-	-	-
1	0.2052	-	-	-	-
2	0.2565	-	-	-	-
3	0.2138	-	-	-	-
4	0.1336	-	-	-	-
5	0.0668	1	0.0668	-	-
6	0.0278	2	0.0556	1	0.0278
7	0.0099	3	0.0297	2	0.0198
8	0.0031	4	0.0124	3	0.0198
9	0.0009	5	0.0045	4	0.0036
10	0.0009	6	0.0045	5	0.0015
$\sum$	1	-	$I_R(4)=0.1708$	-	$I_R(5)=0.062$

Table 15.79: Probability density distribution with respect to the missing quantity

It appears from the table above that changing the initial stock S from 4 to 5 units decreases the average shortage stock by passing it from 0.1708 to 0.062. But from this result, we can't do anything for now because at our present level of development! This would mean that by taking an initial stock of 10, we would have an average shortage stock of zero (... which does not take us to anything interesting...).

But still we can draw an interesting intermediate result. Indeed let us look on how varies the difference of average break (easily generalizable result - we can make the proof on request if necessary):

$$\begin{aligned}
&I_R(S=4)-I_R(S=5)=\sum_{x=5}^{10}(x-4)P(X=x)-\sum_{x=6}^{10}(x-5)P(X=x)\\
&=(5-4)P(X=5)+(6-4)P(X=6)+(7-4)P(X=7)+(8-4)P(X=8)\\
&+(9-4)P(X=9)+(10-4)P(X=10)-(6-5)P(X=6)-(7-5)P(X=7)\\
&-(8-5)P(X=8)-(9-5)P(X=9)-(10-5)P(X=10)\\
&=1P(X=5)+(2-1)P(X=6)+(3-2)P(X=7)+(4-3)P(X=8)+(5-4)P(X=9)\\
&+(6-5)P(X=10)\\
&=P(X=5)+P(X=6)+P(X=7)+P(X=8)+P(X=9)+P(X=11)\\
&=\sum_{x=5}^{10}P(X=x)=P(X>4)
\end{aligned}\tag{15.4.195}$$

The result is the same if the probability distribution is continuous!

In other words (be careful to what we say !!!) the decrease of average rupture caused by increasing the initial stock of one unit previously dimensioned to $S=4$ is equal to the cumulative probability that the demand is strictly greater than that of the original stock (i.e. $P(X>4)$).

In other words, in case this is not crystal clear (...), the fact of increasing the initial stock certainly decreases the probability of average rupture, but in exchange creates a risk that there are fewer buyers who may meet the offer.

Finally, we can write:

$$I_R(S+1) - I_R(S) = -P(X > S) \tag{15.4.196}$$

The table below shows the decreasing of expected out of stock we obtain by increasing by one unit the initial stock (and respectively the probability of customers able to consume the whole stock...):

x	$P(x)$	$I_R(x) - I_R(x+1)$
0	0.0821	0.9179
1	0.2052	0.7127
2	0.2565	0.4562
3	0.2138	0.2424
4	0.1336	0.1088
5	0.0668	0.0420
6	0.0278	0.0142
7	0.0099	0.0043
8	0.0031	0.0012
9	0.0009	0.0003
10	0.0009	0

Table 15.80: Average rupture by increasing the initial stock of one unit

Now let us look at the unsold $I_P(S)$ as a random function of the initial stock S. Their mean is of course given by (use tables if needed to understand):

$$\boxed{I_P(S) = \sum_{x=0}^{S} (S-x)P(X)} \tag{15.4.197}$$

Obviously, if the probability distribution is continuous (or at least approximated as such), the latter relation is written:

$$I_P(S) = \int\limits_0^S (S-x)f(X)\mathrm{d}x \tag{15.4.198}$$

What we can write:

$$\begin{aligned}
I_P(S) &= \mathrm{E}(S-X) = \sum_{x=0}^{S}(S-x)P(X) = \sum_{x=0}^{+\infty}(S-x)P(X) - \sum_{x=S+1}^{+\infty}(S-x)P(X)\\
&= S\sum_{x=0}^{+\infty}P(X) - \sum_{x=0}^{+\infty}xP(X) - \left[-\sum_{x=S+1}^{+\infty}(x-S)P(X)\right]\\
&= S - \sum_{x=0}^{+\infty}xP(X) - \left[-\sum_{x=S+1}^{+\infty}(x-S)P(X)\right] = S - \sum_{x=0}^{+\infty}xP(X) - [-I_R(S)]\\
&= S - \sum_{x=0}^{+\infty}xP(X) + I_R(S) = S - \bar{x} + I_R(S)
\end{aligned} \tag{15.4.199}$$

Therefore:

$$I_P(S) = S - \bar{x} + I_R(S) \quad (15.4.200)$$

which is then the residual stock of end of period. It is a remarkable result that will allow us to determine S^* only from $I_R(S)$. We can also again consider as obvious that the result will be the same if the probability distribution is continuous.

This last relation can also be written after rearrangement:

$$\bar{x} - I_R(S) = S - I_P(S) \quad (15.4.201)$$

where the term on the left represents the average demand satisfied and the right term average offer used. So this relationship is a special equality of balance between offer and demand.

We can also check this from the table below with a specific example:

$$I_P(S=4) = S - \bar{x} + I_R(S) = 4 - 2.5 + 0.1708 = 1.6708 \quad (15.4.202)$$

x	$4-x$	$(4-x)P(X)$
0	4	0.3284
1	3	0.6156
2	2	0.5130
3	1	0.2138
4	0	-
5	-	-
6	-	-
7	-	-
8	-	-
9	-	-
10	-	-
		$I_P(4) = 1.6708$

Table 15.81: Mean of unsold items

Finally we can write an expression of the management cost $C(S)$, according to the average rupture:

$$C(S) = C_P I_P(S) + C_R I_R(S) = C_P(S - \bar{x} + I_R(S)) + C_R I_R(S) \quad (15.4.203)$$

or what is written after rearrangement:

$$\boxed{C(S) = C_P \cdot (S - \bar{x}) + (C_P + C_R) I_R(S)} \quad (15.4.204)$$

Then it follows under the assumption that:

$$\begin{aligned} C(S+1) - C(S) &= [C_P \cdot (S+1) - C_P\bar{x}) + (C_P + C_R) I_R(S+1)] - [C_P(S - \bar{x}) + (C_P + C_R) I_R(S)] \\ &= C_P + (C_P + C_R)(I_R(S+1) - I_R(S)) \end{aligned} \quad (15.4.205)$$

Which gives using the results obtained previously:

$$C(S+1)-C(S)=C_P+(C_P+C_R)(-P(X>S)) \tag{15.4.206}$$

Under these conditions, the relations:

$$\left.\begin{matrix} C(S^*)-C(S^*+1)<0 \\ C(S^*)-C(S^*-1)<0 \end{matrix}\right\} \Leftrightarrow \left\{\begin{matrix} C(S^*+1)-C(S^*)>0 \\ C(S^*)-C(S^*-1)<0 \end{matrix}\right. \tag{15.4.207}$$

can be written using the prior-previous result:

$$\begin{cases} C_P+(C_P+C_R)(-P(X>S^*))>0 \\ C_P+(C_P+C_R)(-P(X>S-1))<0 \end{cases} \tag{15.4.208}$$

Therefore:

$$\begin{cases} \dfrac{C_P}{C_P+C_R}>P(X>S^*) \\ \dfrac{C_P}{C_P+C_R}<P(X>S^*-1) \end{cases} \tag{15.4.209}$$

Hence S^* is optimal if:

$$\boxed{P(X>S^*)<\frac{C_P}{C_P+C_R}<P(X>S^*-1)} \tag{15.4.210}$$

The result is known in the literature under "newsvendor optimal stochastic stock problem" (there are many versions of this problem).

In our numerical example, we then have:

$$\frac{C_P}{C_P+C_R}=\frac{25}{25+35}\cong 0.417 \tag{15.4.211}$$

and this lies thanks to our table between:

$$P(X>2)=0.4562 \qquad P(X>3)=0.2424 \tag{15.4.212}$$

hence the initial daily optimal inventory also named "minimum stock" to put into production (or order) to minimize the management cost $C(S)$:

$$S^*=3 \tag{15.4.213}$$

It's a number that is obviously very close to the modal value of the initial distribution.

Note that in practice, however, employees who are controlling supply chain in multinational companies have no idea of prices, margins and costs that occur in the shop of their customers. Therefore they get these information (sales, prices, margins, etc.) by paying their customers to get the data (most of time into Microsoft® Excel® data file).

Often practitioners simply take the modal value or the value corresponding to a 95% coverage of the periodic request (this becomes somewhat arbitrary). In the case of our little exercise, for example, the modal value of the initial stock rounded to the nearest integer value would be 2 and at a threshold of 95% would be equal to 5. As a precaution, however, there is a tendency to take rather the modal value (it is better to avoid to throw and it is better to say to the boss we missed and unknown amount of sales quantity rather than to give an exact amount of products returned or throw[60]...).

---

[60] This is a typical behaviour of supply chain manager that don't know statistics or how to communicate them

15.4.4.3 Wilson's Models

There are several stock management optimization models (statistical, Wilson, ABC, 20/80, VSM, ...). Among them, we wanted to stop on the "Wilson's Models" with its three variations that are the best known in the academic world (but not necessarily the most realistic...).

We therefore consider three situations:

1. The company resupplies by ordering batches thanks to external suppliers and then there is no stocks inertia and it redoes an order when the safety stock is reached. We speak then of "Wilson's model with resupply".
2. The company resupplies by an internal production, which then implies a given inertia to return to the desired level of stock. We speak then of "Wilson's model without resupply" (for which all results can be very quickly deduced from the first model without redoing all the mathematical developments).
3. The company resupplies by ordering batches thanks to external suppliers and then there is no stocks inertia and it redoes an order when the safety stock is reached but with inertia and please customers to wait. We speak then of "Wilson's model with waiting time".

Remarks

R1. This model also named the "Economic Lot Size Model" or "Economic Batch Quantity" (EBQ) has for purpose to determine the frequency and optimal resupply quantity for a store, a factory, etc. It is commonly used by supply chain services in large structures. It was actually introduced in 11913 (holocene calendar)...

R2. When the Wilson model is applied to cash management but rather than with inventory costs we work with trading costs, fixed cost of making securities, etc. We then speak of "Baumol-Allais-Tobin model".

The purpose is to determine the strategy that must be adopted so that the total periodic (annual, monthly, weekly, daily, ...) of the orders or manufacturing of goods minimizes the total cost of acquisition and ownership for stocks of the company. We talk then sometimes about "just in time supply chain management" or more simply "JIT supply chain management".

The existence of stocks within a company leads the supply chain manager to ask the question of the optimal level of these latter, avoiding at least two major pitfalls:

1. "Over-stocking", source of costs for the company (physical storage costs, handling costs, premises and land used costs, associated costs, security assurances costs[61], costs immobilized capitals, human unemployment, etc.).

---

[61] The FSA company (Financial Security Assurance) provides insurance to corporate and municipal borrowers in the bond market. FSA determines what added collateral and surplus cashflow each deal needs to bring the bond to investment grade and arranges for the issuer to place necessary collateral into a special corporation controlled by FSA. FSA then rents the issuers its triple-A rating, saving the issuers money through lower interest rates and exacting a hefty premium for itself.

2. "Sub-stocking" which may result in stock ruptures that are detrimental to the production activity or the business activity of the company (factory stoppage, sales loss, customers loss, quality loss, increase in stress for employees, etc.).

Thus, the different models of supply chain management are intended to minimize the management cost in this system of constraints by determining the resupply frequency and the associated quantity.

Consider first a purely qualitative approach. For each reference, the quantities in stock change over time, for example in the following shape:

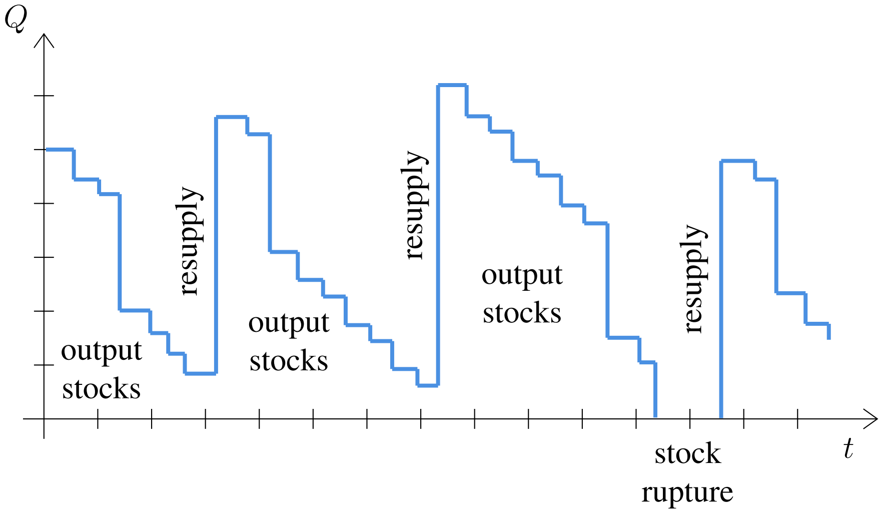

Figure 15.304: **First resupply strategy**

Simplifying we get a graph named "sawtooth supply chart":

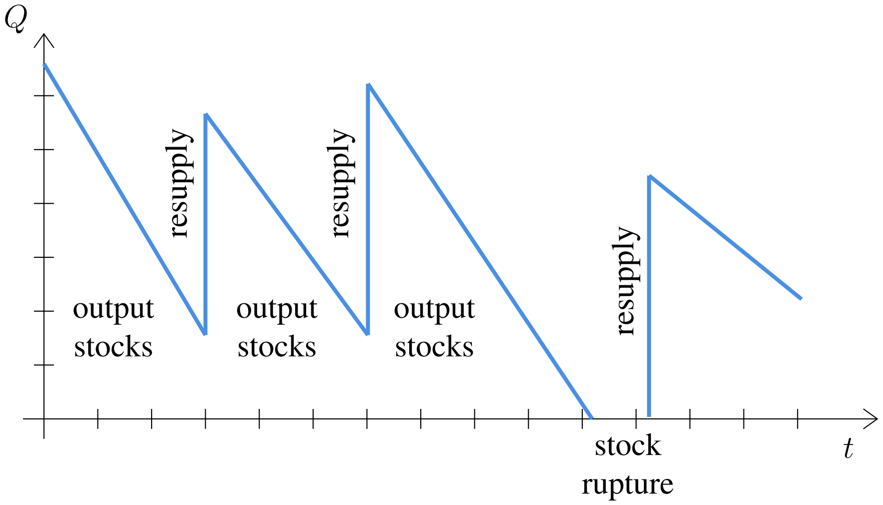

Figure 15.305: **Simplified sawtooth corresponding diagram**

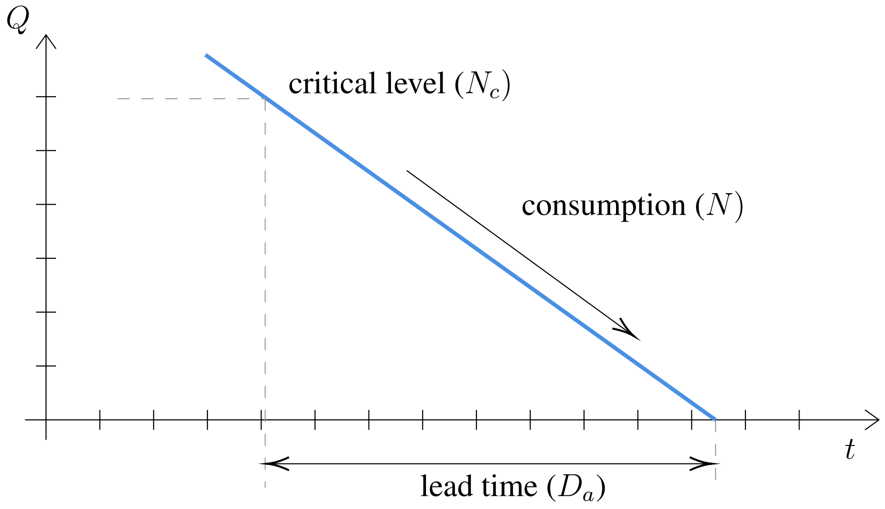
where we are in a typical situation of "supply chain management at non-zero rotation" (that is to say, when unsold can be sold at a later time).

To avoid stock rupture, we must of course ensure that the entry of an order takes place, at the latest, when the inventory quantity becomes zero:



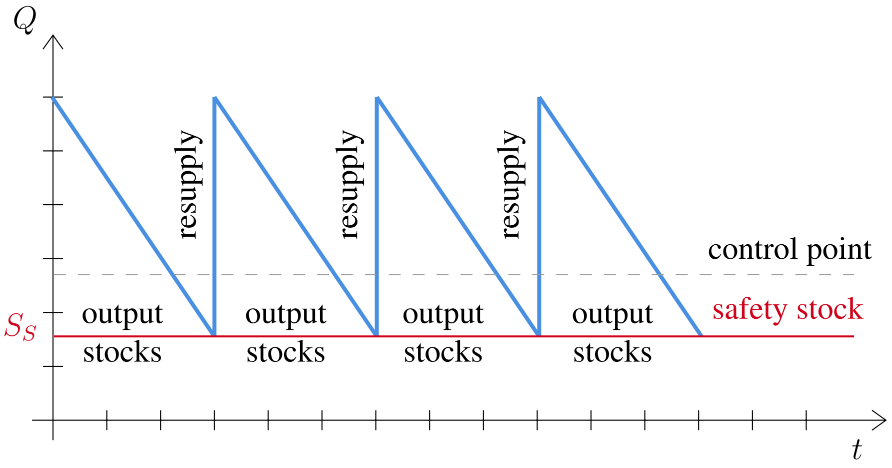
Q
critical level (N_c)
consumption (N)
t
lead time (D_a)

Figure 15.306: **Visual principle of the strategy**

If we consider a constant consumption of a quantity N per unit of time (day, month, year, etc.) and that we know in advance the lead time (in days, months, years, etc.) then if everything is put in equivalent units (e.g. daily) we have the critical level which is given by:

$$N_c = ND_a \tag{15.4.214}$$

which is also assimilated to the justified terminology of "control point" since this is the amount we have in stock from which we must launch a new procurement order:



Q
resupply
resupply
resupply
control point
S_S
output stocks
output stocks
output stocks
output stocks
safety stock
t

Figure 15.307: **Control point representation (sawtooth diagram)**

Thus, if the consumption is of 10 units per day, and the lead time is 15 days, then the critical level is of 150 units.

To prevent hazards (strike, transport, consumption variation, replacements, ...) we plan a safety stock S_s:

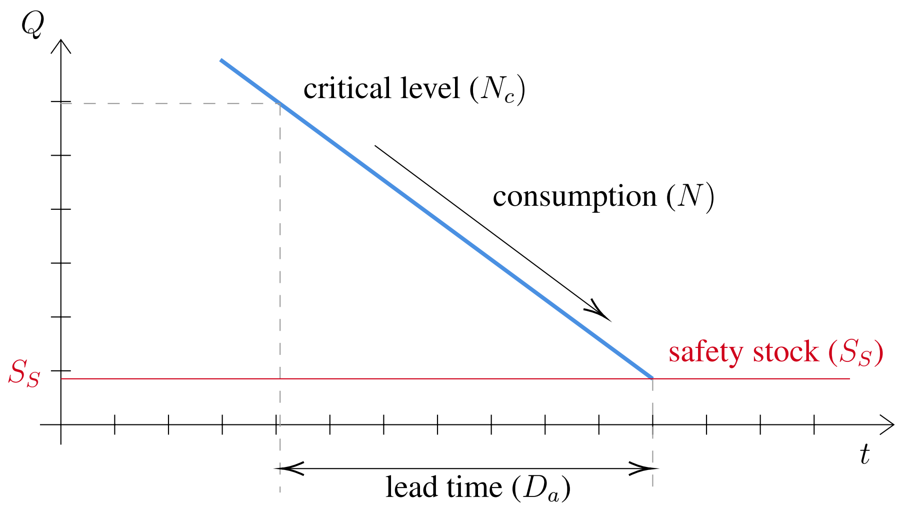


Figure 15.308: Representation of safety stock on the sawtooth pattern

We then have for the critical level:

$$N_c = S_s + ND_a \tag{15.4.215}$$

Let us now see the influence of the number of deliveries on the cost of storage (since the higher the rate of retention is bigger, more the storage costs are high). Suppose for this that the market consumes 100 units per month and this regularly. In the case of a single annual supply, the consumption is represented by the following diagram (no safety stock in order to simplify the example):

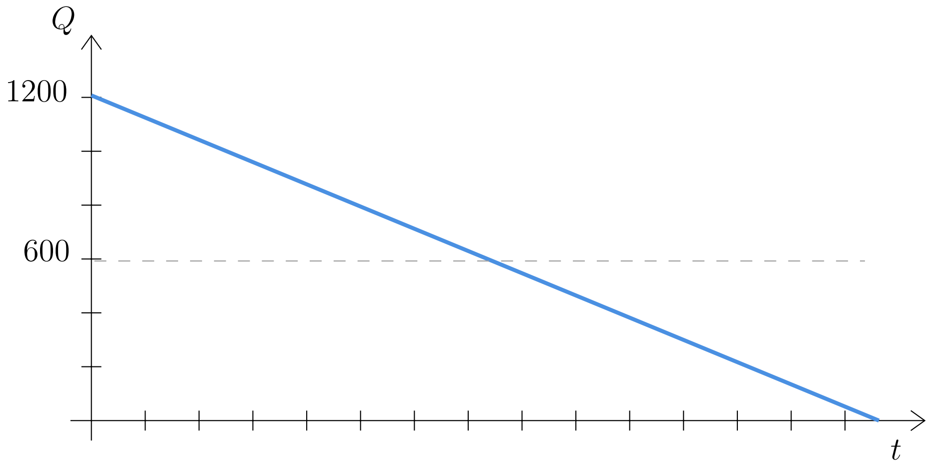

Figure 15.309: Representation of the effect of a single supply

where we immediately see that the average stock is 600. The average stock is obtained by simple arithmetic average or simply using the definition of the integral average (see section Statistics page 569) of the consumption function:

$$\mu_f = \frac{1}{b-a}\int\limits_a^b f(t)\mathrm{d}t = \frac{1}{12-0}\int\limits_0^1 2(-100t+1,200)\mathrm{d}t = 600 \tag{15.4.216}$$

thus trivially half maximum stock (or otherwise seen: the area of the rectangle triangle divided by T...).

And if we divide into two resupply, then we have:

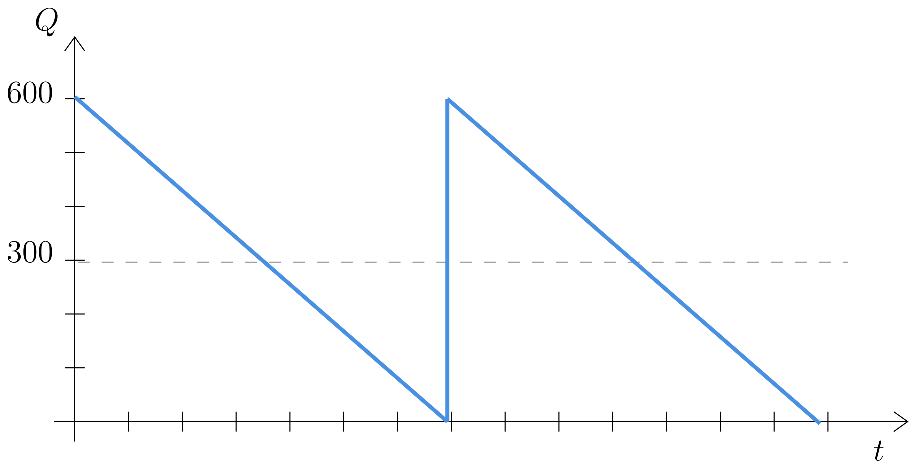

Figure 15.310: **Representation of the effect of a double supply**

Therefore an average stock twice lower and therefore an average storage cost twice lower too (therefore we understand better what the JIT supply chain management is the best way to management stocks in the point of view of costs). But of course we must associate the cost of supply to it (when there is one). It is at this level of complexity that comes precisely the mathematical formalization of Wilson.

Each purchase order or production order hence costs something to the company. The "launch cost" or "cost of purchase" or "restocking cost" to produce or order new batches represent by definition all related costs (administrative, machine settings, preparation, communication, ages, etc.) relatively to the fact of placing an order (or production) and is assumed to be proportional to the quantity. These costs are determined using analytical cost accounting.

Thus, the cost of an order is obtained by dividing the total operating cost of the purchasing department by a significant and relevant magnitude. For example, the number of annually purchased orders (or orders of manufacturing). The cost of a manufacturing launch will be calculated by dividing the total cost of running the manufacturing services, in which, we must add the cost of machines maintenance and wages by of manufacturing launches.

These values depend mainly on the company, of its choices in cost accounting methods. It is difficult to define a range of standard values. Many companies do not know accurately how much cost them an order or a production launch (and many simply do not know how to make an analysis...) and as most manager don't know how to make use of probability distributions the decisions are even more difficult for the executive board.

The cost of ownership of the stock consists of expenses related to the physical storage but also the non-remuneration of capital tied up in the stock (or even the cost of debt to finance the stock). For this last reason, this cost is considered to be proportional to the value of the average stock and the holding period of the stock (at lest on short periods because in reality it is an exponential as a factor of $(1+t\%)^n$).

The annual possession/ownership rate $t_O\%$ is the cost of ownership down to a monetary unit of stored material. It is calculated by dividing the total annually cost of ownership by the average annual stock. This rate typically and obviously fluctuate depending on the product value stored in the stock, depending on the type of articles and the quality of their inventory management.

Wilson has established a famous formula to determine the optimum stock quantity based on some assumptions that we will study right now!

Remark

In reality it seems that the model was developed by the production engineer Ford W. Harris in 11913 (holocene calendar), but R. H. Wilson, a consultant who applied it extensively, and K. Andler are given credit for their in-depth analysis.

15.4.4.3.1 Wilson's model with resupply

The highly simplified assumptions of this model are:

H1. The periodic demand (ask) is known and certain (deterministic and stable in other words).

H2. The ordered quantities are constant at each period.

H3. Shortages (stock-outs) occurs at end of period (so there is never a lack of stock and therefore no unknown risks).

H4. The production time is constant and the resupply is instantaneous.

H5. All costs (stocks, articles, procurement, production, manufacturing ...) are time invariant.

H6. Cost of ownership (also named "carrying cost" sometimes) is proportional to the value (short time hypothesis).

H7. The planning horizon is infinite.

And according to the authors this list of assumptions vary more or less (certain assumptions being implicit or being relatively trivial or forgotten/hidden).

Remarks

R1. We assume that the stock management is done in a given time period.

R2. Based on these assumptions/hypothesis, we conclude that there will be the same level of resupply at every period, and that total cost of shortage is zero.

Let us define:

- $t_O\%$ the periodic possession/ownership rate.

- N the quantity corresponding to a demand or respectively the number of items consumed per period.
- Q is the quantities of resupplies or parts launched for manufacturing in once during this same time (batch sizes).
- P_U the unit purchase price of the pieces (price assumed as constant!).
- S_S the considered safety stock for this pieces (also assumed as constant over time) to answer to fluctuations over time (fluctuations also assume to be constant over time).
- C_L the global cost by resupply/acquisition by order or of manufacturing launch.

From this primitive variables we can also create the following common variables:

- The "unit cost of storage" often (but not always!) calculated on the basis of the unit purchase price of a pieces:

  $$C_{US}=t\%P_U \qquad (15.4.217)$$

- The "stocks inertia" which can be seen more explicitly as the "number of periodic launches" (or the replenishment rate) to meet the demand. The inertia of the stock thus has the dimension of a reciprocal of the time:

  $$J_S=\frac{N}{Q} \qquad (15.4.218)$$

- The "inertia cost" or respectively the "cost of acquisition" or "launch cost" or "restocking cost" is therefore per period unit:

  $$J_C=\frac{N}{Q}C_L=J_SC_L \qquad (15.4.219)$$

  The latter is assumed to be proportional to the consumption! What is important to see is that the launch cost is inversely proportional to the amount Q and therefore it tends to zero as Q tends to infinity. Having said that, normally we will have in most theoretical cases $Q\leq N$.

- The average stock in the company in the assumption of a constant consumption (linear decrease of the stock) and a constant level of security within the time period is trivially by period by:

  $$\bar{S}=S_S+\frac{Q}{2} \qquad (15.4.220)$$

The "periodic cost of ownership", also named "cost of ownership" or "management cost" or "storage cost" is then given by:

$$C_P=t_O\%P_U\bar{S}=t_O\%P_U\left(S_S+\frac{Q}{2}\right) \qquad (15.4.221)$$

So this is the function of a straight line (whose intercept is non-zero if the safety stock is not zero) if we consider that only Q is the variable. It is important to note that this cost does not take into account the volume discount concepts made by commercial...

These proposals therefore lead us to the equation of the "total cost of resupply", also named "total cost of storage" that we will seek to minimize:

$$C_{\text{tot}}(Q)=J_C+C_P=\left(\frac{N}{Q}C_L\right)+\left(S_S+\frac{Q}{2}\right)t_{\text{O}}\%P_U \tag{15.4.222}$$

and giving an hyperbolic type curve of cumulative costs:

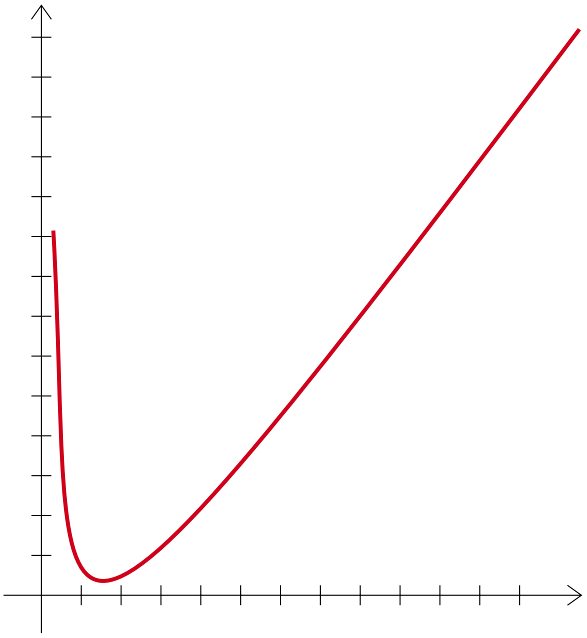

Figure 15.311: **Cumulative costs** $C_{\text{tot}}(Q)$

Seeking the economic quantity Q_e is finding the value of Q for which the total cost is minimal (in other words this is to find the batch size that allows to make the best return on investment of all the costs of storage, manufacturing, etc.), that is to say, mathematically, the value Q_e for which the derivative of the total cost C_{tot} with respect to the quantity Q is zero:

$$\frac{\mathrm{d}C_{\text{tot}}}{\mathrm{d}Q}=-\frac{N}{Q^2}C_L+\frac{1}{2}t_{\text{O}}\%P_U=0 \tag{15.4.223}$$

Hence the "Wilson relation" (after an elementary algebraic computation), also simply named "Wilson formula" for the "optimal economic quantity/batch":

$$\boxed{Q_e=\sqrt{\frac{2NC_L}{t_{\text{O}}\%P_U}}=\sqrt{\frac{2NC_L}{C_{US}}}} \tag{15.4.224}$$

which is therefore for reminder, the batch size that minimizes the total cost (independent of the safety stock which vanishes when we do the derivative). We notice that the economic quantity is proportional to the square root of the consumption. So an item sold 100 more times as expected by a company requires a 10 times greater average stock.

Obviously once known the economic quantity, it becomes easy to calculate the "optimal management cost for period" $C_{\text{tot},e}$ by injecting Q_e in the relation obtained previously:

$$C_{\text{tot},e}(Q)=\left(\frac{N}{Q}C_L\right)+\left(S_S+\frac{Q}{2}\right)t_O\%P_U \tag{15.4.225}$$

and also the "optimal resupply rate or frequency" as given by the ratio:

$$J_S=\frac{N}{Q}=\frac{N}{\sqrt{\dfrac{2NC_L}{C_{US}}}}=\sqrt{\frac{C_{US}N}{2C_L}}=\sqrt{\frac{NP_Ut_O\%}{2C_L}} \tag{15.4.226}$$

We then have after a little bit elementary algebraic manipulations the "optimal cost of management by period" that is given by:

$$\begin{aligned}C_{\text{tot},e}(Q)&=\left(\sqrt{\frac{C_{US}N}{2C_L}}C_L\right)+\left(S_S+\frac{\sqrt{\dfrac{2NC_L}{C_{US}}}}{2}\right)t_O\%P_U=\sqrt{\frac{C_{US}C_LN}{2}}+\frac{\sqrt{\dfrac{2NC_L}{C_{US}}}}{2}C_{US}+S_SC_{US}\\&=\sqrt{\frac{C_{US}C_LN}{2}}+\sqrt{\frac{NC_LC_{US}}{2}}+S_SC_{US}=2\sqrt{\frac{NC_LC_{US}}{2}}+S_SC_{US}=\sqrt{2NC_LC_S}+S_SC_{US}\end{aligned} \tag{15.4.227}$$

where the term:

$$C_{\text{tot},e}(Q)=\sqrt{2NC_LC_S} \tag{15.4.228}$$

is named the "total variable cost".

As often, managers like to make sensitivity analysis (we have already mentioned this in our study of "break-even analysis" page 8047). In the field of Supply Chain Management it is traditional to analyse the sensitivity of the relative change in total storage cost compared to the optimal cost of management by period:

$$\frac{C_{\text{tot}}}{C_{\text{tot},e}}=\frac{\dfrac{N}{Q}C_L+\dfrac{Q}{2}t_O\%P_U+S_St_O\%P_U}{\sqrt{2NC_LC_{US}}+S_SC_{US}}=\frac{\dfrac{N}{Q}C_L+\dfrac{Q}{2}C_{US}+S_SC_{US}}{\sqrt{2NC_LC_{US}}+S_SC_{US}} \tag{15.4.229}$$

But as S_SC_{US} (cost of safety stock) is assumed to be independent of the quantity, it is customary to consider only the relative variation regardless of this term such that (...):

$$\frac{C_{\text{tot}}}{C_{\text{tot},e}}\cong\frac{\dfrac{N}{Q}C_L+\dfrac{Q}{2}C_{US}}{\sqrt{2NC_LC_{US}}} \tag{15.4.230}$$

Finally, it is customary to simplify the analytical expression of this last relation in the following way after some elementary algebraic manipulations:

$$\begin{aligned}\frac{C_{\text{tot}}}{C_{\text{tot},e}}&\cong\frac{\dfrac{N}{Q}C_L+\dfrac{Q}{2}C_{US}}{\sqrt{2NC_LC_{US}}}=\frac{NC_L}{Q\sqrt{2NC_LC_{US}}}+\frac{QC_{US}}{2\sqrt{2NC_LC_{US}}}\\&=\frac{NC_L}{Q\sqrt{2NC_LC_{US}}}\frac{\sqrt{2NC_LC_{US}}}{\sqrt{2NC_LC_{US}}}+\frac{Q}{2\sqrt{\dfrac{2NC_LC_{US}}{C_{US}^2}}}\\&=\frac{\sqrt{2NC_LC_{US}}}{2QC_{US}}+\frac{Q}{2\sqrt{\dfrac{2NC_L}{C_{US}}}}=\frac{\sqrt{2NC_LC_{US}}}{2QC_{US}}+\frac{Q}{2Q_{\text{tot},e}}\\&=\frac{1}{2Q}\sqrt{\frac{2NC_LC_{US}}{C_{US}^2}}+\frac{Q}{2Q_e}=\frac{1}{2Q}\sqrt{\frac{2NC_L}{C_{US}}}+\frac{Q}{2Q_e}=\frac{1}{2Q}Q_e+\frac{Q}{2Q_e}=\frac{1}{2}\left(\frac{Q_e}{Q}+\frac{Q}{Q_e}\right)\end{aligned}\tag{15.4.231}$$

so this is a fairly aesthetic result... that the reader will notice is always positive!

Obviously we can also deduce from the relation of the optimum resupply frequency the "optimal resupply period" then given by (the inverse of the frequency definition):

$$T_e=\frac{1}{f_e}=\frac{1}{J_S}=\frac{1}{\dfrac{Q}{N}}=\sqrt{\frac{2C_L}{C_{US}N}}=\sqrt{\frac{2C_L}{NP_Ut_O\%}}\tag{15.4.232}$$

If we report on a graph the functions:

- The launching cost (supply) in function of the quantities:

$$J_C=\frac{N}{Q}C_L=J_SC_L\tag{15.4.233}$$

- The cost of ownership based in function of the quantities:

$$C_P=t_O\%P_U\bar{S}=t_O\%P_U\left(S_S+\frac{Q}{2}\right)\tag{15.4.234}$$

- The total costs in function of the quantities:

$$C_{\text{tot}}(Q)=J_C+C_P=\left(\frac{N}{Q}C_L\right)+\left(S_S+\frac{Q}{2}\right)t_O\%P_U\tag{15.4.235}$$

the economic quantity is at the intersection of the two curves, launch and possession (when the cost of ownership is equal to the cost of acquisition), or at the inflection point of the total cost curve. In practice, however, it is possible to accurately control the economic quantity, we will choose a batch size that meets the various constraints and included in the "economic area":

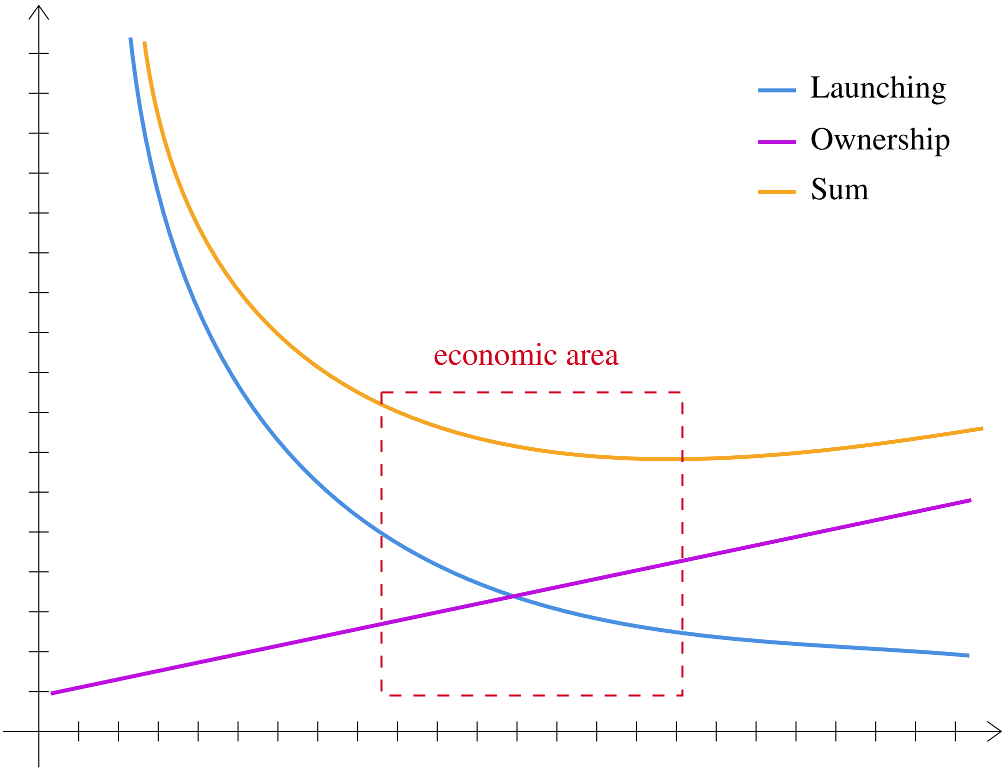

Figure 15.312: **Representation of the economic area**

Obviously in some companies the goal is rather to try to reduce the unit cost of storage C_{US} to reach the equivalent of the demand as economic quantity Q_e. We then have with some elementary algebra:

$$Q_e=\sqrt{\frac{2NC_L}{C_{US}}}\Rightarrow Q_e^2=\frac{2NC_L}{C_{US}}:=N^2 \tag{15.4.236}$$

that is to say the optimal unit storage costs if the supply amount Q is imposed:

$$C_{US,e}=\frac{2C_L}{N} \tag{15.4.237}$$

The reader must know that we often consider that the entire Wilson model can be summarized to the 5 below relations:

$$\boxed{\begin{aligned}&C_{\text{tot},e}(Q)=\sqrt{2NC_LC_{US}}+S_SC_{US}\\&Q_e=\sqrt{\frac{2NC_L}{t_O\%P_U}}=\sqrt{\frac{2NC_L}{C_{US}}}\\&T_e=\sqrt{\frac{2C_L}{NP_Ut_O\%}}=\sqrt{\frac{2C_L}{NC_{US}}}\\&C_{US,e}=\frac{2C_L}{N}\\&\frac{C_{\text{tot}}}{C_{\text{tot},e}}\cong\frac{1}{2}\left(\frac{Q_e}{Q}+\frac{Q}{Q_e}\right)\end{aligned}} \tag{15.4.238}$$

There is another type of scenario that must be studied. If order (resupply) in larger quantities, thus benefiting from a discount, it certainly increases the costs of ownership but theoretically reduces the number of annual orders.

The goal for the manager is of course to check mathematically that the discount granted by the supplier does not lead to induced higher costs than the discount itself (otherwise the manager would be incompetent!).

To do this, we must reduce all costs to a unique item such that the unit total cost will be written:

$$C_U = \frac{C_{\text{tot}(Q)}}{N} + P_U = \left(\frac{C_L}{Q}\right) + \frac{\left(\frac{Q}{2} + S_S\right) t\% P_U}{N} + P_U \tag{15.4.239}$$

This relation is important as it gives the possibility to determine the discount value for the latter to be interesting.

To know the discount threshold R for a given quantity, we replace in the above relation, Q by the target quantity Q' and P_U by $P_U(1-R)$, where R is the discount percentage.

Then we have to solve:

$$C_U \geq \left(\frac{C_L}{Q'}\right) + \frac{\left(\frac{Q'}{2} + S_S\right) t\% P_U(1-R)}{N} + P_U(1-R) \tag{15.4.240}$$

We will determine therefore the value of R under which the discount does not compensate the internal costs.

In the practice we cannot order most of time the exact optimal economic quantity Q_e, especially because of the minimum order quantity (MOQ) imposed by suppliers. It is therefore more interesting to focus on the "economic area", defined by the lower area of the total cost curve.

Because of its simplified assumption and its deterministic aspect, the Wilson model can only provide at best an order of amplitude of the solution if the consumption and/or prices are subject to fluctuations (as the economic quantity is dependent of the parameters: storage costs and resupply cost).

Also it should be noticed that the use of resupply is "anti-flexible" par definition. This type of politic takes frequently important consequences, risk to inflate the stock of finite products, reporting costs and losses downstream of the process.

However, the Wilson's model is interesting for the fact that it can also be applied quite well to human resources in some special cases.

✍**Example:**

The company MAC uses an article X330 for which the projected consumption of the year N should be $4,000$ items. The data are the following:

- The unit cost of Article X330 is $P_U = 8$.- (regardless of currency)
- The procurement/launch cost of an order is $C_L = 100$.-
- The rate of possession of the stock is $t\% = 10\%$ by year.

- The safety stock is of 250 units

The supplier of this article, to encourage its customers to increase the size of their orders, offer to the company the following conditions:

C1. Ordered quantity less than $2,000$ units: unit price $P_U = 8$.-

C2. Ordered quantity less between $2,000$ and $3,500$ units: discount of 2%

C3. Ordered quantity more than $3,500$ units: discount of 3%

The question is to know what is the best choice for the company (buyer)?

The price varies then depending on the quantity such that given a selected quantity, the discount applies on same manner equivalent to all items in the batch (this is named a "uniform discount").

According to the statement and according to the quantity Q of supply, we know that:

1. If $Q < 2,000 \Rightarrow P_U := P_1 = 8$.-
2. If $2,000 < Q < 3,500 \Rightarrow P_U := P_2 = 8 - 2\% \cdot 8 = 7.84$.-
3. If $Q \geq 3,500 \Rightarrow P_U := P_3 = 8 - 3\% \cdot 8 = 7.76$.-

Using the Wilson relation of the optimal economic batch, we will calculate the economic quantity Q_e for the most advantageous price, that is to say P_3:

$$Q_e = \sqrt{\frac{2NC_L}{t_O\% P_U}} = \sqrt{\frac{2 \cdot 4,000 \cdot 100}{7.76 \cdot 10\%}} \cong 1,015 \tag{15.4.241}$$

But to get the price P_3 it must be ordered at least $3,500$ items so there is contradiction and this solution is therefore out of the area! Identical calculations (that we leave to the reader...) show that only the economic quantity Q_e of P_1 satisfies the constraints $Q < 2,000$.

Therefore, the optimal resupply period will be:

$$T_e = \sqrt{\frac{2C_L}{C_S N}} = \sqrt{\frac{2 \cdot 100}{(10\% \cdot 8) \cdot 4,000}} = 0.25 = 91.25 \text{ days} \tag{15.4.242}$$

and the optimal management cost per period is given by:

$$C_{\text{tot},e} = \sqrt{2NC_L C_{US}} + S_S C_S = \sqrt{2 \cdot 4,000 \cdot 100 \cdot (10\% \cdot 8)} + 250(10\% \cdot 8) = 1,000.\text{-} \tag{15.4.243}$$

Caution!!! For the latter calculation, some authors include the cost of safety stock $S_S C_{US}$ of the quantity N. This is a choice rather questionable and that would need to be clarified.

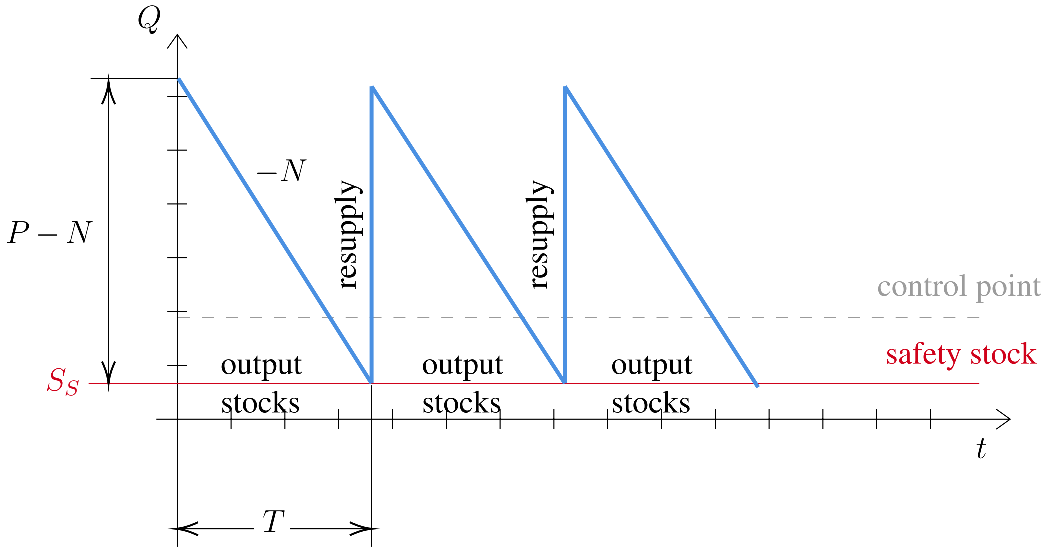
Finally, the impact on the total cost of management if we increase or decrease the amount of $\pm 30\%$ compared to the economic quantity is given by (sensitivity analysis):

$$\begin{aligned}\frac{C_{\text{tot}}}{C_{\text{tot},e}}&=\frac{1}{2}\left(\frac{Q_e}{Q}+\frac{Q}{Q_e}\right)=\frac{1}{2}\left(\frac{1}{1.3}+\frac{1.3}{1}\right)\cong 1.0346\\ \frac{C_{\text{tot}}}{C_{\text{tot},e}}&=\frac{1}{2}\left(\frac{Q_e}{Q}+\frac{Q}{Q_e}\right)=\frac{1}{2}\left(\frac{1}{0.7}+\frac{0.7}{1}\right)\cong 1.0643\end{aligned}\qquad(15.4.244)$$

So obviously, this only increases costs and as we have seen on the graph earlier, the curve being not symmetrical, the two results are not equal.

15.4.4.3.2 Wilson's model without resupply

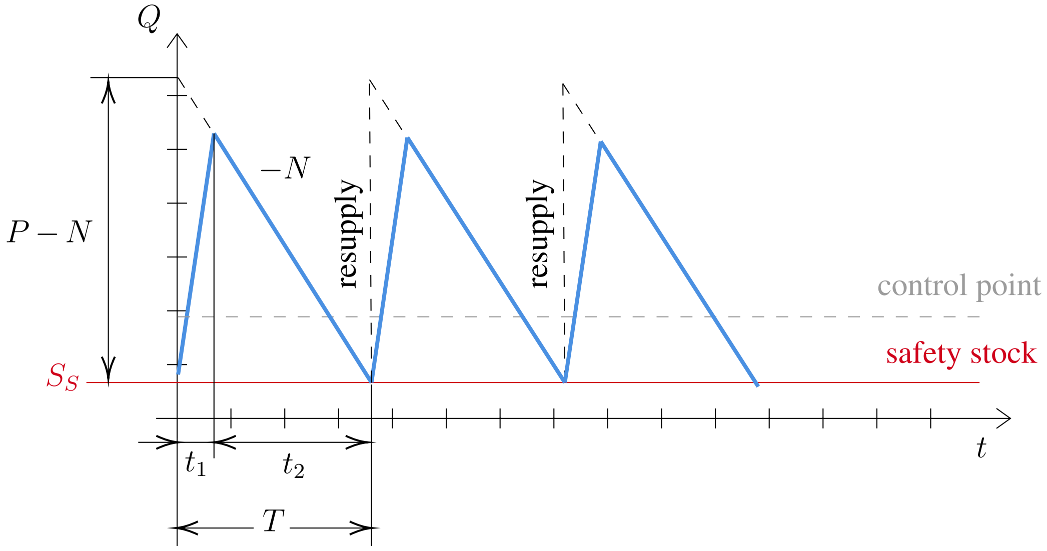
In the previous model, we have assume for recall a sawtooth stock management of the following form:



Q
$P-N$
$-N$
resupply
resupply
control point
safety stock
S_S
output stocks
output stocks
output stocks
t
T

Figure 15.313: **Wilson model with resupply**

In the model that will interests us now, we will consider a supply chain management with a resupply inertia often due to an internal house production such as follows:



Q
$P-N$
$-N$
resupply
resupply
control point
safety stock
S_S
t_1
t_2
t
T

Figure 15.314: **Wilson model without resupply**

As for the Wilson model with resupply, the demand in production is done at the command point. But there is big difference! We can observe that during the production at a rate of P parts per unit of time t_1 the consumption N per period T (reported to the production unit time), is already using the newly created stocks!!!

Do we have to redo all the calculations of the previous model? The answer is: not at all!!! Because if we think a little bit by observing the hyperbolic function of the total cost of storage that we have proved earlier above:

$$C_{\text{tot}}(Q) = J_C + C_P = \left(\frac{N}{Q}C_L\right) + \left(S_S + \frac{Q}{2}\right) t_O\%P_U \tag{15.4.245}$$

It is obvious that the first term due to resupply has no reason to change. The third term, due to safety stock, has no reason to change either! So there remains only the second term represented by the average cost of storage that is necessarily different!

Therefore the average storage is no longer:

$$\frac{Q}{2} \tag{15.4.246}$$

We can easily calculate the average area of the triangle using the Heron's formula available for any triangle and already proved in the section of Geometric Shapes. But the problem in this case is that we want to make the variable Q appear in the average stock! We can then not use Heron's formula. The idea will be the following (refer the previous figure):

When the company don't have any stock more, it launches for a given time t_1 the production at a rate of P elements per unit time until it reaches the cumulative targeted quantity Q. Then we have:

$$Q = Pt_1 \tag{15.4.247}$$

But at the same time production is running (and also after), the company uses (sell) N elements per unit time. The real stock will therefore be at time t_1 (under the obvious condition that P is greater than N) the maximum inventory:

$$\text{Inv}_{\text{max}} = Pt_1 - Nt_1 = (P-N)t_1 \tag{15.4.248}$$

This maximum inventory corresponds therefore to the height of our general triangle (always refer to previous figure) but we wish it to make appear our target stock Q. So, for this, there is now nothing more simple using prior-previous relation:

$$\text{Inv}_{\text{max}} = (P-N)t_1 = (P-N)\frac{Q}{P} = \left(1 - \frac{N}{P}\right) Q \tag{15.4.249}$$

Therefore the average stocks become:

$$\frac{1}{2}\left(1 - \frac{N}{P}\right) Q \tag{15.4.250}$$

So we see that the only difference between the two models is the factor:

$$\left(1 - \frac{N}{P}\right) \tag{15.4.251}$$

Therefore, the relations obtained for the Wilson model with resupply (at least the most important one) and that were for reminder:

$$\begin{aligned}
&C_{\text{tot},e}(Q)=\sqrt{2NC_LC_{US}}+S_SC_{US}\\
&Q_e=\sqrt{\frac{2NC_L}{t_O\%P_U}}=\sqrt{\frac{2NC_L}{C_{US}}}\\
&T_e=\sqrt{\frac{2C_L}{NP_Ut_O\%}}=\sqrt{\frac{2C_L}{NC_{US}}}\\
&C_{US,e}=\frac{2C_L}{N}\\
&\frac{C_{\text{tot}}}{C_{\text{tot},e}}\cong\frac{1}{2}\left(\frac{Q_e}{Q}+\frac{Q}{Q_e}\right)
\end{aligned}\tag{15.4.252}$$

become (the last relations does not change):

$$\boxed{\begin{aligned}
&C_{\text{tot},e}(Q)=\sqrt{2NC_LC_{US}\left(1-\frac{N}{P}\right)}+S_SC_{US}\\
&Q_e=\sqrt{\frac{2NC_L}{\left(1-\dfrac{N}{P}\right)t_O\%P_U}}=\sqrt{\frac{2NC_L}{\left(1-\dfrac{N}{P}\right)C_{US}}}\\
&T_e=\sqrt{\frac{2C_L}{\left(1-\dfrac{N}{P}\right)NP_Ut_O\%}}=\sqrt{\frac{2C_L}{\left(1-\dfrac{N}{P}\right)NC_{US}}}\\
&C_{US,e}=\frac{2C_L}{N\left(1-\dfrac{N}{P}\right)}
\end{aligned}}\tag{15.4.253}$$

The adaptation of the relations of periodic cost of ownership and total cost of supply are also immediate.

Remark

For Q_e and T_e some textbooks use the notation (...):

$$\begin{aligned}
C_{\text{tot},e}(Q)&=\sqrt{2\lambda C_LC_{US}(1-\rho)}+S_SC_{US}\\
Q_e&=\sqrt{\frac{2C_L\lambda}{\left(1-\dfrac{\lambda}{\mu}\right)C_{US}}}=\sqrt{\frac{2C_L\lambda}{(1-\rho)\,C_{US}}}\\
T_e&=\sqrt{\frac{2C_L}{\left(1-\dfrac{\lambda}{\mu}\right)\lambda C_{US}}}=\sqrt{\frac{2C_L}{(1-\rho)\,\lambda C_{US}}}
\end{aligned}\tag{15.4.254}$$

So unlike the model with resupply, we see that only a new variable P appears and that is the "production speed" or "production rate" (elements produced per unit time) to allow a production of N elements per unit time. What the reader must not forget when applying in practice this model is to bring P and N at the same time unit!!!

✍**Example:**

Suppose $C_L = 100$.- per time unit, $C_{US} = 5$.- per time unit, the demand rate is worth $\lambda = 200$ and the production rate is $\mu = 1,000$ and we no have any safety stock ($S_S = 0$). Then we have:

$$\rho = \frac{\lambda}{\mu} = \frac{200}{1,000} = 0.2 \tag{15.4.255}$$

The optimal order quantity is then:

$$Q_e = \sqrt{\frac{2C_L\lambda}{(1-\rho)\,C_{US}}} = \sqrt{\frac{2\cdot 100\cdot 200}{(1-0.2)\cdot 5}} = 100 \tag{15.4.256}$$

and the optimal resupply period will be:

$$T_e = \sqrt{\frac{2C_L}{(1-\rho)\,\lambda C_{US}}} = \sqrt{\frac{2\cdot 100}{(1-0.2)\cdot 200\cdot 5}} = 0.50 \tag{15.4.257}$$

And the optimal management cost per period is given by:

$$C_{\text{tot},e}(Q) = \sqrt{2\lambda C_L C_{US}\,(1-\rho)} + S_S C_{US} = \sqrt{2\cdot 200\cdot 100\cdot 5\,(1-0.2)} + 0\cdot 5 = 400.- \tag{15.4.258}$$

15.4.4.3.3 Wilson's model with resupply and break-up

Still in the classics of academic studies (the rest being only a stochastic mix of different scenarios based on the same reasoning), let us see now the Wilson's model with (instantaneous) resupply but where the break-up and short selling (with penalty counterpart) is allowed (so there is no safety stock anymore!!!). We will represent this scenario by the following saw-tooth figure:

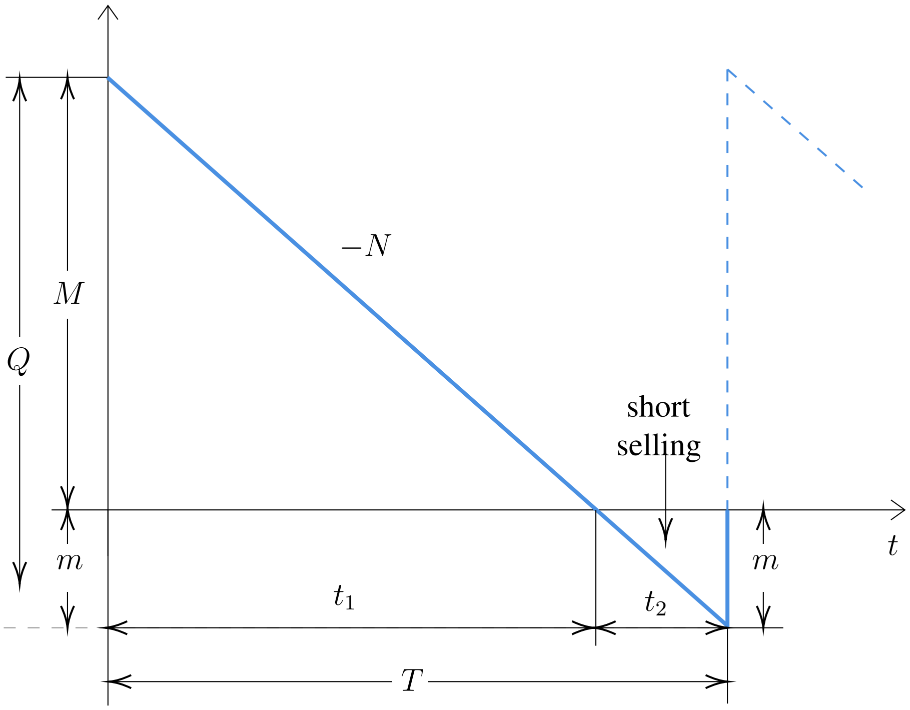


Figure 15.315: Wilson model with resupply and break-up

We will consider C_R as the financial loss (cost) per piece unit during the short-selling period (not having immediate input cash flow makes that we lost money anyway as we can not place it on funds with return yield).

In this case, we have not found a simple way to avoid redoing the calculations of the relations of the Wilson's model with resupply (but if someone has a tip he can contact us!). However it is still elementary algebra and therefore readers should not suffer to much with this kind of exercise style.

We first have trivially by referring to the figure above:

$$\begin{aligned} T &= \frac{Q}{N} \\ t_1 &= \frac{M}{N} \\ t_2 &= T - t_1 = \frac{Q}{N} - \frac{M}{N} = \frac{Q-M}{N} \\ m &= Q - M \end{aligned} \tag{15.4.259}$$

First, the average cost of storage is trivially equal to:

$$\frac{Mt_1}{2} C_{US} = \frac{M\left(\dfrac{M}{N}\right)}{2} C_{US} = \frac{M^2}{2N} C_{US} \tag{15.4.260}$$

The average cost of selling in break-out is also trivially given by:

$$\frac{mt_2}{2} C_R = \frac{(Q-M)\left(\dfrac{Q-M}{N}\right)}{2} C_R = \frac{(Q-M)^2}{2N} C_R \tag{15.4.261}$$

The average total cost for a period is then:

$$C=\frac{M^2}{2N}C_{US}+\frac{(Q-M)^2}{2N}C_R \tag{15.4.262}$$

Let us report this to the time of one period:

$$\frac{C}{T}=\frac{C}{\left(\dfrac{Q}{N}\right)}=\frac{M^2}{2Q}C_{US}+\frac{(Q-M)^2}{2N}C_R \tag{15.4.263}$$

The average total cost per period is then:

$$\begin{aligned}C_t&=\frac{N}{Q}C_L+\frac{M^2}{2Q}C_{US}+\frac{(Q-M)^2}{2Q}C_R\\&=\frac{N}{Q}C_L+\frac{M^2(C_{US}+C_R)}{2Q}+\frac{QC_R}{2}-MC_R\end{aligned} \tag{15.4.264}$$

The problem here is that Q depends on M and vice versa. We'll have to use partial derivatives to fix sometimes one and sometimes the other. Therefore to find the economic quantity we will first arbitrarily determine which is the amount M that will minimize the total average cost per period (in order to get rid of the presence of the variable M in the expression of the quantity economic). We then have taking the partial derivative (thus implying that we maintain Q constant):

$$\frac{\partial C_t}{\partial M}=\frac{M(C_{US}+C_R)}{Q}-C_R=0 \tag{15.4.265}$$

Therefore:

$$M_e=\frac{C_RQ}{C_{US}+C_R} \tag{15.4.266}$$

Now for the economic quantity, we respectively have by taking the partial derivative (so implicitly we fix M):

$$\frac{\partial C_t}{\partial Q}=-\frac{-N}{Q^2}C_L-\frac{M^2(C_{US}+C_R)}{2Q^2}+\frac{C_R}{2}=0 \tag{15.4.267}$$

By injecting in it the prior previous result it comes:

$$-\frac{NC_L}{Q^2}-\frac{\left(\dfrac{QC_R}{C_{US}+C_R}\right)^2(C_{US}+C_R)}{2Q^2}+\frac{C_R}{2}=-\frac{NC_L}{Q^2}-\frac{C_R^2}{2(C_{US}+C_R)}+\frac{C_R}{2}=0 \tag{15.4.268}$$

Thus after some elementary algebraic manipulations:

$$\frac{2NC_L}{Q^2}=\frac{C_RC_{US}}{C_{US}+C_R} \tag{15.4.269}$$

Which gives finally:

$$Q_e=\sqrt{2NC_L\frac{C_{US}+C_R}{C_RC_{US}}}=\sqrt{\frac{2NC_L}{C_{US}}}\sqrt{\frac{C_{US}+C_R}{C_R}} \tag{15.4.270}$$

We then have explicitly:

$$M_e = \frac{C_R}{C_{US}+C_R}Q_e = \frac{C_R}{C_{US}+C_R}\sqrt{2NC_L\frac{C_{US}+C_R}{C_R C_{US}}} = \sqrt{2NC_L\frac{C_R}{C_{US}+C_R}} \tag{15.4.271}$$

The optimal resupply period is then:

$$T_e = \frac{Q_e}{N} = \frac{1}{N}\sqrt{\frac{2NC_L}{C_{US}}}\sqrt{\frac{C_{US}+C_R}{C_R}} = \sqrt{\frac{2C_L}{NC_{US}}}\sqrt{\frac{C_{US}+C_R}{C_R}} \tag{15.4.272}$$

The economic quantity m of rupture gives resupply launch trigger that is then:

$$\begin{aligned} m_e = Q_e - M_e &= \sqrt{\frac{2NC_L}{C_{US}}}\sqrt{\frac{C_{US}+C_R}{C_R}} - \sqrt{\frac{2NC_L}{C_{US}}}\sqrt{\frac{C_R}{C_{US}+C_R}} \\ &= \sqrt{\frac{2NC_L}{C_{US}}}\left(\sqrt{\frac{C_{US}+C_R}{C_R}} - \sqrt{\frac{C_R}{C_{US}+C_R}}\right) \end{aligned} \tag{15.4.273}$$

A practical difficulty of this model is to determine C_R. The idea is then to estimate it on the maximum supposed waiting time of the customer when there is break-up. Starting from:

$$\begin{aligned} t_{2,e} = t_{\text{limit}} = \frac{Q_e - M_e}{N} &= \sqrt{\frac{2C_L}{NC_{US}}}\left(\sqrt{\frac{C_{US}+C_R}{C_R}} - \sqrt{\frac{C_R}{C_{US}+C_R}}\right) \\ &= \sqrt{\frac{2C_L}{NC_{US}}}\left(\sqrt{\frac{(C_{US}+C_R)(C_{US}+C_R)}{C_R(C_{US}+C_R)}} - \sqrt{\frac{C_R C_R}{(C_{US}+C_R)C_R}}\right) \\ &= \sqrt{\frac{2C_L}{NC_{US}}}\left(\sqrt{\frac{(C_{US}+C_R)^2}{C_R(C_{US}+C_R)}} - \sqrt{\frac{C_R^2}{(C_{US}+C_R)C_R}}\right) \\ &= \sqrt{\frac{2C_L}{NC_{US}C_R(C_{US}+C_R)}}\left(\sqrt{(C_{US}+C_R)^2} - \sqrt{C_R^2}\right) \\ &= \sqrt{\frac{2C_L}{NC_{US}C_R(C_{US}+C_R)}}(C_{US}+C_R-C_R) = \sqrt{\frac{2C_L}{NC_{US}C_R(C_{US}+C_R)}}C_{US} \\ &= \sqrt{\frac{2C_L C_{US}}{NC_R(C_{US}+C_R)}} \end{aligned} \tag{15.4.274}$$

And by squaring in the idea of extracting C_R:

$$t_{\text{limit}}^2 = \frac{2C_L C_{US}}{NC_R(C_{US}+C_R)} \Rightarrow C_R(C_{US}+C_R) = \frac{2C_L C_{US}}{Nt_{\text{limit}}^2} \Rightarrow C_R^2 + C_R S_C = \frac{2C_L C_{US}}{Nt_{\text{limit}}^2} \tag{15.4.275}$$

So we finally have an equation of the second degree:

$$C_R^2 + C_R S_C - \frac{2C_L C_{US}}{Nt_{\text{limit}}^2} = 0 \tag{15.4.276}$$

Whose two real roots are (see section Calculus page 1383):

$$C_{R_{1,2}} = \frac{-C_R \pm \sqrt{C_R^2 + 4\frac{2C_L C_{US}}{Nt_{\text{limit}}^2}}}{2} = -\frac{C_R}{2} \pm \sqrt{\left(\frac{C_R}{2}\right)^2 + \frac{2C_L C_{US}}{Nt_{\text{limit}}^2}} \tag{15.4.277}$$

The root to keep is obviously the one that gives a positive cost of rupture. That is to say:

$$C_{R_1}=-\frac{C_R}{2}+\sqrt{\left(\frac{C_R}{2}\right)^2+\frac{2C_LC_{US}}{Nt_{\text{limit}}^2}} \tag{15.4.278}$$

Before moving on to the practical example, the summary is reduced to:

$$\boxed{\begin{aligned}
Q_e&=\sqrt{\frac{2NC_L}{C_{US}}}\sqrt{\frac{C_{US}+C_R}{C_R}}\\
M_e&=\sqrt{\frac{2NC_L}{C_{US}}}\sqrt{\frac{C_R}{C_{US}+C_R}}\\
T_e&=\sqrt{\frac{2NC_L}{C_{US}}}\left(\sqrt{\frac{C_{US}+C_R}{C_{US}+C_R}}+\sqrt{\frac{C_R}{C_{US}+C_R}}\right)\\
t_{\text{limit}}&=\sqrt{\frac{2C_LC_{US}}{NC_R(C_{US}+C_R)}}\\
C_R&=-\frac{C_R}{2}+\sqrt{\left(\frac{C_R}{2}\right)^2+\frac{2C_LC_{US}}{Nt_{\text{limit}}^2}}
\end{aligned}} \tag{15.4.279}$$

✍**Example:**

The company MAC supplies the article X330. In the objective to not to lose customers, the managers decide of an optimal break-up time (meaning: maximum) of 2 days. We have the following data:

$$C_L=200\left[\frac{\$}{\text{resupply}}\right],\; C_{US}=1\left[\frac{\$}{\text{unit}\cdot\text{day}}\right],\; t_{\text{limit}}=2\,[\text{day}],\; N=5\left[\frac{\text{units}}{\text{day}}\right] \tag{15.4.280}$$

Which gives:

$$\begin{aligned}
C_R&=200\left[\frac{\text{units}}{\text{day}}\right]\\
Q_e&=50\;[\text{units}]\\
M_e&=40\;[\text{units}]\\
m_e&=10\;[\text{units}]\\
T_e&=10\;[\text{days}]
\end{aligned} \tag{15.4.281}$$

15.4.5 Queueing Theory

The queueing theories are an extremely powerful and extensive tool (a complete presentation requires at a minimum 300 A4 pages) that gives the possibility to consider and model the bottlenecks in business processes or in logistics, phone (Telecom) exchanges, requests on servers, at the check-out line of shops, or in the toilet of major sports stadiums (...), and also for ticket distribution for huge events, etc. depending on the starting assumptions and constraints. There are numerous example in newspaper of companies or events having very bad reputation because their manager did not use such modelization tools (or consultants knowing these tools....) during a given period of their existence and that have generate a huge frustration by the customers (reputation very hard to correct afterwards!).

Typically, most customers clearly don't like waiting non-value added activity, and if they wait too long, they combine this waste of time to a poor quality of service and share their experience on social networks and this can have afterwards a huge impacts (through other medias such at the television). Similarly, within companies, unoccupied employees or unused equipment represent non-value added activities. To avoid these situations, some of the best of companies and governmental institutions have implemented continuous improvement process whose ultimate goal is the elimination of all forms of waste, including waiting. All these examples show the importance of the analysis of queues. To notice that if a company or administration does not have the financial or intellectual capacity to make use of the queuing theories, the minimum respect for customers is at least to indicate with an inexpensive display, the median waiting time and to provide during this waiting times some entertainment (television, newspapers, magazines, food, drinks, etc.)!

Here is a typical small list of common systems relatives to queuing theory:

System	Customers	Services
Counter-reception	People	Receptionists
Repair workshop	Machines	Technicians
Customs	People	Customs officers
Ticketing	People	Vendors
Garage	Trucks/Cars	Mechanicians
Hospital	Patients	Nursing
Computer	Tasks	Processors, HDD, BUS
Airport	Airplane	Traffic controller
Roads	Cars	Traffic lights
Manufacturing	Tasks	Machines/Workers
Phone	Calls	Exchangers
Public transport	Travellers	Bus/Metro
Washroom	Lines	Washers / Dryers
Safety Check	People	Security guards
...	...	...

Table 15.82: **Examples of typical queues**

Remark

Queuing theory, is a subfield of "discrete-event simulation" (DES) that models the operation of a system as a (discrete) sequence of events in time. Each event occurs at a particular instant in time and marks a change of state in the system. Between consecutive events, no change in the system is assumed to occur; thus the simulation time can directly jump to the occurrence time of the next event, which is named "next-event time progression". DES is a computational science, a mix of theory and experimentation with a computer as the primary piece of laboratory equipment. In other words, discrete-event simulation is a form of computer-aided model building and problem solving. The goal is insight, a better understanding of how systems operate and respond to change (see our `R` companion book for a practical example).

These theories proves to be particularly useful to justify investments, hiring or equipment purchases. More generally, it is an integral part of mathematics management techniques when necessary to find an economic optimum between waiting costs and a system service costs.

The typical problem in companies and governmental administration can be expressed as:

- The human brain is subject to cognitive bias so not accurate enough to take a good decision hence the need of mathematical tool in this field
- What is the optimal number of stations / terminals to be commissioned to process all applications, while avoiding an excessive queue and the departure of some "customers"?
- What is the average/median waiting time of a "customer" in front the station / terminal?
- What is the average/median number of "customers" waiting in the queue?

These questions express the goals of quality and level of service that are:

- An average or median waiting time in the queue or service that should not to be exceed
- A maximum probability of waiting time
- An average/median number of waiting customers

In practice, when the customer is external to the company/administration, the waiting cost is difficult to evaluate because it is an impact rather than a cost that can be accounted (but sure the cost is not null!!!). However, the waiting time can be regarded as a measurement standard service level. The manager decides the acceptable waiting time and he sets up the capacity that can provide this level of service.

When the customer is internal to the company/administration, we can evaluate some costs directly related customer waiting time (machines/information). However we must not conclude too quickly that the cost of an employee that is waiting is equal to his wage during the waiting time (even if this can be true for a small proportion of people...). This would imply that the net decrease in earnings of the company/administration, due to the inactivity of an employee is equal to the wage of the latter, which, a priori, is not easy to prove (excepted for IT or auditing companies that have for only purpose to put consultant into contracts). The employee, whether he works or wait will receive most of time the same salary (absurdity but than can be corrected with modern communication technologies). By cons, its contribution to the earnings of the company is really lost as its productivity is lower. When a machine operator is inactive because he is waiting its productive force (which may include, in addition to his wage, a proportion of the company's fixed costs) is lost. In other words, we must consider not only the physical resource that is on hold, but the value (cost) of all inactive economic resources, and then estimate the loss of profit from this lost productivity. Then the objective of the analysis of queues is to find a compromise between the cost associated with the service capacity and cost of waiting customers.

These theories therefore rely on statistics and algebraic methods that we have studied in the sections of Statistics and Graphs Theory. They are just as most exciting.

To introduce the topic, rather than doing an abstract generalization, we chose to develop the theory around a concrete and classic example that is the Teletraffic. A generalization to other case studies then being relatively easily by analogy.

Let us consider, therefore, a central telephone system regrouping the lines of a group of buildings in a city and not having as many lines going to the network as lines going to the different individuals it serves.

So we can legitimately ask how many lines we need to serve all those subscribers?

To dimension its network, an operator will have to calculate the number of resources to implement so that with a probability extremely close to 1, a user who picks up his telephone can have a circuit (connection). To do this, it will be necessary to develop some relations of probability of blocking. These relations will require statistical modelling of the start and end times of calls as well as the durations of these calls. The following paragraphs will introduce the probability laws used to dimension such networks.

Finally, before we begin, we would like to make available the following summary table of the most important notations that the reader will discover as he reads the developments below and to which he can refer in case of confusion:

Variables	**Information**	**Unit**
λ	Incoming flow of customers in the queue (communication), also named "average arrival rate of calls", or "average arrival frequency". The inverse λ^{-1} gives the average time between arrivals (calls) in the queue.	$[h^{-1}]$
μ	Customer exit flow (communication) corresponding to the processing rate. The inverse μ^{-1} gives the average waiting time during the service (thus once arrived at the end of the queue) also named "average service time".	$[h^{-1}]$
A or ρ	Service utilization rate (per server unit). Assimilated to the concept of "traffic" (somewhat abusively) or "load". Is equal to the ratio λ/μ and must be strictly less than 1 to avoid congestion.	-
C	Total number of customers in the system	-
C_Q	Number of customers waiting in the queue	-
C_S	Number of customers in service (processing)	-
T	Waiting time in the system	[s]
T_Q	Waiting time in the queue	[s]
p_k	Probability of having k customers in the system	-

Table 15.83: **Conventional notations in Queuing Theory**

And let us specify that the parameters to be taken into account are often:

- The type of customer arrival process (data)
- The statistical distribution of service time (processing)
- The number of servers (checkouts)
- The capacity of the system (often assumed to be infinite in practice ...)
- The size of the population
- The service discipline

15.4.5.1 $M/M/\ldots$ arrival times modelisation

In this "$M/M/\ldots$ model" whose origins of notation will be explained further below, we consider calls that start randomly. Let us then take a time interval t and divide this interval into n subintervals of duration t/n.

We choose n large enough for the following assumptions (hypothesis) to be respected:

H1. Only one incoming call can occur in an interval t/n

H2. Call arrival times are independent of each other (the arrival rate is not influenced by the number of calls from the population). This presupposes an infinite population.

H3. The probability that a call arrives in a given subinterval is proportional to a constant factor close to the duration of the subinterval.

We then write the probability p_1 of one call in a subinterval (1) as follows:

$$p_1(1)=\lambda\frac{t}{n} \qquad (15.4.282)$$

Where the 1 in index of the p represents the analysis on 1 call, the 1 between brackets the fact that the analysis is done on 1 subinterval and finally the term λ represents the coefficient of proportionality between the probability and the duration t/n of the subinterval.

The starting hypothesis of considering as zero the probability of having several calls in a subinterval is then written:

$$p_2(1)+p_3(1)+\cdots+p_n(1)+\cdots=\sum_{k=2}^{+\infty}p_k(1)=0 \qquad (15.4.283)$$

The probability of having no call during a sub-interval of time t/n is thus written:

$$p_0(1)=1-\sum_{k=1}^{+\infty}p_k(1) \qquad (15.4.284)$$

By developing, we get:

$$p_0(1)=1-p_1(1)-\sum_{k=2}^{+\infty}p_k(1) \qquad (15.4.285)$$

and using the property defined just above:

$$p_0(1)=1-p_1(1) \qquad (15.4.286)$$

The probability of having k calls arriving during n time intervals is then obtained by considering the number of ways to choose k intervals among n... (since there can not be more than one call per interval).

For each of these solutions, we will then necessarily have k intervals with a single incoming call and $n-k$ intervals with no incoming call. We have seen in the section Statistics that the law which made it possible to get the probability of choosing a certain arrangement of binary issues from a total number of issues was Bernoulli's law given by:

$$P=p^kq^{n-k} \tag{15.4.287}$$

It therefore comes in our case that the probability of one of the solutions will be:

$$p_1(1)^kp_0(1)^{n-k} \tag{15.4.288}$$

The global probability is obtained by summing the probabilities of all the cases, which gives us the binomial law (see section Statistics page 658):

$$p_k(n)=\frac{n!}{k!(n-k)!}p_1(1)^kp_0(1)^{n-k}=C_k^np_1(1)^kp_0(1)^{n-k} \tag{15.4.289}$$

Or, by replacing the probabilities by their values as a function of λ, t, n:

$$p_k(n)=C_k^n\left(\lambda\frac{t}{n}\right)^k\left(1-\lambda\frac{t}{n}\right)^{n-k} \tag{15.4.290}$$

The limit of the probability $p_k(n)$ when n tends to infinity will be equal to the probability of having k call arrivals during a time interval t. We denote by p_k this probability:

$$p_k=\lim_{n\to+\infty}p_k(n) \tag{15.4.291}$$

Then, taking up the different terms of the expression of $p_k(n)$, it comes:

$$\left(1-\lambda\frac{t}{n}\right)^{n-k}=\left(e^{\ln\left(1-\lambda\frac{t}{n}\right)}\right)^{n-k}=e^{(n-k)\ln\left(1-\lambda\frac{t}{n}\right)} \tag{15.4.292}$$

Using the Taylor developments (see section Sequences and Series page 1703):

$$\ln(1+x)=\sum_{n=1}^{+\infty}\frac{(-1)^{n+1}}{n}x^n \tag{15.4.293}$$

Either by taking only the first term, that is, considering x very small:

$$\ln(1+x)\cong x \tag{15.4.294}$$

Therefore:

$$e^{(n-k)\ln\left(1-\lambda\frac{t}{n}\right)}\underset{n\to+\infty}{\cong}e^{(n-k)\left(-\lambda\frac{t}{n}\right)}=e^{-\lambda t-\frac{k}{n}\lambda t}\underset{n\to+\infty}{\cong}e^{-\lambda t} \tag{15.4.295}$$

And for the last part:

$$\begin{aligned}C_k^n\left(\frac{\lambda t}{n}\right)^k&=\frac{n!}{k!(n-k)!}\frac{(\lambda t)^k}{n^k}=\frac{(\lambda t)^k}{k!}\frac{n!}{(n-k)!n^k}\\&=\frac{(\lambda t)^k}{k!}\frac{n(n-1)(n-2)\ldots(n-k+1)}{n^k}\underset{n\to+\infty}{\cong}\frac{(\lambda t)^k}{k!}\end{aligned} \tag{15.4.296}$$

hence after grouping:

$$\boxed{p_k\cong\frac{(\lambda t)^k}{k!}e^{-\lambda t}} \tag{15.4.297}$$

This distribution function is therefore extremely important, since it represents the probability of observing k calls arriving in an interval of duration t (or the probability of observing k customers that are in front of a checkout or server in an interval of duration t) and it is therefore a Poisson distribution (see section Statistics page 686). In practice, it is therefore necessary to ensure before using the relation that will follow in the further developments that this distribution is well respected (with a Chi-square test typically).

Let us consider now the distribution function, named the "Erlang distribution function", which for a given time interval t gives the cumulative probability of having a number k of arrivals greater than or equal to n:

$$F(t,k)=\sum_{k=n}^{+\infty}\frac{(\lambda t)^k}{k!}e^{-\lambda t} \tag{15.4.298}$$

If we derive this function with respect to t this gives the "Erlang distribution function" (the reader may have noticed perhaps that in the penultimate line we thus find an example for the field of Management of the concept of "telescoping series" which had been introduced in the section of Sequences and Series at page 1691):

$$\begin{aligned}\frac{\mathrm{d}F(t,k)}{\mathrm{d}t}&=\frac{\mathrm{d}}{\mathrm{d}t}\sum_{k=n}^{+\infty}\frac{(\lambda t)^k}{k!}e^{-\lambda t}=\sum_{k=n}^{+\infty}\frac{k\lambda(\lambda t)^{k-1}}{k!}e^{-\lambda t}-\sum_{k=n}^{+\infty}\frac{(\lambda t)^k}{k!}\lambda e^{-\lambda t}\\&=\sum_{k=n}^{+\infty}\frac{(\lambda t)^{k-1}}{(k-1)!}\lambda e^{-\lambda t}-\sum_{k=n}^{+\infty}\frac{(\lambda t)^k}{k!}\lambda e^{-\lambda t}=\lambda e^{-\lambda t}\left(\sum_{k=n}^{+\infty}\frac{(\lambda t)^{k-1}}{(k-1)!}-\sum_{k=n}^{+\infty}\frac{(\lambda t)^k}{k!}\right)\\&=\lambda e^{-\lambda t}\sum_{k=n}^{+\infty}\left(\frac{(\lambda t)^{k-1}}{(k-1)!}-\frac{(\lambda t)^k}{k!}\right)=\frac{(\lambda t)^{n-1}}{(n-1)!}\lambda e^{-\lambda t}\end{aligned} \tag{15.4.299}$$

and thus we fall back on a particular form of the distribution function of the Gamma law introduced in the section of Statistics (see page 767). Let us recall the equivalence already presented in the section of Statistics (see page 773) with Microsoft® Excel® 14.0.6123 between the Poisson law, the Chi-2 law and the Gamma law:

=POISSON.DIST($x\in\mathbb{N}$,μ,TRUE)
=1-CHISQ.DIST($2*\mu$,$2*(x+1)$,TRUE)
=1-GAMMA.DIST(μ,$x+1$,1TRUE)

It follows by analogy with the general form of the Poisson law that the parameter λ is the average arrival rate (mean rate of calls) per unit of time (or "Poisson Arrivals See Time Average": PASTA ...). Typically this will be an average number of calls per second (see the Poisson law estimators in the section Statistics at page 825).

Thus, we have for the mean and variance (see section Statistics page 686) the number of calls:

$$\boxed{\mathrm{E}(k)=\lambda\cdot t\qquad\mathrm{V}(k)=\lambda\cdot t} \tag{15.4.300}$$

When the model consider a constant event occurrence rate λ we then speak of "homogeneous Poisson process" (HPP).

✍**Example:**

A very small company wishing to set up a hotline estimates that at the beginning it will receive 8 phone calls per day (i.e. a probability of 1 chance out of 2 to have one call per hour and therefore an average rate λ of 0.5 calls per hour). Then the probability that it receives exactly 4 calls (k) per day and at least 4 calls (k) per day according to the theoretical model of the queuing theory is:

$$\begin{aligned}
p_k(k=4) &\cong \frac{(0.5\cdot 8)^4}{4!}e^{-0.5\cdot 8}=\texttt{POISSON.DIST(4,0.5*8,FALSE)}=19.55\%\\
p_k(k\leq 4) &\cong \sum_{k=0}^{4}\frac{(0.5\cdot 8)^k}{k!}e^{-0.5\cdot 8}=\texttt{POISSON.DIST(4,0.5*8,FALSE)}=62.88\%
\end{aligned}\tag{15.4.301}$$

Where we used the function `POISSON.DIST()` embedded in Microsoft® Excel® 14.0.6123.

Now let us introduce the random variable τ representing the time between two call arrivals. We define for this the probability $A(t)$ which is the probability that the time τ is less than or equal to a value t:

$$A(t)=P(\tau\leq t)\tag{15.4.302}$$

We therefore have:

$$A(t)=1-P(\tau>t)\tag{15.4.303}$$

But, $P(\tau>t)$ represents the cumulative probability that there is no arrival of calls during a time t. This cumulative probability was precisely established above:

$$P(\tau>t)=p_0=\frac{(\lambda t)^0}{0!}e^{-\lambda t}=e^{-\lambda t}\tag{15.4.304}$$

From this we deduce:

$$A(t)=1-e^{-\lambda t}\tag{15.4.305}$$

It is therefore the function of distribution of an exponential law! We can also introduce the probability density of the random variable τ. We thus get:

$$a(t)=\frac{\partial A(t)}{\partial t}=\lambda e^{-\lambda t}\tag{15.4.306}$$

Remark

Let us recall that in the section Statistics, we often did the opposite reasoning. That is to say, given a probability density $a(t)$, we sought the distribution function $A(t)$ through an integration on the domain of definition of the random variable.

The probability density thus makes it possible to calculate the expected mean duration between two call arrivals:

$$\bar{\tau}=\mathrm{E}(\tau)=\int\limits_0^{+\infty}t\cdot a(t)\mathrm{d}t=\int\limits_0^{+\infty}\lambda t e^{-\lambda t}\mathrm{d}t\tag{15.4.307}$$

By integrating by parts, it comes:

$$\mathrm{E}(\tau)=\lambda t\cdot\frac{-1}{\lambda}e^{-\lambda t}\Bigg|_0^{+\infty}+\int\limits_0^{+\infty}\lambda\frac{-1}{\lambda}e^{-\lambda t}\mathrm{d}t=-\int\limits_0^{+\infty}e^{-\lambda t}\mathrm{d}t=\frac{1}{\lambda}\tag{15.4.308}$$

We thus obtain that, for an arrival rate of λ calls, that the expected mean time between calls is equal to $1/\lambda$ (a relatively logical result but still had to be rigorously proved). Indeed, if we have λ that is worth 2 calls per hour, the average arrival time is indeed 0.5 hours $(1/2)$ between calls.

Let us now suppose that no call has arrived until a time t_0 and we want to calculate the probability that a call arrives during a time t after the time t_0

We must therefore calculate the probability of having a duration between two calls less than $t+t_0$ while being greater than t_0

This probability is written $P(\tau\leq t+t_0|\tau>t_0)$. Using the Bayes formula (see section Probabilities page 492):

$$P(B/A)=\frac{P(B\cap A)}{P(A)}\tag{15.4.309}$$

But with the appropriate notations, it comes:

$$P(\tau\leq t+t_0|\tau>t_0)=\frac{P(t_0<\tau\leq t+t_0)}{P(\tau>t_0)}\tag{15.4.310}$$

This probability can also be written:

$$P(\tau\leq t+t_0|\tau>t_0)=\frac{P(\tau\leq t+t_0)-P(\tau\leq t_0)}{P(\tau>t_0)}=\frac{P(\tau\leq t+t_0)-P(\tau\leq t_0)}{1-P(\tau\leq t_0)}\tag{15.4.311}$$

By taking the expressions of the different probabilities:

$$\begin{aligned}P(\tau\leq t+t_0|\tau>t_0)&=\frac{\left(1-e^{-\lambda(t+t_0)}\right)-\left(1-e^{-\lambda t_0}\right)}{1-\left(1-e^{-\lambda t_0}\right)}=\frac{-e^{-\lambda(t+t_0)}+e^{-\lambda t_0}}{e^{-\lambda t_0}}\\&=\frac{-e^{-\lambda t}e^{-\lambda t_0}+e^{-\lambda t_0}}{e^{-\lambda t_0}}=-e^{-\lambda t}+1=1-e^{-\lambda t}\end{aligned}\tag{15.4.312}$$

We thus see that the probability of occurrence of a call during a time t after a duration t_0 during which none has occurred is the same as the probability of occurrence of a call for a duration t, independent of what happened before. We therefore consider that the phenomenon (the exponential law) is "without memory".

15.4.5.2 $M/M/\ldots$ service times modelisation

In this model $M/M/\ldots$ for which we will explain again the origin of the notation later, we will study the probability laws that models the durations of the calls (implicitly: in service once the end of the queue reached). To do this, we proceed as before.

We therefore consider a time interval of duration t which we decompose into n subintervals of duration t/n. We choose n so that the following assumptions remain justified:

H1. The probability that a call terminates during a subinterval is proportional to the duration of that subinterval.

We will denote:

$$\mu\frac{t}{n} \tag{15.4.313}$$

this probability, in which μ represents the coefficient of proportionality.

H2. The probability of a call terminating during a subinterval is independent of the subinterval considered.

We then introduce the random variable θ representing the duration of a call and the probability $H(t)$that the duration of a call is less than or equal to t:

$$H(t)=P(\theta\leq t) \tag{15.4.314}$$

The probability that a call that started at $t=0$ does not end before t is then written:

$$P(\theta>t)=1-H(t) \tag{15.4.315}$$

This probability is equal to the probability that the call does not end in any of the n subintervals of duration t/n:

$$1-H(t)=\left(1-\mu\frac{t}{n}\right)^n \tag{15.4.316}$$

By taking n towards infinity, we get:

$$1-H(t)=\lim_{n\rightarrow+\infty}\left(1-\mu\frac{t}{n}\right)^n=\lim_{n\rightarrow+\infty}e^{n\ln\left(1-\mu\frac{t}{n}\right)}\cong\lim_{n\rightarrow+\infty}e^{n\left(1-\mu\frac{t}{n}\right)}=e^{-\mu t} \tag{15.4.317}$$

We thus obtain the expression of the probability that a call has a duration less than or equal to t:

$$H(t)=1-e^{-\mu t} \tag{15.4.318}$$

We can deduce the associated probability density, denoted $h(t)$:

$$\boxed{h(t)=\frac{\partial H(t)}{\partial t}=\mu e^{-\mu t}} \tag{15.4.319}$$

which corresponds to an exponential law (the time that a customer use to be served at a check-out or server - period of service - or so that his call is processed once at the end of the queue, follows then an exponential law!). In practice, it is therefore necessary to ensure before using the relations that follow that this distribution is well respected (with a Chi-square test typically).

In the same way as in the preceding paragraphs, the average call duration (average time between two ends of calls in service) is obtained by calculating (always the same integration by parts as above):

$$\bar{\theta}=\mathrm{E}(\theta)=\int\limits_{0}^{+\infty} th(t)\mathrm{d}t=\frac{1}{\mu} \tag{15.4.320}$$

In conclusion, we have μ calls that cease per second and we have an expected mean call duration in service equal to:

$$\frac{1}{\mu} \tag{15.4.321}$$

Indeed, if we have, for example, 2 calls in-service that stop per hour, this gives us an average time of 0.5 hour $(1/2)$ of service per call.

The ratio:

$$A=\frac{\lambda}{\mu} \tag{15.4.322}$$

represents therefore the number of calls that appear in the queue on the number of calls in service that end during the same time interval (mean service time), that is, it simply represents the traffic (or in other words, the "traffic intensity") or from another point of view the average use of the service whose unit is the "Erlang" (we will recall this definition several times thereafter...).

✍**Example:**

In a store, there are 240 customers per hour and it takes an average of 28 seconds to process a customer (average service time). Knowing that the length of service follows an exponential law and the distribution of arrivals a Poisson law, what is the intensity of the traffic and the rate of occupation of the check-out stations if the store has only two of them?

The traffic is therefore given by the number of customers per hour divided by the number of customers processed per hour. As it takes 28 seconds to process one and there are $3,600$ seconds in an hour, we have the following traffic intensity:

$$A=\frac{240}{\dfrac{3'600}{28}}=1.866\,[\,\text{Erlangs}] \tag{15.4.323}$$

The average load (or occupancy rate) per check-out station (server), knowing that there are two of them, is therefore:

$$\frac{1.866}{2}=0.93=93\% \tag{15.4.324}$$

It is this latter value which will ultimately be taken as the value of traffic A per station (check-out/server) for subsequent calculations.

The probabilities of appearance of calls and end of calls that have been developed in the preceding paragraphs make it possible to model the complete process of appearance and end of calls.

15.4.5.3 Kendall queues notation

A notation was developed by D. G. Kendall in 11953 (holocene calendar) to represent the queues following the intensive (and numerous) developments of the mathematical models concerning them. The reduced form of this notation named "Kendall notation" or "Kendall-Lee notation" is:

$$\boxed{A/B/C}$$

where:

- A is the customer arrival process in the system (distribution interarrival law)
- B is the distribution of the service time of the customers in the system (distribution law)
- C is the number of servers in the system.

Common notations for A are:

- M for Markovian or memoryless arrival Poisson time process
- G general distribution (any arbitrary distribution allowed)
- E_k Erlang distribution

Common notations for B are:

- M for Markovian or memoryless arrival exponential time process
- G general distribution (any arbitrary distribution allowed)
- E_k Erlang distribution

For example, the $M/M/1$ notation means that the clients arrive in the system according to a Poisson distribution modelled by a Markov chain (see section Probabilities page 537), that the processing time follows an exponential distribution (modelled by a Markov chain as well) and the system consisting of a single server based on a first-in first-out principle (FIFO) in an infinite-population and steady-state queue. This corresponds respectively to the three following relations which we have proved above for the probability of arrival of k calls in a given time:

$$p_k \cong \frac{(\lambda t)^k}{k!}e^{-\lambda t} \tag{15.4.325}$$

The probability that the processing time (service time) is equal to a certain value:

$$h(t)=\mu e^{-\mu t} \tag{15.4.326}$$

and the probability of having k customer (communications):

$$p_k=A^k(1-A) \tag{15.4.327}$$

In general, we use the notation:

$$\boxed{A/B/C:d/e/f}$$

where:

- d is the capacity of the system, or the maximum number of customers allowed in the system including those in service. When the number is at this maximum, further arrivals are turned away. If this number is omitted, the capacity is assumed to be unlimited, or infinite.
- e is the service discipline or priority order that jobs in the queue, or waiting line, are served (see examples further below)
- f is the size of calling source. The size of the population from which the customers come. If this number is omitted, the population is assumed to be unlimited, or infinite.

The parameter of queue's discipline e has typically the following properties:

- FIFO/FCFS (First In First Out/First Come First Served): The customers are served in the order they arrived in.
- LIFO/LCFS (Last in First Out/Last Come First Served): The customers are served in the reverse order to the order they arrived in.
- SIRO (Service In Random Order): The customers are served in a random order with no regard to arrival order.
- SJF (Shortest Job First): The customer with shortest ranked treatments are served before
- ...

If this parameter is omitted, the discipline is assumed to be a FIFO one.

Thus, $M/M/1$ would be written without omitting anything in our study case above:

$$M/M/1:\infty/\text{FIFO}/\infty$$

We also find variants in the literature of the definition above which does not always help in the reading of various textbooks about the subject (absence of ISO standards doesn't help)...

15.4.5.4 Modelling of arrivals and departures $M/M/1$

At every instant a certain number of calls will appear and others will end. We can therefore model the state where we are at a given moment as a chain of states.

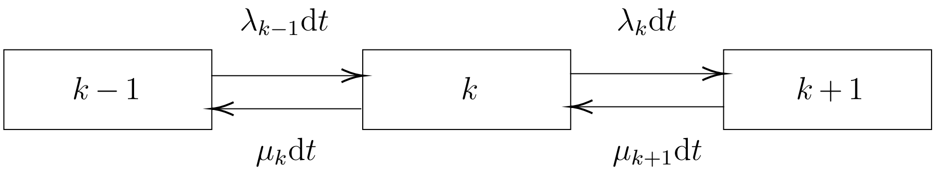
Each state represents the number of calls in progress. We therefore conceive that if at a given instant there are k calls, we can pass only in two adjacent states according to our hypotheses: $k-1$ and $k+1$.

We then recognize a Markov chain (see section Probabilities page 537). The probability of going from a state i to a state j during a time $\mathrm{d}t$ will therefore be denoted:

$$p_{ij}(\mathrm{d}t) \tag{15.4.328}$$

We then introduce the following state transition probabilities:

- Being in state k, the probability $p_{k,k+1}(\mathrm{d}t)$ to go to the state $k+1$ during a time interval $\mathrm{d}t$ will be denoted $\lambda_k \mathrm{d}t$
- Being in state k, the probability $p_{k,k-1}(\mathrm{d}t)$ to go to the state $k-1$ during a time interval $\mathrm{d}t$ will be denoted $\mu_k \mathrm{d}t$
- Being in the state $k+1$, the probability $p_{k+1,k}(\mathrm{d}t)$ to pass to the state k during a time interval $\mathrm{d}t$ will be denoted $\mu_{k+1}\mathrm{d}t$
- Being in the state $k-1$, the probability $p_{k-1,k}(\mathrm{d}t)$ to go to state k during a time interval $\mathrm{d}t$ will be denoted $\lambda_{k-1}\mathrm{d}t$



The quantities λ_k and μ_k are rates of arrival (appearance) and departure (end) of calls of the same type as those used in the preceding paragraphs. The only difference is that these rates have in index the state in which the system is.

We can then introduce the state probability, that is, the probability of being in a state k at time t. Let us denoted $p_k(1)$ this probability (to be compared with the notation $p_j(n)$ used for the discrete-time Markov chains in the section of Probabilities).

The variation of this probability during a time interval $\mathrm{d}t$ is then equal to the probability of joining this state from a state $k-1$ or a state $k+1$ minus the probability of leaving this state to go to a state $k-1$ or to a state $k+1$.

What is written:

$$\frac{\mathrm{d}p_k(t)}{\mathrm{d}t} = \lambda_{k-1}p_{k-1}(t) + \mu_{k+1}p_{k+1}(t) - (\lambda_k + \mu_k)\,p_k(t) \tag{15.4.329}$$

Assuming the system stable, that is, assuming that it stabilizes on fixed state probabilities when time tends to infinity, we can write that:

$$\lim_{t\to+\infty}\frac{\mathrm{d}p_k(t)}{\mathrm{d}t}=0 \tag{15.4.330}$$

We can then denote $p_k=p_k(t)$ hence finally:

$$\lambda_{k-1}p_{k-1}(t)+\mu_{k+1}p_{k+1}(t)-(\lambda_k+\mu_k)\,p_k(t)=0 \tag{15.4.331}$$

We could have introduced this last relation in another way: It simply expresses the fact that the probability of starting from a state is equal to that to arrive at it (it is perhaps more simple like this).

This relation is satisfied for any $k\geq 0$ with the following mathematical conditions (because otherwise these terms have no mathematical meaning):

$$p_{-1}=0 \qquad \lambda_{-1}=0 \tag{15.4.332}$$

and the following real logical condition (calls not yet existing can not end...):

$$\mu_0=0 \tag{15.4.333}$$

Remark

Let us emphasize that the stability of probabilities means that there is an equal probability p_k of leaving the state that to join it.

By using (see above):

$$\lambda_{k-1}p_{k-1}(t)+\mu_{k+1}p_{k+1}(t)-(\lambda_k+\mu_k)\,p_k(t)=0 \tag{15.4.334}$$

we get therefore:

$$\begin{aligned}
&p_1=\frac{\lambda_0}{\lambda_1}p_0\\
&p_2=\frac{1}{\mu_2}\left[(\lambda_1+\mu_1)\frac{\lambda_0}{\mu_1}p_0-\lambda_0p_0\right]=\frac{\lambda_1\lambda_0}{\mu_2\mu_1}p_0\\
&p_3=\frac{1}{\mu_3}\left[(\lambda_2+\mu_2)\frac{\lambda_1\lambda_0}{\mu_2\mu_1}p_0-\lambda_1\frac{\lambda_0}{\mu_1}p_0\right]=\frac{\lambda_2\lambda_1\lambda_0}{\mu_3\mu_2\mu_1}p_0\\
&\ldots
\end{aligned} \tag{15.4.335}$$

We then find quite easily the general form:

$$p_k=\left(\prod_{i=0}^{k-1}\frac{\lambda_i}{\mu_{i+1}}\right)p_0 \tag{15.4.336}$$

Since the system is necessarily in one of the states, we have the following relation which must be satisfied:

$$\sum_{k=0}^{+\infty}p_k=1 \tag{15.4.337}$$

By replacing with the antecedent relationship:

$$\sum_{k=0}^{+\infty}\left(\prod_{i=0}^{k-1}\frac{\lambda_i}{\mu_{i+1}}\right)p_0=1 \tag{15.4.338}$$

This also gives:

$$p_0+\sum_{k=1}^{+\infty}\left(\prod_{i=0}^{k-1}\frac{\lambda_i}{\mu_{i+1}}\right)p_0=1 \tag{15.4.339}$$

and therefore:

$$p_0=\frac{1}{1+\displaystyle\sum_{k=1}^{+\infty}\left(\prod_{i=0}^{k-1}\frac{\lambda_i}{\mu_{i+1}}\right)} \tag{15.4.340}$$

If we now consider a system with a single line and infinite capacity (steady state), the quantities λ_k (call arrival rate) and μ_k (call departure rates) will have identical values for all k. That is, we consider that the arrival rate and the starting rate are constant regardless of the position in which the queue is located. We then have the last relation which simplifies:

$$p_0=\frac{1}{1+\displaystyle\sum_{k=1}^{+\infty}\left(\prod_{i=0}^{k-1}\frac{\lambda_i}{\mu_{i+1}}\right)}=\frac{1}{1+\displaystyle\sum_{k=1}^{+\infty}\left(\frac{\lambda}{\mu}\right)^k} \tag{15.4.341}$$

Using the result proved in the section Sequences and Series (Gauss series see at page 1666) we have under precise necessary conditions of convergence (A must be strictly smaller than 1):

$$p_0=\frac{1}{1+\displaystyle\sum_{k=1}^{+\infty}\left(\frac{\lambda}{\mu}\right)^k}=\frac{1}{\displaystyle\sum_{k=0}^{+\infty}\frac{1}{\left(\dfrac{\lambda}{\mu}\right)^k}}=\frac{1}{\dfrac{1}{1-\dfrac{1}{\dfrac{\mu}{\lambda}}}}=\frac{1}{\dfrac{1}{1-\frac{\lambda}{\mu}}}=1-\frac{\lambda}{\mu}=1-A \tag{15.4.342}$$

Since k represents the number of calls, this last relation gives the probability of having 0 calls (clients) for a given permanent traffic A on the line.

Using:

$$p_k=\left(\prod_{i=0}^{k-1}\frac{\lambda_i}{\mu_{i+1}}\right)p_0 \tag{15.4.343}$$

We then have in generality for this type of system the probability of having k calls in steady state which is given by:

$$p_k=\left(\frac{\lambda}{\mu}\right)^k(1-A)=A^k(1-A) \tag{15.4.344}$$

It follows that the expected mean of number of communications (clients) in the system (in the queue + in service) is then by definition of the expected mean:

$$\mathrm{E}(C)\sum_{k=0}^{+\infty}k\cdot p_k=\sum_{k=0}^{+\infty}kA^k(1-A)=(1-A)\sum_{k=0}^{+\infty}kA^k \tag{15.4.345}$$

since p_k represents the probability that there are k calls in the system at any time (queue + in service). However, we have seen in the section of Sequences and Series that:

$$\sum_{i=0}^{n} q^i = \frac{1-q^{n+1}}{1-q} \tag{15.4.346}$$

and if q is strictly less than 1 and n tends to infinity, we immediately have:

$$\sum_{i=0}^{+\infty} q^i = \frac{1}{1-q} \tag{15.4.347}$$

If we derive this last relation:

$$\frac{\mathrm{d}}{\mathrm{d}q}\sum_{i=0}^{+\infty} q^i = \sum_{i=0}^{+\infty} iq^{i-1} = \frac{1}{(1-q)^2} \tag{15.4.348}$$

and by multiplying by q then it comes:

$$q\frac{\mathrm{d}}{\mathrm{d}q}\sum_{i=0}^{+\infty} iq^{i-1} = \sum_{i=0}^{+\infty} iq^{i} = \frac{q}{(1-q)^2} \tag{15.4.349}$$

It then comes to the end for the expected mean of the number of customers in the system:

$$\mathrm{E}(C) = (1-A)\sum_{i=0}^{+\infty} kA^k = (1-A)\sum_{i=1}^{+\infty} kA^k = (1-A)\frac{A}{(1-A)^2} = \frac{A}{1-A} \tag{15.4.350}$$

If we want to know the expected mean of the number of customers waiting in the queue only, we must understand that at every moment we have a probability p_k that there are k customers in the system but as 1 among these is always in service (i.e. out of the queue), we still have $k-1$ really waiting in the queue. Therefore:

$$\begin{aligned}\mathrm{E}(C_Q) &= \sum_{k=0}^{+\infty}(k-1)p_k = \sum_{k=1}^{+\infty} kp_k - \sum_{k=1}^{+\infty} p_k = (1-A)\sum_{k=1}^{+\infty} kA^k - (1-p_0)\\ &= \frac{A}{1-A} - A = \frac{A}{1-A} - \frac{A(1-A)}{1-A} = \frac{A-A+A^2}{1-A} = \frac{A^2}{1-A}\end{aligned} \tag{15.4.351}$$

Knowing the number of communications (or customers) we have on the single line throughout the system, we then have the expected mean of the waiting time (average waiting time), denoted $\mathrm{E}(T)$ which will be given by the ratio of the expected mean of the number of communications (customers) $\mathrm{E}(C)$ in steady state on line by the arrival rate of the calls:

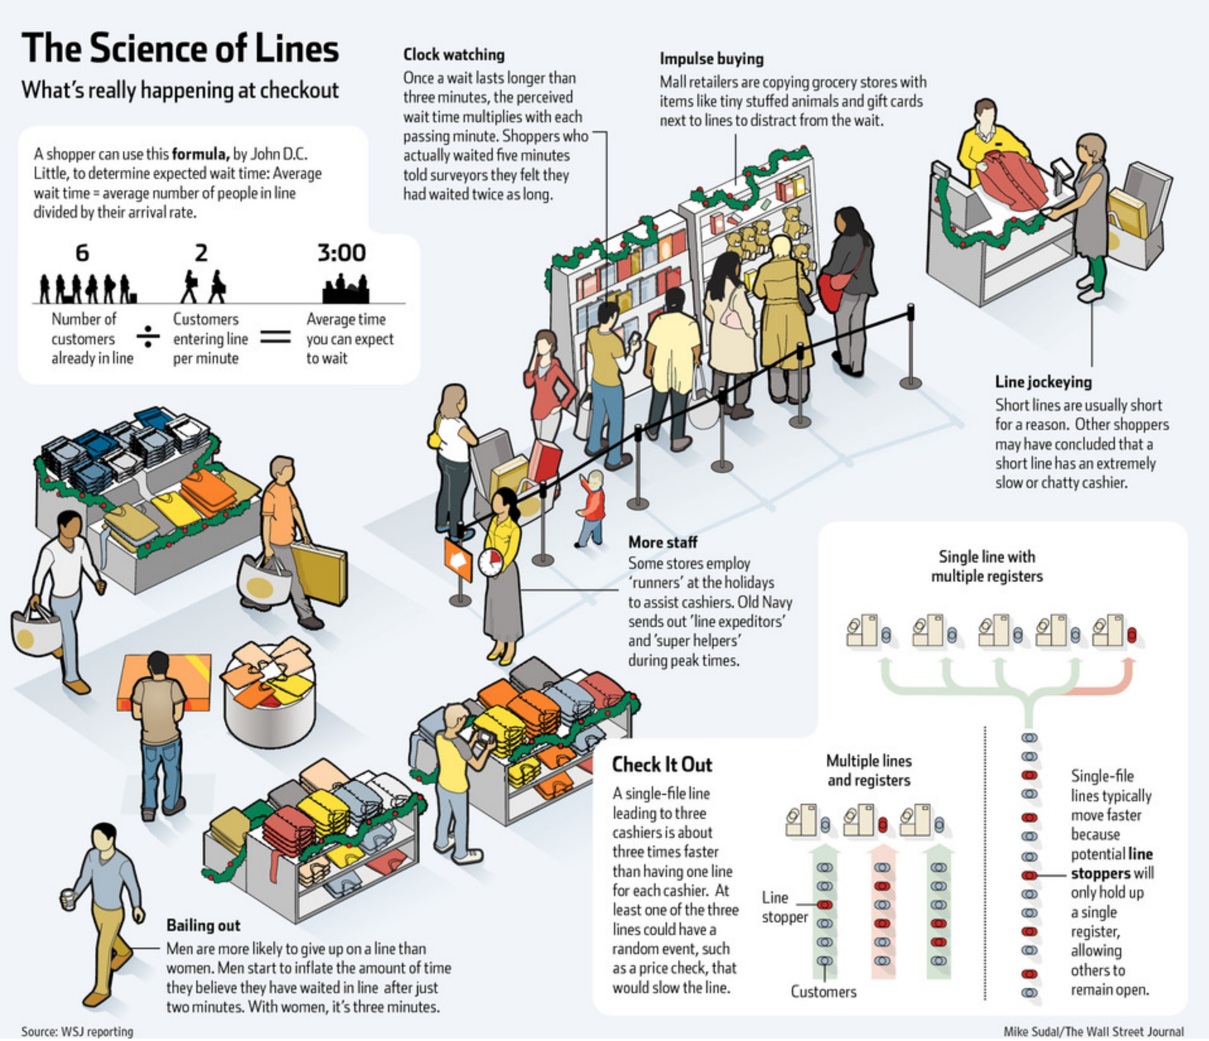
$$\mathrm{E}(T) = \frac{\mathrm{E}(C)}{\lambda} \tag{15.4.352}$$

and often written in textbooks as:

$$\boxed{L = \lambda W} \tag{15.4.353}$$

that is to say long-term average number of customers in a stable system L is equal to the long-term average effective arrival rate, λ, multiplied by the average time a customer spends in the system, W.

This result, named "Little's law" (John Little having strictly demonstrated that the relation is valid for any type of queue), is intuitive in this case. Actually, let's take a random call. When it arrives in the system, it will be statistically facing $\mathrm{E}(C)$ customers waiting. When it leaves the system, there will have been in it an average time $\mathrm{E}(T)$. So during this mean time, $\lambda\mathrm{E}(T)$ calls will have arrived behind him in the system. In steady state, the number of calls left behind on departure must equal the number of arrivals. Hence the equality $\lambda\mathrm{E}(T)=\mathrm{E}(C)$ from which we then deduce immediately the Little's law.



The Science of Lines
What's really happening at checkout
A shopper can use this formula, by John D.C. Little, to determine expected wait time: Average wait time = average number of people in line divided by their arrival rate.
6
2
3:00
Number of customers already in line
÷
Customers entering line per minute
=
Average time you can expect to wait
Clock watching
Once a wait lasts longer than three minutes, the perceived wait time multiplies with each passing minute. Shoppers who actually waited five minutes told surveyors they felt they had waited twice as long.
Impulse buying
Mall retailers are copying grocery stores with items like tiny stuffed animals and gift cards next to lines to distract from the wait.
Line jockeying
Short lines are usually short for a reason. Other shoppers may have concluded that a short line has an extremely slow or chatty cashier.
More staff
Some stores employ 'runners' at the holidays to assist cashiers. Old Navy sends out 'line expeditors' and 'super helpers' during peak times.
Single line with multiple registers
Check It Out
A single-file line leading to three cashiers is about three times faster than having one line for each cashier. At least one of the three lines could have a random event, such as a price check, that would slow the line.
Multiple lines and registers
Line stopper
Customers
Single-file lines typically move faster because potential **line stoppers** will only hold up a single register, allowing others to remain open.
Bailing out
Men are more likely to give up on a line than women. Men start to inflate the amount of time they believe they have waited in line after just two minutes. With women, it's three minutes.
Source: WSJ reporting
Mike Sudal/The Wall Street Journal

Figure 15.316: **The science of lines (source: The Wall Street Journal)**

We then have for the expected mean of waiting time in the system:

$$\mathrm{E}(T)=\frac{\mathrm{E}(C)}{\lambda}=\frac{\dfrac{A}{1-A}}{\lambda}=\frac{A}{\lambda(1-A)}=\frac{\dfrac{\lambda}{\mu}}{\lambda\left(1-\dfrac{\lambda}{\mu}\right)}=\frac{1}{\dfrac{\mu}{\lambda}\lambda\left(1-\dfrac{\lambda}{\mu}\right)}=\frac{1}{\mu-\lambda}\qquad(15.4.354)$$

To determine the waiting time in the queue only, it is sufficient to subtract the processing /

service time from the linearity property of the mean (average call duration in service):

$$\mathrm{E}(T_Q)=\mathrm{E}(T)-\frac{1}{\mu}=\frac{1}{\mu-\lambda}-\frac{1}{\mu}=\frac{1}{\mu}\left(\frac{1}{1-A}-1\right)=\frac{1}{\mu}\left(\frac{1-1+A}{1-A}\right)=\frac{1}{\mu}\left(\frac{A}{1-A}\right) \tag{15.4.355}$$

that we often found in the literature in the following form:

$$W_Q=\frac{1}{\mu-\lambda}-\frac{1}{\mu}=\frac{\lambda}{\mu(\mu-\lambda)} \tag{15.4.356}$$

If there are n servers (or cashiers) we don't change the value of μ as from the point of view of one customer that has to choose ONE server (or cashier) the fact that there are more than 1 server (or cashier) does not influence the fact the he has to pass anyway by one of the server (or cashier), but we divide λ by n as if the servers are equiprobably chosen by the customers he can divide the number of customers arriving customers by the number of cashiers such that:

$$\boxed{W_Q=\frac{\dfrac{\lambda}{n}}{\mu\left(\mu-\dfrac{\lambda}{n}\right)}} \tag{15.4.357}$$

with the condition that (otherwise the expected mean will be negative):

$$\frac{\lambda}{\mu}<n \tag{15.4.358}$$

✍**Example:**

If we have $n=3$ (cashiers), $\lambda=1/2$ per minute (30 customers arriving per hour), and $\mu=1/5$ per minute (customers rate served by each cashier equal to 12 customers served per hour) then:

$$W_Q=\frac{\dfrac{\lambda}{n}}{\mu\left(\mu-\dfrac{\lambda}{n}\right)}=25\,[\text{minutes}] \tag{15.4.359}$$

To summarize, since there are many parameters and results, we have for a type $M/M/1$ queue (according to the Kendall notation):

Information	$M/M/1$
Probability of empty system	$1-A$
Waiting probability	A
Number of customers in the system	$\mathrm{E}(C)=\dfrac{A}{1-A}$
Average number of customers in the system	$\mathrm{E}(C_Q)=\dfrac{A^2}{1-A}$
Number of customers in service (treatment)	$A=\dfrac{\lambda}{\mu}$
Average time in the whole system	$\mathrm{E}(T)=\dfrac{\mathrm{E}(C)}{\lambda}=\dfrac{1}{\mu-\lambda}$
Average time in the queue	$\mathrm{E}(T_Q)=\dfrac{1}{\mu}\left(\dfrac{A}{1-A}\right)$
Condition of equilibrium (for one server!)	$\dfrac{\lambda}{\mu}<1$
Probability of having k customers	$p_k=A^k(1-A)$

Table 15.84: $M/M/1$ **queue summary of important relations**

We see that some relations diverge to infinity when the permanent traffic A tends to unity. This is why we had imposed above that this parameter is strictly less than unity!

We should for each possible type of queue, detail the proof of the corresponding relation above, which is long and laborious (it is a job/specialization on its own right and there are really good textbooks of more than 400 pages on the subject like [415]).

✍**Example:**

Let us consider that we have a numerical control machine processing parts one at a time. Assume that $\lambda=8$ parts per hour (number of pieces arriving on average per hour) and that $\mu=10$ parts per hour (number of pieces coming out on average per hour). We have then:

$$A=\frac{\lambda}{\mu}=\frac{8}{10}=80\% \tag{15.4.360}$$

Which corresponds to the traffic or occupancy rate of the machine.

The expected number of parts in the system (machine + queue) is given by:

$$\mathrm{E}(C)=\frac{A}{1-A}=\frac{0.8}{1-0.8}=4 \tag{15.4.361}$$

The expected number of parts waiting in the queue only is given by:

$$\mathrm{E}(C_Q)=\frac{A^2}{1-A}=\frac{0.8^2}{1-0.8}=3.2 \tag{15.4.362}$$

The expected waiting time in the system is given by:

$$\mathrm{E}(T)=\frac{1}{\mu-\lambda}=\frac{1}{10-8}=0.5 \tag{15.4.363}$$

that is to say 30 minutes.

The expected waiting time in the queue only is given by:

$$\mathrm{E}(T_Q)=\frac{1}{\mu}\left(\frac{A}{1-A}\right)=\frac{1}{10}\left(\frac{0.8}{1-0.8}\right)=0.4 \qquad (15.4.364)$$

that is to say 24 minutes.

And the probability that there are 5 pieces in the system (execution + expectation):

$$p_k=A^k(1-A)=0.8^5(1-0.8)\cong 6.5\% \qquad (15.4.365)$$

15.4.5.5 Probability of standby in a $M/M/k/k$ queue (Erlang-B formula)

We are interested here in a system with N communication channels (each channel is supposed to support a call rate with an immediate response). If the N channels are busy, incoming calls are considered lost (eg, no dial tone). We are talking about "blocking the system" or "ruining the system". It is therefore a limited queue of type $M/M/k/k$ according to the Kendall notation, also named "system with loss".

We will try to estimate this probability of blocking according to the number of available channels and the traffic.

Given what was stated on the memoryless character of the call arrival process, we can consider that the probability:

$$p_k = \lambda_k \mathrm{d}t \tag{15.4.366}$$

to have k calls in the state k is independent of the state of the system such that:

$$p_k = p = \lambda \mathrm{d}t \tag{15.4.367}$$

Thus, at each state k of the system, the Poisson-type probability law is valid. The difference in treatment is that rather than considering states, we will consider that a communication channel can be considered as a state of its own.

But for the probability of end of call, we have:

$$p_k = \mu_k \mathrm{d}t = k\mu \mathrm{d}t \tag{15.4.368}$$

Indeed, this probability just reflects the fact that if k calls are in progress each has a probability $\mu\mathrm{d}t$ to terminate, hence the sum that gives $k\mu\mathrm{d}t$. We have then:

$$\mu_k = k \cdot \mu \tag{15.4.369}$$

Thus, by injecting these relations in:

$$p_0 = \frac{1}{1 + \displaystyle\sum_{k=1}^{+\infty} \left(\prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} \right)} \tag{15.4.370}$$

it comes:

$$p_0 = \frac{1}{1 + \displaystyle\sum_{k=1}^{N} \left(\prod_{i=0}^{k-1} \frac{\lambda}{(i+1)\mu} \right)} = \frac{1}{1 + \displaystyle\sum_{k=1}^{N} \left(\left(\frac{\lambda}{\mu}\right)^k \frac{1}{k!} \right)} \tag{15.4.371}$$

Introducing then (which must be strictly less than 1 if we want the following developments to converge to a finite value: ergodic Markov chain):

$$A = \frac{\lambda}{\mu} \tag{15.4.372}$$

which is for recall the number of calls that appear on the number of calls that end in a given time interval (average service time), which is actually simply the "traffic" (or the "traffic intensity" or "traffic rate"), then it comes:

$$p_0=\frac{1}{1+\sum\limits_{k=1}^{N}\left(\dfrac{A^k}{k!}\right)} \tag{15.4.373}$$

or by introducing the 1 in the summation:

$$p_0=\frac{1}{\sum\limits_{k=0}^{N}\left(\dfrac{A^k}{k!}\right)} \tag{15.4.374}$$

Since k represents the number of calls, this last relation gives the probability of having 0 calls (clients) for a given permanent traffic A in the system.

By reporting p_0 in the following expression of p_k (probability of being in the state k therefore...) obtained above:

$$p_k=\left(\prod_{i=0}^{k-1}\frac{\lambda_i}{\mu_{i+1}}\right)p_0 \tag{15.4.375}$$

it comes:

$$p_k=\left(\prod_{i=0}^{k-1}\frac{\lambda_i}{\mu_{i+1}}\right)p_0=\left(\prod_{i=0}^{k-1}\frac{\lambda_i}{\mu_{i+1}}\right)\frac{1}{\sum\limits_{k=0}^{N}\left(\dfrac{A^k}{k!}\right)} \tag{15.4.376}$$

And considering the character without memory, we have the relation:

$$\prod_{i=0}^{k-1}\frac{\lambda_i}{\mu_{i+1}}=\prod_{i=0}^{k-1}\frac{\lambda}{(i+1)\cdot\mu}=\prod_{i=1}^{k}\frac{\lambda}{i\cdot\mu}=\frac{A^k}{k!} \tag{15.4.377}$$

it comes:

$$p_k=\left(\prod_{i=0}^{k-1}\frac{\lambda_i}{\mu_{i+1}}\right)p_0=\left(\prod_{i=0}^{k-1}\frac{\lambda_i}{\mu_{i+1}}\right)\frac{1}{\sum\limits_{k=0}^{N}\left(\dfrac{A^k}{k!}\right)}=\frac{\dfrac{A^k}{k!}}{\sum\limits_{k=0}^{N}\left(\dfrac{A^k}{k!}\right)} \tag{15.4.378}$$

where the k can unfortunately be confusing. It is necessary to do some cleaning! In the numerator, the k refers to the number of channels (servers, lines, operators or terminals) and at the denominator the N also. It is therefore necessary to rewrite this more appropriately:

$$\boxed{p_k=\frac{\dfrac{A^N}{N!}}{\sum\limits_{k=0}^{N}\left(\dfrac{A^k}{k!}\right)}} \tag{15.4.379}$$

which therefore gives the probability of placing on hold (and thus the probability of saturation / blocking) of a system having N channels of finite capacity according to the principle of first in / first out and for a traffic A (expressed in "Erlang") and in which communications are lost if placed on hold.

This relation is sometimes denoted in the literature in the form of:

$$\pi_k=\frac{\dfrac{\rho^k}{k!}}{\displaystyle\sum_{i=0}^{k}\left(\frac{\rho^i}{i!}\right)} \tag{15.4.380}$$

This relation is very important in queuing theory and is named the "Erlang-B formula".

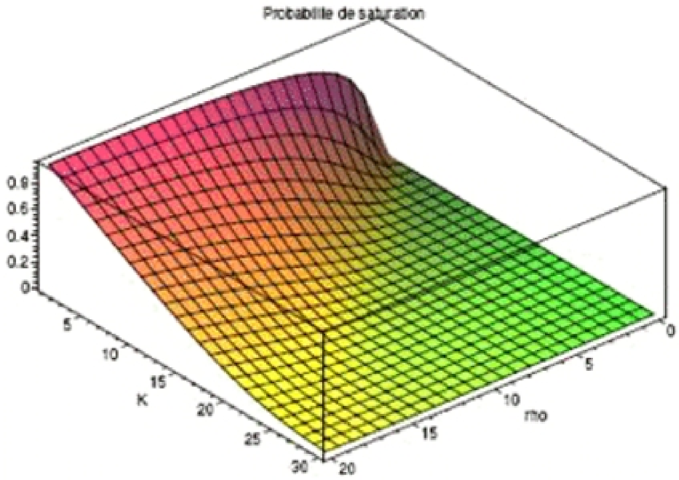


Figure 15.317: **Probability of saturation (smoothed plot of the Erlang-B function)**

This relation is at the basis for the design of circuit-switched networks. Indeed, the problem of sizing a circuit switch is as follows: Given the traffic in number of calls per unit of time A in Erlang, find the number of service units k such that the probability that a call arrives in a system that has become blocking is lower than a certain value.

The probability obtained then represents the quality of service offered by the network from the point of view of the usage. And about the traffic A, that latter is estimated on the basis of the number of existing and / or future telephone installation based on an average activity per station and per application (telephone, fax, terminal, computer server, etc.).

✍**Example:**

E1. What is the probability of saturation of a hotline (whose duration of service follows an exponential law and the distribution of the arrivals follows a Poisson law) knowing that the traffic A of the line is estimated to be 2 [Erlang] (1 call per hour for 1 call processed by $1/2$ hour - hence a ratio of 2 to 1) for a single telephone line ($N=1$)

using the Erlang-B model:

$$p_k = \frac{\dfrac{2^1}{1!}}{\dfrac{2^0}{0!}+\dfrac{2^1}{1!}} \cong 67\% \qquad (15.4.381)$$

E2. In a company, we have counted 200 calls during the peak hours of an average of 6 minutes per hour (average service time). What is the probability of saturation with 20 operators (knowing that the length of service follows an exponential law and the distribution of arrivals a Poisson law)?

The biggest difficulty here is to calculate the traffic! There are thus 200 calls per hour with 10 calls processed only per hour (since 6 minutes per call in an hour of 60 minutes gives: 10 calls). The traffic A is therefore $200/10$ or 20 Erlang. Applying then the previous relation, we have:

$$p_k = \frac{\dfrac{20^{20}}{20!}}{\displaystyle\sum_{k=0}^{20}\dfrac{20^k}{k!}} \cong 15.89\% \qquad (15.4.382)$$

In the industry, a saturation rate of 0.01% is assumed. By playing with a spreadsheet like Microsoft® Excel® and the Target Value tool, we quickly find that N must be equal to 30.

15.4.5.6 Probability $M/M/K/+\infty$ of standby (Erlang-C formula)

Let us consider now a system for which calls can be queued before being served when the k servers are blocked. It is therefore an unlimited capacity queue of type $M/M/k/+\infty$ according to the Kendall notation.

With this system, we always have:

$$p_k = p = \lambda \mathrm{d}t \qquad (15.4.383)$$

But for the probability of end of call the analysis becomes more subtle. First there is the probability that the calls on the available N-channels will cease and that is given by:

$$\mu_k \mathrm{d}t = k\mu \mathrm{d}t \quad \forall\, 0 \leq k \leq N-1 \qquad (15.4.384)$$

But as soon as the number of calls is greater than the number of communication channels available, the probability that the calls cease is:

$$\mu_k \mathrm{d}t = N\mu \mathrm{d}t \quad \forall\, k \geq N \qquad (15.4.385)$$

Which means that regardless of the number of calls, N have the probability of being put on hold (standby) as soon as k (the number of calls) is greater than or equal to N.

Thus, to summarize:

$$\mu_k \mathrm{d}t = \begin{cases} k\mu \mathrm{d}t & \forall\, 0 \leq k \leq N-1 \\ N\mu \mathrm{d}t & \forall\, k \geq N \end{cases} \tag{15.4.386}$$

Using:

$$p_k = \left(\prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} \right) p_0 \tag{15.4.387}$$

We get by decomposition of the product term:

$$p_k = \left(\prod_{i=0}^{N-1} \frac{\lambda}{(i+1)\mu} \prod_{i=N}^{k-1} \frac{\lambda}{N\mu} \right) p_0 = \left(\frac{A^N}{N!} \frac{A^{k-N}}{N^{k-N}} \right) p_0 \tag{15.4.388}$$

Hence finally:

$$p_k = \begin{cases} \dfrac{A^N}{N!} p_0 & \forall\, 0 \leq k \leq N-1 \\ \dfrac{A^N}{N!} \dfrac{A^{k-N}}{N^{k-N}} p_0 & \forall\, k \geq N \end{cases} \tag{15.4.389}$$

Using the expression of p_0:

$$p_0 = \frac{1}{1 + \displaystyle\sum_{k=1}^{+\infty} \left(\prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} \right)} \tag{15.4.390}$$

We can decompose the summation:

$$p_0 = \frac{1}{1 + \displaystyle\sum_{k=1}^{N-1} \left(\prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} \right) + \sum_{k=N}^{+\infty} \left(\prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} \right)} \tag{15.4.391}$$

and decompose the second product:

$$\begin{aligned} p_0 &= \frac{1}{1 + \displaystyle\sum_{k=1}^{N-1} \left(\prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} \right) + \sum_{k=N}^{+\infty} \left(\prod_{i=0}^{N-1} \frac{\lambda}{(i+1)\mu} \prod_{i=N}^{k-1} \frac{\lambda}{N\mu} \right)} \\ &= \frac{1}{1 + \displaystyle\sum_{k=1}^{N-1} \left(\prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} \right) + \sum_{k=N}^{+\infty} \left(\frac{A^N}{N!} \frac{A^{k-N}}{N^{k-N}} \right)} \\ &= \frac{1}{1 + \displaystyle\sum_{k=1}^{N-1} \frac{A^k}{k!} + \frac{A^N}{N!} \sum_{k=N}^{+\infty} \left(\frac{A^{k-N}}{N^{k-N}} \right)} \\ &= \frac{1}{\displaystyle\sum_{k=0}^{N-1} \frac{A^k}{k!} + \frac{A^N}{N!} \sum_{k=N}^{+\infty} \left(\frac{A^{k-N}}{N^{k-N}} \right)} \\ &= \frac{1}{\displaystyle\sum_{k=0}^{N-1} \frac{A^k}{k!} + \frac{A^N}{N!} \sum_{k=0}^{+\infty} \left(\frac{A}{N} \right)^k} \end{aligned} \tag{15.4.392}$$

Under the assumption that:

$$\frac{A}{N}<1 \tag{15.4.393}$$

The sum:

$$\sum_{k=0}^{+\infty}\left(\frac{A}{N}\right)^k \tag{15.4.394}$$

can be simplified. Indeed, by putting:

$$\frac{N}{A}=x \tag{15.4.395}$$

it comes:

$$\sum_{k=0}^{+\infty}\frac{1}{x^k} \tag{15.4.396}$$

and as we have prove it in our study of the Zeta function (see section Sequences and Series page 1682) this sum can be written in the form:

$$\sum_{k=0}^{+\infty}\frac{1}{x^k}=\frac{1}{1-\dfrac{1}{x}} \tag{15.4.397}$$

Therefore:

$$\sum_{k=0}^{+\infty}\left(\frac{A}{N}\right)^k=\frac{1}{1-\dfrac{A}{N}} \tag{15.4.398}$$

So finally:

$$p_0=\frac{1}{\displaystyle\sum_{k=0}^{N-1}\frac{A^k}{k!}+\frac{A^N}{N!}\frac{1}{1-\dfrac{A}{N}}} \tag{15.4.399}$$

Since k represents the number of calls, this last relation gives the probability of having 0 calls (customers) for a given permanent traffic A in the system.

We thus have for $\forall k\geq N$:

$$p_k=\frac{A^N}{N!}\frac{A^{k-N}}{N^{k-N}}p_0=\frac{\dfrac{A^N}{N!}\dfrac{A^{k-N}}{N^{k-N}}}{\displaystyle\sum_{k=0}^{N-1}\frac{A^k}{k!}+\frac{A^N}{N!}\frac{1}{1-\dfrac{A}{N}}}=\frac{\dfrac{A^N}{N!}\dfrac{A^{k-N}}{N^{k-N}}}{\displaystyle\sum_{k=0}^{N-1}\frac{A^k}{k!}+\frac{A^N}{N!}\frac{N}{N-A}} \tag{15.4.400}$$

The cumulative probability of queuing is denoted $C(N,A)$. It is equal to:

$$C(N,A)=\sum_{k=N}^{+\infty}p_k=\sum_{k=N}^{+\infty}\frac{A^N}{N!}\frac{A^{k-N}}{N^{k-N}}p_0=\frac{\displaystyle\sum_{k=N}^{+\infty}\frac{A^N}{N!}\frac{A^{k-N}}{N^{k-N}}}{\displaystyle\sum_{k=0}^{N-1}\frac{A^k}{k!}+\frac{A^N}{N!}\frac{N}{N-A}}$$

$$=\frac{\displaystyle\frac{A^N}{N!}\sum_{k=N}^{+\infty}\frac{A^{k-N}}{N^{k-N}}}{\displaystyle\sum_{k=0}^{N-1}\frac{A^k}{k!}+\frac{A^N}{N!}\frac{N}{N-A}}=\frac{\displaystyle\frac{A^N}{N!}\sum_{k=0}^{+\infty}\left(\frac{A}{N}\right)^k}{\displaystyle\sum_{k=0}^{N-1}\frac{A^k}{k!}+\frac{A^N}{N!}\frac{N}{N-A}} \quad (15.4.401)$$

By proceeding exactly as in the preceding paragraphs, we get finally:

$$\boxed{C(N,A)=\frac{\displaystyle\frac{A^N}{N!}\frac{N}{N-A}}{\displaystyle\sum_{k=0}^{N-1}\frac{A^k}{k!}+\frac{A^N}{N!}\frac{N}{N-A}}} \quad (15.4.402)$$

which therefore gives the probability of putting on hold (and thus of saturation / blocking - that is to say all servers are blocked) upon arrival in a system having N channels with infinite capacity according to the principle of the first in/first out (FIFO) and for a constant traffic A (expressed in "Erlang") and in which communications can be placed on hold (at the opposite to the Erlang-B model). This last relation is named the "Erlang-C formula". Traditionally we write this last relation as following:

$$C(N,A)=P(W) \quad (15.4.403)$$

the "W" coming from "Wait".

The model proposed above is obviously open to criticism because in reality the capacity of the queue is finite and some clients give up when the wait is too long.

✍**Example:**

If we take an arrival rate of 1 call per minute and an average service time of 5 minutes, then we have:

$$A=\frac{\lambda}{\mu}=\lambda\frac{1}{\mu}=1\cdot 5=5 \quad (15.4.404)$$

If we take a number N of 7 servers, we have:

$$C(N,A)=\frac{\displaystyle\frac{A^N}{N!}\frac{N}{N-A}}{\displaystyle\sum_{k=0}^{N-1}\frac{A^k}{k!}+\frac{A^N}{N!}\frac{N}{N-A}}=\frac{\displaystyle\frac{5^7}{7!}\frac{7}{7-5}}{\displaystyle\sum_{k=0}^{6}\frac{5^k}{k!}+\frac{5^7}{7!}\frac{7}{7-5}}\cong 0.3241 \quad (15.4.405)$$

Therefore 32.41% cumulative probability of being put on hold (standby). What a is little too much ... (an empirical rule is to look for the number N of servers so that the latter value falls below 20%).

15.4.6 Insurance

Insurance is an operation in which a person (the "insurer") groups other persons (the "insured") into mutual insurance schemes in order to put them in a position to compensate each other for possible losses (losses) to which expose them certain risks[62], thanks to amounts of cash (premiums or contributions) paid by each insured individual to a common mass (cohort) managed by the insurer.

quote 15.4:8170.#89

> *Insurance is when you buy coverage when you need it. Reality is when you buy the option of going to court for coverage when you need it.*

The common denominator of the majority of laws define the insurance contract as a contract whereby, subject to the payment of a fixed or variable premium, one party, the insurer, undertakes to another party, the insured (also named "policyholder") to provide a benefit stipulated in the contract in the event of an uncertain event that the insured or the beneficiary, as the case may be, has an interest in not being realized.

Obviously, the insurance transaction results in the transfer (total or partial) of the financial consequences of the risk incurred by the insured to an insurance company. Therefore, upon entering into the contract, the insurer and the insured agree to:

- Of an event or list of events, included in the insurance policy, and guaranteed by the insurer.
- A premium paid by the insured to the insurer.

The expenses assumed by the insurer may correspond to:

- Either to indemnities to be paid to third parties, in respect of the liability (civil, professional or other) of the insured in a given laps of time
- Either to repair partially or totally to the damage sustained by the latter.

Remark

We decided to put the study of Insurance in the section of Quantitative Management rather in that of Economy as we have never seen until now a Manager (even the best one) deal with options, shares and so on... (this is the job of Finance graduate people). But we have seen quite often Managers, and this is normal as the degree of difficulty is quite low, seek for insurances contracts to mitigate the risks of some projets that they have to manage.

---

[62] For a list of most common risks in project management the reader can refer to the French free PDF: *Gestion de projets pour ingénieurs et scientifiques* (Project management for engineers and scientists)

The main assumptions used in the insurance industry are as follows:

H1. From a legal point of view, an insurance contract is a "random contract" valid only to cover risks with a random component.

H2. The "rule of the game" of the risk must be stable within a period of time considered as long (at least a few years).

H3. The maximum possible loss must not be too great in relation to the insurer's solvency margin.

H4. The average risk premium must be identifiable and quantifiable according to well-chosen explanatory statistical variables in order to allow a segmentation of risk management (small anecdote: when actuaries are criticized for their segregation practices, we often hear the answer: *We do not discriminate, but differentiate*...).

H5. The risks must be independent (and if they are identical distributed in terms of probabilities and weighting this is better ...) and demonstrated to be such significantly using statistical tools.

H6. There must be a market in the sense that the supply and demand for insurance must arrive at an equilibrium price (in a sense, the equivalent of the absence of arbitrage opportunity in finance).

H7. Mathematical expected mean is considered to be the price of the right pure premium to be paid by the insured.

NOAH, THERE WILL BE A FLOOD, AND IT WILL DESTROY ALL OF CREATION
DON'T WORRY, I'VE GOT INSURANCE

Definitions (#15.4.721):

D1. The "pure premium" is in the field of insurance chosen as the mathematical expected mean value of the burden. It corresponds to the minimum premium that an insurer may ask for not be ruin with certainty.

D2. The "safety charge" is the amount that comes in addition of the pure premium and allows the insurer to withstand the volatility of refunds.

D3. The "management fee charge" is the amount that is added to the previous two and is related to the operation of their company, contract management, premium recovery, investment of assets (basic technical premium), taxes...

D4. The "commercial expenses charge" is added to the previous three and is linked to the acquisition of contracts (commission of intermediaries, costs of commercial networks, advertising).

D5. In the end, all the costs are reflected in the "commercial premium" that is the one communicated to the customer.

We can already conclude that in the case of a compulsory or voluntary state Care insurance system, management and commercial costs will always be lower, under the assumption of an equal management method, and a private system of wage attribution...

Remark

For obvious reasons, it shall be mandatory (as for every business), and required by an ad hoc legislation, that for every price (an especially in the insurance industry), that the percentage of the price allocated to marketing, commercial, management, etc. to be communicated.

15.4.6.1 Premium pricing

So the insurer does not know exactly what the amount of claims is going to be. By taxing contracts at the pure premium level (and assuming a symmetrical loss distribution), the insurer loses money one year on two. In the absence of capital, this situation would quite quick lead to bankruptcy.

To protect himself, the insurer adds to its premium a security charge. Numerous methods of determining it are possible, none having so far largely supplanted the others:

- Charge proportional to the pure premium: The coefficient of proportionality reflects the insurer's view of the volatility of risk.
- Charge dependent on the standard deviation of the losses: This method is a slight formalization of the previous one. It poses a problem because it will introduce a security load that will depend on winnings (actual loss less than the pure premium), excepted if we use the semi-variance.
- Charge dependent on a certain quantity of losses (eg the third quartile). Such a charge ensures that the premium will be sufficient in a predetermined number of cases but does not give any information on technical losses.

Let us consider the case where the population would be heterogeneous, in extenso two classes S_A, S_B of risk coexist in the population of respective weight n_A, n_B with of course:

$$\frac{n_A}{n_A+n_B}+\frac{n_B}{n_A+n_B}=\frac{n_A}{n}+\frac{n_B}{n}=\frac{n_A+n_B}{n}=100\% \tag{15.4.406}$$

Let us consider a health insurance with two categories of insured (healthy young A / seniors at risk B).

To simplify the example to the extreme, let us imagine that the insurer knows, by means of its internal statistics, that an individual in group A will cost the insurance a sum defined by a statistical distribution law that we will denote here:

$$F_X^A(x) \rightarrow P(X_A \leq x) \tag{15.4.407}$$

Then to any cost x is associated a given some cumulative probability given by the function F_X^A. Similarly for group B:

$$F_X^B(x) \rightarrow P(X_B \leq x) \tag{15.4.408}$$

If we randomly select an individual in the portfolio, if θ refers to the group (traditional insurance notation for groups), the insurer should therefore claim in pure premiums for group A:

$$\text{E}[S_A] = \text{E}[S|\theta = A] = \mu_A \tag{15.4.409}$$

hence the expected mean of the function F_X^A.

Same for group B:

$$\text{E}[S_B] = \text{E}[S|\theta = B] = \mu_B \tag{15.4.410}$$

And for a random individual in both groups:

$$\mu_S = \text{E}[S] = \text{E}[\text{E}(S|\theta)] = \frac{n_A}{n}\mu_A + \frac{n_B}{n}\mu_B \tag{15.4.411}$$

The latter case is named the "solidarity mechanism". So the good risks pay for the bad risks ... In fact it's a good way to guarantee "equality" between insured people but not "equity" hence the huge problems that encounters some governments for their system of insurance. The mathematical models of all insurance I know so fare don't take into account the equity that is in physics a fundamental principle of proportion (but don't ask economists to do physics...).

The variance of the pure premium will be given by the relation proved in the Statistics section when studying the properties of the variance (variance of two statistical series as seen at page 595):

$$\sigma_S^2 = \frac{n_A\sigma_A^2 + n_B\sigma_B^2}{n_A + n_B} + n_A n_B \frac{(\mu_A - \mu_B)^2}{(n_A + n_B)^2} \tag{15.4.412}$$

Where we see that the term:

$$(\mu_A - \mu_B)^2 \geq 0 \tag{15.4.413}$$

at the numerator corresponds to the homogeneity of the two groups. Hence, heterogeneity increases the variability of the pure premium in the solidarity mechanism especially when equity is not taking into account.

Now let us imagine the case where:

$$\mu_A < \mu_B \tag{15.4.414}$$

and a private insurance (1) which practices the solidarity mechanism and another insurance (2) which does not practice it. In the present case, we must distinguish two situations from an economic point of view:

If all the insured are rational (therefore somewhat... egoistic) then:

- Healthy young people representing group A will go to private insurance (2) which has segmented the risks and therefore allows the young people to pay less.
- Seniors in poorer health, representing group B, go to private insurance (1), which has not segmented risks, but which, by ideology, has applied the principle of solidarity.

The conclusion is that private insurance (1) will quickly go bankrupt because:

- The good risks no longer compensate the solidarity mechanism because of selfishness
- We are in a competitive market where insurance are not ideological ...

This fact is named the "anti-selection problem" or "adverse selection" based on the approach of G. Akerlof, Nobel Prize for Economics in 12001 (holocene calendar).

The conclusion is that the privatization of insurance based on a solidarity principle can not work without incurring additional costs for pure premiums because of a periodic anti-selection that generates a constant flow of insured persons moving from one insurance to another and thus generates important administrative, marketing and computer costs! So in every point the suppression of competition (concurrence) remains better in terms of solidarity but not in terms of jobs for insurance employees (who would then be for the majority unemployed...) or for the advantages of some CEO and politicians....!!!!!

Thus, the elimination of competition (concurrence) for insurance services which all have equivalent quality services (as it is the case of health insurance in Switzerland, for example) eliminates the principle of anti-selection, applies in a concrete way the solidarity mechanism wanted by the state and finally reduces the costs due to the comings and goings (flow) of the insured and the development of IT tools of business-management costing millions to each insurance and which incur costs which in the end are passed on to the price of the commercial premium!

In addition, in order to reduce overall volatility (global standard deviation), insurance should theoretically segment the risks indefinitely, making it an unsustainable system for certain specific areas of insurance.

But it must be remembered that this conclusion is valid only if the insurance benefits are identical (or quasi-similar) in a given market!

There is also a recurring issue in the field of insurance, named "moral hazard", which is based on the observation that those who insure tend to be less cautious than those who do not insure themselves. In other words, insurance generates risk and this is very important factor that explain cost increase of solidarity insurance systems!

15.4.6.2 Taking account of the return on experience

So far, to determine an insurance premium, we have noticed that it was possible to integrate exogenous variables (gender, age, children, vehicle power, nationality, environment, etc.). But an important point not to be neglected is the return on experience of an insured's claims. Let's see a concrete example!

Suppose that the number of claims over one year for a given insured follows a Poisson law (law of rare events) given for recall by (see section Statistics page 686):

$$P_k = \frac{\mu^k}{k!}e^{-\mu} \tag{15.4.415}$$

which is written in the field of insurance:

$$P_\theta = \frac{\mu^\theta}{\theta!}e^{-\mu} \tag{15.4.416}$$

Let us suppose that the insured population is separated into three classes of risk according to a Poisson distribution such as:

$$\begin{aligned} P(\theta=1) &= \frac{1^\theta}{\theta!}e^{-1} \rightarrow 70\% \\ P(\theta=2) &= \frac{2^\theta}{\theta!}e^{-2} \rightarrow 20\% \\ P(\theta=3) &= \frac{3^\theta}{\theta!}e^{-3} \rightarrow 10\% \end{aligned} \tag{15.4.417}$$

In other words, 70% of the total population follows a Poisson's law of expected mean equal to 1 (good risk class), 20% follows Poisson's law of expected mean equal to 2 (average risk class) , and 10% follows a Poisson's law of expected mean equal to 3 (class of bad risks).

Obviously, the overall expected mean of an individual in the portfolio is the expected mean of the "mixed distribution":

$$\mu = \mathrm{E}(\theta) = 70\% \cdot 1 + 20\% \cdot 2 + 10\% \cdot 3 = 1.4 \tag{15.4.418}$$

Let us suppose that the costs of an incident are fixed and that the indemnity amount is of $1,000$.- . We can then ask what the premium should be for an insured, knowing that the first year he had 2 claims. What is equivalent to ask ourselves: what is the number of claims that he could have in the second year?

If we denote by X_1 the number of claims of the first year, and X_2 the number of claims a posteriori knowing X_1 we thus find ourselves with a problem of conditional probability (a Bayesian approach in other words ...) according to what we have studied in the section of Probabilities (see page 492):

$$P(X_2|X_1=2) = \frac{P(X_1 \cap X_2)}{P(X_1)} = \frac{P(X_1=2 \cap X_2)}{P(X_1=2)} \tag{15.4.419}$$

where we adopted in accordance with the tradition in the field of insurance the notation "|" to indicate we are dealing with conditional probabilities.

But we can not calculate the numerator because we do not know in advance what the will be the value of X_2. We will therefore calculate the expected conditional mean in order to get around this problem:

$$\mathrm{E}(X_2|X_1=2)=\frac{\mathrm{E}(X_1\cap X_2)}{\mathrm{E}(X_1)}=\frac{\mathrm{E}(X_1=2\cap X_2)}{\mathrm{E}(X_1=2)} \tag{15.4.420}$$

First we have:

$$\mathrm{E}(X_1=2)=70\%\cdot\frac{1^2}{2!}e^{-1}+20\%\cdot\frac{2^2}{2!}e^{-2}+10\%\cdot\frac{3^2}{2!}e^{-3}=0.205 \tag{15.4.421}$$

This last calculation (expected mean of the mixed distribution) being written in the field of insurance in the following way:

$$\mathrm{E}(X_1=2)=\sum P(\Theta=\theta)P(X_1=2|\Theta=\theta)=\sum P(\Theta=\theta)\frac{\theta^2}{2!}e^{-\theta} \tag{15.4.422}$$

If we consider the two random variables to be independent:

$$\mathrm{E}(X_1=2\cap X_2)=\mathrm{E}((X_1=2)(X_2))=\mathrm{E}(X_1=2)\mathrm{E}(X_2)=0.205\cdot\mathrm{E}(X_2) \tag{15.4.423}$$

It then comes immediately that:

$$\mathrm{E}(X_2|X_1=2)=\frac{\mathrm{E}(X_1\cap X_2)}{\mathrm{E}(X_1)}=\frac{\mathrm{E}(X_1=2\cap X_2)}{\mathrm{E}(X_1=2)}=\mathrm{E}(X_2) \tag{15.4.424}$$

We therefore fall back on a known value corresponding to the pure premium:

$$\begin{aligned}\mathrm{E}(X_2)&=70\%\cdot\theta_1+20\%\cdot\theta_2+10\%\cdot\theta_3\\&=70\%\cdot1+20\%\cdot2+10\%\cdot3=1.4=\mathrm{E}(\theta)\end{aligned} \tag{15.4.425}$$

Identical to the calculation of:

$$\mathrm{E}(X_1)=70\%\cdot\theta_1+20\%\cdot\theta_2+10\%\cdot\theta_3=1.4=\mathrm{E}(\theta) \tag{15.4.426}$$

Therefore the random variables X_1, X_2 are confused with that of the class of risk!

This system obviously is not conform to the bonus-malus concept. We must then consider that the two random variables are not independent (in fact it is the very definition of the bonus-malus!).

Thus, if the two random variables are not independent, we have:

$$\begin{aligned}&\mathrm{E}(X_1=2\cap X_2)=\mathrm{E}\left(\frac{\theta^2}{2!}e^{-\theta}\cap\theta\right)=\sum P(\Theta=\theta)\left(\frac{\theta^2}{2!}e^{-\theta}\cdot\theta\right)\\&=70\%\cdot\frac{1^2}{2!}e^{-1}\cdot1+20\%\cdot\frac{2^2}{2!}e^{-2}\cdot2+10\%\cdot\frac{3^2}{2!}e^{-3}\cdot3=0.304\end{aligned} \tag{15.4.427}$$

and therefore:

$$\mathrm{E}(X_2|X_1=2)=\frac{\mathrm{E}(X_1=2\cap X_2)}{\mathrm{E}(X_1=2)}=\frac{0.304}{0.205}=1.484 \tag{15.4.428}$$

To compare with the pure premium without bonus-malus of 1.4!

What is tricky with this method is that when we accumulate years... this Bayesian approach becomes painful. Indeed, imagine that we would like to determine the pure premium of the third year knowing that of the second year, the insured had 1 accident the second year. We then have the conditional expected mean:

$$\text{E}(X_3|X_1=2,X_2=1)=\frac{\text{E}((X_1=2,X_2=1)\cap X_3)}{\text{E}(X_1=2,X_2=1)} \tag{15.4.429}$$

that we leave the development to the reader ...

We notice from what has been seen above that the expected mean of a mixed distribution defined by:

$$\text{E}(X)=p_1 f_{\bar{X}_1}(X)+\cdots+p_n f_{\bar{X}_n}(X)=\sum_{i=1}^{n} p_i f_{\bar{X}_i}(X) \tag{15.4.430}$$

is therefore trivially given by:

$$\text{E}(X)=\mu=\sum_{i=1}^{n} p_i\mu_i \tag{15.4.431}$$

15.4.6.3 Discounting factor of a retirement insurance

Let us now look for something that has absolutely nothing to do with what we have just calculated and which is the discount factor (see section Economy page 7558) by which we must divide a savings balance at the beginning of retirement, to allocate the resulting amount every year during retirement, depending on life expectancy, as well as interest and inflation rates. The approach here will be to question ourselves what level of savings it will be necessary to have accumulated at the beginning of retirement to obtain a pension of 1.- (real) each year during retirement. It is from this level of saving necessary to receive 1.- that it will be possible to use any savings balance to derive what annuity will be available to the saver.

First, we will define the parameters used:

- Number of retirement periods (years or months): m
- Savings balance at period k: S_k
- Periodic benefit (which we assume here annual): p
- Periodic rate of inflation (assumed here constant and annual): i
- Average geometric market rate of return (assumed constant and annual): R
- Discount factor at age m: a_m

Thus, as mentioned above, we are looking for the initial level of savings, denoted S_0, which will make possible to get a periodic benefit (therefore annual in this case), p, equal to 1.- indexed to inflation i.

Starting from the initial balance $S_0=S$, assuming that benefits are paid at the beginning of the year (praenumerando), we can derive the remaining balance at the end of the first retirement period as well:

$$S_1=(S-p)\cdot(1+R) \tag{15.4.432}$$

More precisely, the pensioner will have received an amount p for the first period, leaving the residual to be exposed to the geometric mean return on market R.

Then, in a similar way and considering that the benefits are indexed to inflation i, we can calculate this balance at the end of the second period and any subsequent period k:

$$S_2=[(S-p)(1+R)-(1+i)p]\,(1+R) \tag{15.4.433}$$

or:

$$S_2=S(1+R)^2-p(1+R)^2-p(1+R)(1+i) \tag{15.4.434}$$

or:

$$\begin{aligned}S_3&=\left[S(1+R)^2-p(1+R)^2-p(1+R)(1+i)-p(1+i)^2\right](1+R)\\&=S(1+R)^3-p(1+R)^3-p(1+R)^2(1+i)-p(1+R)(1+i)^2\\&=S(1+R)^3-p(1+R)(1+i)^2-p(1+R)^2(1+i)-p(1+R)^3\end{aligned} \tag{15.4.435}$$

And so on ... It comes then:

$$S_k=S(1+R)^k-p\sum_{j=1}^{k}(1+R)^j(1+i)^{k-j} \tag{15.4.436}$$

or otherwise written:

$$S_k=S(1+R)^k-p(1+i)^k\sum_{j=1}^{k}\left(\frac{1+R}{1+i}\right)^j=S(1+R)^k-p(1+i)^k\sum_{j=1}^{k}q^j \tag{15.4.437}$$

Thus we have, to one given term, a geometric series of reason q known in the last term. We have indeed proved in the section of Sequences and Series (see page 1656) that for j ranging from 0 to n this one is equal to:

$$S_n=u_0\frac{1-q^{n+1}}{1-q} \tag{15.4.438}$$

and therefore:

$$\sum_{j=1}^{k}\left(\frac{1+R}{1+i}\right)^j=\left(\frac{1+R}{1+i}\right)\sum_{j=0}^{k-1}\left(\frac{1+R}{1+i}\right)^j=\left(\frac{1+R}{1+i}\right)\frac{1-\left(\dfrac{1+R}{1+i}\right)^k}{1-\dfrac{1+R}{1+i}}=\frac{1-\left(\dfrac{1+R}{1+i}\right)^k}{\dfrac{1+i}{1+R}-1} \tag{15.4.439}$$

It is therefore possible for us to rewrite, for the last retirement period m, the balance as follows:

$$S_m=S(1+R)^m-p(1+i)^m\frac{1-\left(\dfrac{1+R}{1+i}\right)^m}{\dfrac{1+i}{1+R}-1} \tag{15.4.440}$$

Let us notice that in the unlikely and special case where the average geometric market return is equal to inflation, i.e. if $i=R$, we have:

$$\begin{aligned}S_m&=S(1+R)^m-p(1+i)^m\sum_{j=1}^{m}\left(\frac{1+R}{1+i}\right)^j=S(1+R)^m-p(1+R)^m\sum_{j=1}^{m}\left(\frac{1+R}{1+R}\right)^j\\&=S(1+R)^m-p(1+R)^m\sum_{j=1}^{m}1^j=S(1+R)^m-p(1+R)^m\sum_{j=1}^{m}m=(1+R)^m\left[S-p\cdot m\right]\end{aligned} \tag{15.4.441}$$

At this stage, the reason why the term S_m is an important parameter is that it is the retiree's balance at the end of his retirement period, that is, at his death. It will be assumed here that the retiree does not plan a legacy and therefore:

$$S_m=0 \tag{15.4.442}$$

Consequently, for $R\neq i$, this is equivalent to find S for which:

$$S_m=S(1+R)^m-p(1+i)^m\frac{1-\left(\dfrac{1+R}{1+i}\right)^m}{\dfrac{1+i}{1+R}-1}=0 \tag{15.4.443}$$

We can then establish in this case that for $R\neq i$:

$$S=p\frac{(1+i)^m}{(1+R)^m}\frac{1-\left(\dfrac{1+R}{1+i}\right)^m}{\dfrac{1+i}{1+R}-1}=p\left(\frac{1+i}{1+R}\right)^m\frac{1-\left(\dfrac{1+R}{1+i}\right)^m}{\dfrac{1+i}{1+R}-1} \tag{15.4.444}$$

And in the unlikely and special case where the average geometric return of the market is equal to inflation, that is, if $R=i$, we have:

$$S_m=(1+R)^m\left[S-p\cdot m\right]=0 \tag{15.4.445}$$

and we deduce in this special case a logical result:

$$S=p\cdot m \tag{15.4.446}$$

For what follows, we come back to the realistic case where $r\neq i$ and thus with:

$$S=p\left(\frac{1+i}{1+R}\right)^m\frac{1-\left(\dfrac{1+R}{1+i}\right)^m}{\dfrac{1+i}{1+R}-1} \tag{15.4.447}$$

and let us put:

$$b=\left(\frac{1+R}{1+i}\right)=1+r \tag{15.4.448}$$

The prior-previous relation is then written in a somewhat more condensed form:

$$S=p\frac{1}{b^m}\frac{1-b^m}{b-1} \tag{15.4.449}$$

where:

$$\boxed{a_m = \frac{1}{b^m}\frac{1-b^m}{b-1}} \tag{15.4.450}$$

is therefore the discounting factor. In addition, we have the following relation giving the expected mean of being alive at age a (age corresponding to the assumed age of death in the present case) introduced and proved in the section of Populations Dynamics:

$$m = e(a,s) - a + 1 \tag{15.4.451}$$

with for recall the function $e(a,s)$ representing the conditional life expectancy at age a and for sex s.

15.4.6.4 Pension insurance (life annuities)

We will now study a rent that is not paid in a certain way but in a "life annuity" way, that is to say, which depends on the survival of the insured. It will therefore be necessary to multiply each term of the rent by the probability that it will be paid to the insured.

Obviously, in the majority of cases, what will interest us will be the "present value" of the life annuities in order to know what the insurer will have to pay (and thus what he must have capitalized).

We consider mainly the following type of annuity:

1. **Life annuity:** You will receive regular income as long as you live. You can opt for monthly, quarterly, half-yearly or annual payouts depending on the product.
2. **Joint life annuity:** You will receive regular income as long as you live. After you, your life partner will continue getting regular income
3. **Life annuity with return of purchase price:** You will receive regular income as long as you live. After you, your children will get back the initial lump sum amount paid by you
4. **Life annuity guaranteed for 5/10/15 years:** You will receive regular income for a guaranteed period (5/10/15 years). In case of your demise within this period, your nominee will receive regular income till the end of the guaranteed period.
5. **Joint life annuity with return of purchase price:** You will receive regular income as long as you live. After you, your life partner will continue getting regular income. After both of you, your children will get the initial lump sum amount paid by you.
6. **Immediate annuity with regular payout:** Your income flow will start immediately upon investing, followed by payouts at regular intervals selected by you.
7. **Deferred annuity:** You will receive regular periodic payments starting at a future date selected by you.

We will see some of them! But before that, let us recall that we have seen in the section of Populations Dynamics (see page 7300) that the probability of being alive at a year $x+1$ knowing that one is alive at an age x is given by:

$$ {}_1p_x=\frac{S_{x+1}}{S_x}<1 \qquad (15.4.452)$$

and let us recall (following a reader's request) that the present value of a capital C_0 at constant rate payable in 1 year is given by (see section Economy page 7557):

$$C_0=\frac{C_1}{(1+t\%)^1} \qquad (15.4.453)$$

that gives the sum to be placed at a rate $t\%$ to have after one year the capital C_1.

By combining probability of survival with current value, we can define in the case of an annuity the unique premium (UP) of the old-age pension as:

$$\text{UP}=C_0\cdot {}_1p_x \qquad (15.4.454)$$

If the insured is alive at maturity, the insured wins the game (in reality they often win both ...), otherwise it is the insurer (where in that latter case he is really winning a lot of money!).

Obviously in the above case, extremely simplified, there is only one payment from the insurer. But in reality there may be several (this is what we are going to study), the payment of the insured may not be in the form of a single premium, the average geometric market rate may not be constant (the latter being treated normally with Monte Carlo simulations).

So even if what we are going to see is very simplified compared to what is done in insurance by the actuaries, it already gives a search path for more elaborate models.

15.4.6.4.1 Temporary life annuity

The "temporary life annuity" consist for the insurer to pay annuity terms, as long as the insured is alive but not more than n years after he has reached a given age x but immediately after the insured has paid his single premium (which corresponds precisely to the age x in question). The objective is therefore to determine the capital (current value) that the insurer must have accumulated at the time of the payment of these pensions (this capital may also be claimed in the form of multiple payments rather than in the form of a unique premium).

Obviously this case is quite unrealistic because few people will pay a single premium (big sum of money) at a time x of their lives to start right away to receive annuities. But it is pedagogically interesting before discussing the type of deferred life annuity and which is a little more realistic.

The temporary praenumerando life annuity (i.e. the present value of the unit life annuity payable praenumerando as long as the insured is alive but at most for n years) is given by the following relation which follows from the developments made in the section Economy (see page 7565) with the only small difference that one finds there coefficients of probability of survival:

$$\boxed{\ddot{a}_{\overline{x:n}|}=1+f_e\frac{S_{x+1}}{S_x}+f_e^2\frac{S_{x+2}}{S_x}+\ldots+f_e^{n-1}\frac{S_{x+n-1}}{S_x}=\sum_{t=0}^{n-1}f_e^t\frac{S_{x+t}}{S_x}} \qquad (15.4.455)$$

where for recall (see section Economy page 7558) we have the discount factor (in this case we should instead use the term "capitalization factor") which is:

$$f_e=\frac{1}{1+t\%} \tag{15.4.456}$$

In general, the term (see section Population Dynamics page 7300):

$$_{m|}E_x=f_e^m\frac{S_{x+m}}{S_x}=f_e^m\,{}_{m|}p_x \tag{15.4.457}$$

is named "probable value of deferred capital".

The postnumerando temporary life annuity (present value of a unit life annuity payable postnumerando as long as the insured is alive but for maximum during n years) is given by:

$$\boxed{a_{\overline{x:n|}}=f_e\frac{S_{x+1}}{S_x}+f_e^2\frac{S_{x+2}}{S_x}+\ldots+f_e^n\frac{S_{x+n}}{S_x}=\sum_{t=1}^{n}f_e^t\frac{S_{x+t}}{S_x}} \tag{15.4.458}$$

✍**Example:**

We wish to pay an annuity of $1,000$.- during 3 years to a 40 year old man. What is the single premium that he will have to pay if neither interest nor mortality are involved in the calculations is given by:

$$\text{UP}_{(1)}=1,000+1,000+1,000=1,000\cdot 3 \tag{15.4.459}$$

if only the interest is considered in the calculations:

$$\text{UP}_{(2)}=1,000\cdot f_e+1,000\cdot f_e^2+1,000\cdot f_e^2=1'000\cdot a_{\overline{3|}}\leq PU_{(1)} \tag{15.4.460}$$

and finally taking into account interest and mortality:

$$\text{UP}_{(3)}=1,000\cdot f_e\cdot\frac{S_{41}}{S_{40}}+1,000\cdot f_e^2\cdot\frac{S_{42}}{S_{40}}+1,000\cdot f_e^3\cdot\frac{S_{43}}{S_{40}}=1,000\cdot a_{\overline{40:3|}}<PU_{(2)} \tag{15.4.461}$$

15.4.6.4.2 Deferred life annuity

The "deferred life annuities" account for the majority of annuity insurance contracts. The insured person always pays a single premium in order to receive an annuity if he is alive at a certain age (at the age of retirement for example), so he begins receiving the annuity k years after paying the single premium, but this time until his death.

The praenumerando deferred life annuity (present value of a unit life annuity deferred of k years and payable praenumerando until death of the insured) is given by:

$$\boxed{{}_{k|}\ddot{a}_x=f_e^k\frac{S_{x+k}}{S_x}+f_e^{k+1}\frac{S_{x+k+1}}{S_x}+\ldots+f_e^{\omega-x}\frac{S_\omega}{S_x}=\sum_{t=k}^{\omega-x}f_e^t\frac{S_{x+t}}{S_x}} \tag{15.4.462}$$

where ω is the last value (line number) of the life table. The reader may notice that if we set $k=1$ (without delay) and $\omega=x+n$, we fall back on a temporary postnumerando life annuity $a_{\overline{x:n}|}$.

Thus, normally for a same age x and a same supposed annuity duration, the present value of the deferred life annuity (single premium) is lower than that of the temporary life annuity and this the smaller is the delay.

The postnumerando deferred life annuity (current value of a deferred life annuity of k years and payable postnumerando until death of the insured) is given by:

$$\boxed{{}_{k|}a_x=f_e^{k+1}\frac{S_{x+k+1}}{S_x}+f_e^{k+2}\frac{S_{x+k+2}}{S_x}+\cdots+f_e^{\omega-x}\frac{S_\omega}{S_x}=\sum_{t=k+1}^{\omega-x}f_e^t\frac{S_{x+t}}{S_x}} \tag{15.4.463}$$

Obviously, the two annuities above have the same end because given that it is until death, it is difficult to pay in postnumerando of the death...

Let us also notice that it is possible mathematically to create a temporary AND deferred annuity but it is rare and therefore we will not study it here.

Remark

Unlike certain annuities, as far as we know there is no simplified formula for a quick calculation of these pensions based on mortality tables. The use of a spreadsheet software or the programming of these functions makes it easy to calculate the current values of the lifetime benefits. At the time when computers were not existing, we built tables named "commutations numbers" that made it possible to obtain the required information.

15.4.7 Sensitivity Analysis

The mathematical models we have seen previously are defined by a series of equations, input variables and parameters aimed at characterizing some process under investigation. Some examples might be a climate model, an economic model, a project planning model, etc.. Increasingly, such models are highly complex, and as a result their input/output relationships may be poorly understood. In such cases, the model can be viewed as a black box, i.e. the output is an opaque function of its inputs.

Quite often, some or all of the model inputs are subject to sources of uncertainty, including errors of measurement, absence of information and poor or partial understanding of the driving forces and mechanisms. This uncertainty imposes a limit on our confidence in the response or output of the model. Further, models may have to cope with the natural intrinsic variability of the system (aleatory), such as the occurrence of stochastic events.

Good modelling practice requires that the modeller provides an evaluation of the confidence in the model. This requires, first, a quantification of the uncertainty in any model results ("uncertainty analysis") and second, an evaluation of how much each input is contributing to the output uncertainty. Sensitivity analysis addresses the second of these issues (although uncertainty analysis is usually a necessary precursor), performing the role of ordering by importance the strength and relevance of the inputs in determining the variation in the output.

Remarks

R1. Uncertainty analysis investigates the uncertainty of variables that are used in decision-making problems in which observations and models represent the knowledge base. In other words, uncertainty analysis aims to make a technical contribution to decision-making through the quantification of uncertainties in the relevant variables. Many high level managers like to say that a management model is never complete until it has a quantification tool associated with it!

R2. Sensitivity and Uncertainty analysis belongs both to the field of knowledge named "uncertainty quantification" that is the science of quantitative characterization and reduction of uncertainties in both computational and real world applications.

The process of recalculating outcomes under alternative assumptions to determine the impact of variable under sensitivity analysis can be useful for a range of purposes, including:

- Testing the robustness of the results of a model or system in the presence of uncertainty.
- Increased understanding of the relationships between input and output variables in a system or model.
- Identifying model inputs that cause significant uncertainty in the output and should therefore be the focus of attention if the robustness is to be increased (perhaps by further research).
- Searching for errors in the model (by encountering unexpected relationships between inputs and outputs).

- Model simplification by fixing model inputs that have no effect on the output, or identifying and removing redundant parts of the model structure.
- Enhancing communication from modellers to decision makers (e.g. by making recommendations more credible, understandable, compelling or persuasive).
- Finding regions in the space of input factors for which the model output is either maximum or minimum or meets some optimum criterion (see optimization and Monte Carlo filtering).
- In case of calibrating models with large number of parameters, a primary sensitivity test can ease the calibration stage by focusing on the sensitive parameters. Not knowing the sensitivity of parameters can result in time being uselessly spent on non-sensitive ones.

Taking an example from economics, in any budgeting process there are always variables that are uncertain. Future tax rates, interest rates, inflation rates, headcount, operating expenses and other variables may not be known with great precision. Sensitivity analysis answers the question, "if these deviate from expectations, what will the effect be (on the business, model, system, or whatever is being analysed), and which variables are causing the largest deviations?"

Sensitivity analysis is a variation on scenario analysis (deterministic naive modelization) that is useful in pinpointing the areas where forecasting risk is especially severe in any field of corporate finance, project management, lean management, supply chain management.

There are a large number of approaches to perform a sensitivity analysis, many of which have been developed to address one or more of the constraints discussed above. They are also distinguished by the type of sensitivity measure, be it based on (for example) variance decompositions, partial derivatives or elementary effects. In general, however, most procedures adhere to the following outline:

1. Quantify the uncertainty in each input (e.g. ranges, probability distributions). Note that this can be difficult and many methods exist to elicit uncertainty distributions from subjective data.
2. Identify the model output to be analysed (the target of interest should ideally have a direct relation to the problem tackled by the model).
3. Run the model a number of times using some design of experiments, dictated by the method of choice and the input uncertainty.
4. Using the resulting model outputs, calculate the sensitivity measures of interest.

In some cases this procedure will be repeated, for example in high-dimensional problems where the user has to screen out unimportant variables before performing a full sensitivity analysis.

However, in the field of management (projects, finance, statistics) and multivariate case, the sensitivity analysis is at a graduate level a simple technique based on the use of the linear Pearson correlation coefficient that we have studied in the section Statistics (see page 614) and for which a possible writing form in the bivariate discrete case was explicitly:

$$R_{x,y}=\frac{\sum_{k=1}^{n}x_k y_k-\frac{1}{n}\sum_{k=1}^{n}x_k\sum_{k=1}^{n}y_k}{\sqrt[4]{\left[\sum_{k=1}^{n}x_k^2-\frac{1}{n}\left(\sum_{k=1}^{n}x_k\right)^2\right]\left[\sum_{k=1}^{n}y_k^2-\frac{1}{n}\left(\sum_{k=1}^{n}y_k\right)^2\right]}} \quad (15.4.464)$$

Some common difficulties in sensitivity analysis include:

1. Too many model inputs to analyse. Screening can be used to reduce dimensionality.
2. The model takes too long to run
3. There a unsuspected non-linearities and correlations
4. There is not enough information to build probability distributions for the inputs. Probability distributions can be constructed from expert elicitation, although even then it may be hard to build distributions with great confidence. The subjectivity of the probability distributions or ranges will strongly affect the sensitivity analysis.
5. Piecewise sensitivity. This is when one performs sensitivity analysis on one sub-model at a time. This approach is non conservative as it might overlook interactions among factors in different sub-models

Let us begin with the theory of the first method that is strictly speaking not a sensitivity analysis but that many managers (non-scientific) consider as it...

15.4.7.1 Direct Bias Method

The "direct bias method" also named the "one factor at a time" (OFAT) method is also well known in Design of Experiments (DOE). In fact it is the easiest method and it can be applied in a deterministic, probabilistic or stochastic way. It is quite useful when the board committee wants to know the influence of a given factor only for a given amplitude!

OFAT customarily involves:

1. Changing one input variable, keeping others at their baseline (nominal) values, monitoring the output then,
2. Returning the variable to its nominal value, the repeating for each of the other inputs in the same way

Consider that we have an output model given by:

$$y=f(\vec{x},t) \quad (15.4.465)$$

where $\vec{x}$ is the vector of all the variables x_i components that can be time dependent or not.

1. The "deterministic univariate direct bias method" consists simply by doing the following relative calculation:

$$\frac{\Delta y(t)}{y(t)}=\frac{f((x_1(t),\ldots,x_i(t)\pm\delta_{i,t},\ldots,x_n(t)),t)-f((x_1(t),\ldots,x_n(t)),t)}{f((x_1(t),\ldots,x_n(t)),t)} \tag{15.4.466}$$

where the variation $\delta_{i,t}$ is chosen arbitrarily by the practitioner that must keep in mind that the output is not necessarily proportional to the input variation!!!!

The ratio above is a "relative-output/nominal output" but some practitioners prefers a "relative/relative" analysis. Thus if δ_i is express in percentage change of $x_i(t)$ we will write obviously:

$$\frac{\Delta y(t)}{y(t)}=\frac{f((x_1(t),\ldots,x_i(t)\cdot\delta_{i,t},\ldots,x_n(t)),t)-f((x_1(t),\ldots,x_n(t)),t)}{f((x_1(t),\ldots,x_i(t),\ldots,x_n(t)),t)} \tag{15.4.467}$$

Furthermore depending on the amplitude of $\delta_{i,t}$ some non-null correlation can appear with other factor could in reality occur!

This technique is quite limited as you must do as many calculations as you have scenarios (variable inputs ranges).

When the practitioner use this punctual naive estimation method we often speak of "univariate scenario analysis" or "univariate What-If Analysis" and in the special case where only three punctual estimates are used such as the optimistic, expected, pessimistic values:

$$\vec{x}_i(t)=\begin{pmatrix}x_{i,\text{O}}(t)\\x_{i,\text{V}}(t)\\x_{i,\text{P}}(t)\end{pmatrix} \tag{15.4.468}$$

we then speak of "univariate three point estimate analysis".

So in this case sensitivity analysis is done using a large number of probabilistic What-If analysis or Three point estimate analysis. Sadly spreadsheet software like Microsoft® Excel® have made this term and method popular and most people thinks that this tool is the Graal... In fact it is just a high-school level analysis tool that should never be used in a firm if the CEO or CFO are graduated from a good university otherwise you will have quite a lot of problems to keep your job since the results are very poorly predictive and accurate!

Such an analysis is very easy to implement in any spreadsheet software like Microsoft® Excel® with multiple input values. As this is more a high school subject we will not give any example about this.

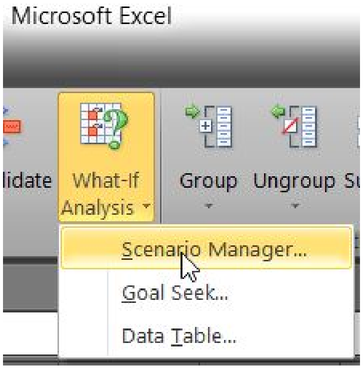

Figure 15.318: What-If Scenario Manager tool in Microsoft® Excel® 14.0.7166

Microsoft never implemented until now an equivalent tool for multivariate cases even if their spreadsheet has the capacity to do it with a little bit more formatting (typically a structure near that one of the PivotTables).

If we apply the same procedure as above but with two variables:

$$\vec{x}_i(t)=\begin{pmatrix} x_{i,1}(t) \\ \vdots \\ x_{i,n}(t) \end{pmatrix} \qquad \vec{x}_j(t)=\begin{pmatrix} x_{j,1}(t) \\ \vdots \\ x_{j,m}(t) \end{pmatrix} \tag{15.4.469}$$

The total number of combinations we can do is obviously:

$$\text{Card}(\vec{x}_i(t))\times\text{Card}(\vec{x}_j(t))=nm \tag{15.4.470}$$

Why speak about this special case??? Because as it can be visualized as a double entry table, many spreadsheet software offer a "Data Table" tool to make "deterministic bivariate direct bias method". Indeed, a spreadsheet software like Microsoft® Excel® provides us a tool in this purpose (for more details, see a Microsoft® Excel® book as this is only basic stuff):

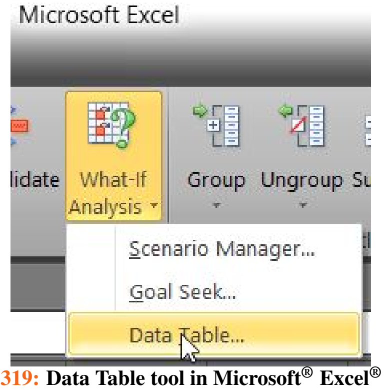

Figure 15.319: Data Table tool in Microsoft® Excel® 14.0.7166

And example based on the minimal order quantity of Wilson's model gives with a little bit formatting:

	A	B	C	D	E	F	G	H	I
1	N:	250	C_L:	5.00	t%:	10%			
2	Q:	100	S_S:	50	P_U:	5.00			
3									
4	52.50	10	20	30	40	60	80	100	120
5	1	30.50	18.50	14.83	13.25	12.17	12.13	12.50	13.08
6	1.25	31.88	20.00	16.46	15.00	14.17	14.38	15.00	15.83
7	1.5	33.25	21.50	18.08	16.75	16.17	16.63	17.50	18.58
8	1.75	34.63	23.00	19.71	18.50	18.17	18.88	20.00	21.33
9	2	36.00	24.50	21.33	20.25	20.17	21.13	22.50	24.08
10	2.25	37.38	26.00	22.96	22.00	22.17	23.38	25.00	26.83
11	2.5	38.75	27.50	24.58	23.75	24.17	25.63	27.50	29.58
12	2.75	40.13	29.00	26.21	25.50	26.17	27.88	30.00	32.33
13	3	41.50	30.50	27.83	27.25	28.17	30.13	32.50	35.08
14	3.25	42.88	32.00	29.46	29.00	30.17	32.38	35.00	37.83

Figure 15.320: Data Table tool illustration with Microsoft® Excel® 14.0.7166

2. The "univariate probabilistic direct bias method" consist simple to admit that $x_i(t)$ is not punctual but fluctuate and follow a density probabilistic function $f_i(t)$:

$$P(X \geq x_i(t)) = F_{i,t}(x_i(t)) \tag{15.4.471}$$

and that:

$$F_{i,t}^{-1}(P(X \geq x_i(t))) = x_i(t) \tag{15.4.472}$$

Using the property we saw in the section of Numerical Methods (see page 6710), we have:

$$\{x_i(t)\} = F_{i,t}^{-1}(\mathcal{U}) \tag{15.4.473}$$

Therefore the idea is not the measure $\Delta y(t)/y(t)$ anymore but based on a simulation of n values:

$$P(Y(t) \leq y(t)) = \hat{F}_n\left(\frac{f((x_1(t), \ldots, F_{i,t}^{-1}(\mathcal{U}), \ldots, x_n(t)), t) \leq y(t)}{n}\right) \tag{15.4.474}$$

If once again the practitioner prefers a "relative input/relative output" then we take:

$$\delta_{i,t} = F_{i,t}^{-1}(\mathcal{U}) \tag{15.4.475}$$

and then the analysis becomes:

$$\begin{aligned} &P\left(\frac{\Delta Y(t)}{Y(t)} \leq \frac{\Delta y(t)}{y(t)}\right) \\ &= \hat{F}_n\left(\frac{\dfrac{f((x_1(t), \ldots, x_i(t)F_{i,t}^{-1}(\mathcal{U}), \ldots, x_n(t)), t) - f((x_1(t), \ldots, x_n(t)), t)}{f((x_1(t), \ldots, x_n(t)), t)} \leq y(t)}{n}\right) \end{aligned} \tag{15.4.476}$$

The information we get therefore is not the same as previously. Before we had a relative variation for the output for a given variation of the input. Now we have a probabilistic distribution of all possible outcomes. These are two distinct things that are complementary!!!

3. The "probabilistic or deterministic univariate forecast bias method" consists simply by doing the same both calculations as before but at any given time t. Therefore the practitioner must make usage of the forecasting techniques we saw in the section of Economy (see page 7896).

   For example the most common usage is a "nominal input/nominal output" with probabilistic bias and therefore we get a stochastic model such that:

$$\begin{aligned} &P(\hat{Y}(t+\Delta t) \leq y(t+\Delta t)) \\ &= \hat{F}_n\left(\frac{f((x_1(t+\Delta t), \ldots, F_{i,t+\Delta t}^{-1}(\mathcal{U}), \ldots, x_n(t+\Delta t)), t) \leq y(t+\Delta t)}{n}\right) \end{aligned} \tag{15.4.477}$$

15.4.7.2 Correlation Method

The correlation method, involves fitting a regression to the model response and using the regression coefficient as direct measures of sensitivity. This method is considered by many consultants as the real "sensitivity analysis".

Let us first recall that the correlation coefficient is given as (see section Statistics page 614):

$$R_{x,y}=\frac{\displaystyle\sum_{k=1}^{n}x_ky_k-\frac{1}{n}\sum_{k=1}^{n}x_k\sum_{k=1}^{n}y_k}{\sqrt{\left[\displaystyle\sum_{k=1}^{n}x_k^2-\frac{1}{n}\left(\sum_{k=1}^{n}x_k\right)^2\right]\left[\displaystyle\sum_{k=1}^{n}y_k^2-\frac{1}{n}\left(\sum_{k=1}^{n}y_k\right)^2\right]}} \tag{15.4.478}$$

and a perfectly equivalent notation already proved in the section of Numerical Methods:

$$R_{x,y}=\frac{\displaystyle\sum_{k}(x_k-\bar{x})(y_k-\bar{y})}{\sqrt{\displaystyle\sum_{k}(x_k-\bar{x})^2\sum_{k}(y_k-\bar{y})^2}} \tag{15.4.479}$$

with for recall:

$$-1<R_{x,y}<+1 \tag{15.4.480}$$

The idea is that if we have a main variable that depends on multiple dependent variables then we calculate the correlation coefficient (or the coefficient of determination which is simply the square of the correlation coefficient) of the main variable with each of the probabilistic simulations of the underlying variables.

Let us take a simple example that applies to the world of project management (as it is the expertise domain of the author of these lines). Imagine a project schedule that is made only of a critical path (see section Graph Theory page 3016) based solely only on two tasks A and B. Imagine that first task A time execution distribution is the best fitted with a non-truncated Normal law (yes it's stupid but its only for the example!!!) such as:

$$t(A)=\mathcal{N}(\mu,\sigma)=\mathcal{N}(8,1) \tag{15.4.481}$$

that is to say an expected duration of 8 days and a standard deviation of 1 day and the task B is supposed to be spread over a period following a beta distribution (according to the recommendation of PMI and the theory seen previously...) of parameters $(5,12)$. Thus an optimistic duration 5 days and a pessimistic duration of 12 days:

$$P_{a,b}=\frac{(x-a)^{\alpha-1}(x-a)^{\gamma-1}}{(b-a)^{\alpha+\gamma+1}B(\alpha,\gamma)}=\frac{(x-5)^{3+\sqrt{2}-1}(x-5)^{3-\sqrt{2}-1}}{(12-5)^{3+\sqrt{2}+3-\sqrt{2}+1}B(3+\sqrt{2},3-\sqrt{2}} \tag{15.4.482}$$

Let us do for an application example with a Monte Carlo simulation (see section Numerical Methods page 6708) of $1,000$ iterations with the English version of Microsoft® Excel® 11.8346 (even if it is most more efficient to use a software like Palisade @Risk):

	B	C	D
1	A	B	Somme
2	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C2+B2
3	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C3+B3

12	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C12+B12
13	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C13+B13
14	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C14+B14
15	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C15+B15
16	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C16+B16
17	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C17+B17
18	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C18+B18
19	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C19+B19
20	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C20+B20
21	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C21+B21
22	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C22+B22
23	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C23+B23
24	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C24+B24
25	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C25+B25
26	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C26+B26
27	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C27+B27
28	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C28+B28
29	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C29+B29
30	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C30+B30
31	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C31+B31
32	=NORMINV(RANDBETWEEN(1;10000)/10000;8;1)	=BETAINV(RANDBETWEEN(1;10000)/10000;3+SQRT(2);3-SQRT(2);5;12)	=C32+B32

Figure 15.321: Simulation of two small tasks respectively with a Normal and Beta distribution

Then we calculate always with the English version of Microsoft® Excel® 11.8346 the correlation coefficient:

	F	G
1	Coeff. C/A	Coeff. C/B
2	=PEARSON(B2:B1001;D2:D1001)	=PEARSON(C2:C1001;D2:D1001)

Figure 15.322: Correlation coefficient between the sums and each task

Which gives:

	F	G
1	Coeff. C/A	Coeff. C/B
2	0.64	0.75

Figure 15.323: Corresponding correlation values

Either as it is customary in the field of sensitivity analysis in the form of a "Tornado chart":

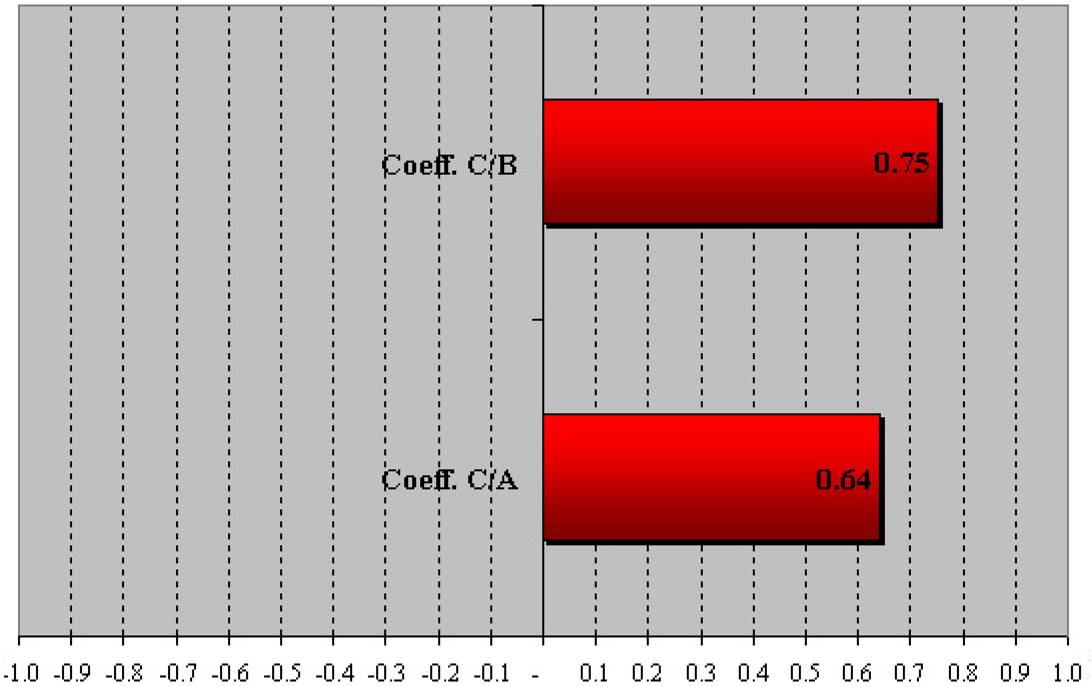

Figure 15.324: **Tornado chart build with Microsoft® Excel® 11.8346**

It is dangerous to use the (Pearson) correlation coefficient when the relationship between the endogenous variable and the exogenous variable is not linear! However, modern softwares can identify almost any other type of relation (exponential, logarithmic, power, polynomial) and make the necessaries transformation to bring the equation to that of the straight line (see section Numerical Methods page 6322). However, this manipulation can also lead to major errors in some cases. The majority of specialized softwares then use the empirical definition of the regression we saw in the section of Numerical Methods (see page 6333):

$$R_{x,y}^2 = 1 - \frac{\text{SSR}}{\text{SST}} \tag{15.4.483}$$

and then use optimization techniques (see section Numerical Methods page 6645) to determine the parameters of the that minimize the R^2 according to previous relation.

A specialized software that the author of these lines like to use and to teach to quickly get this kind of analysis on complex situations is @RISK from Palisade that gives the following graph:

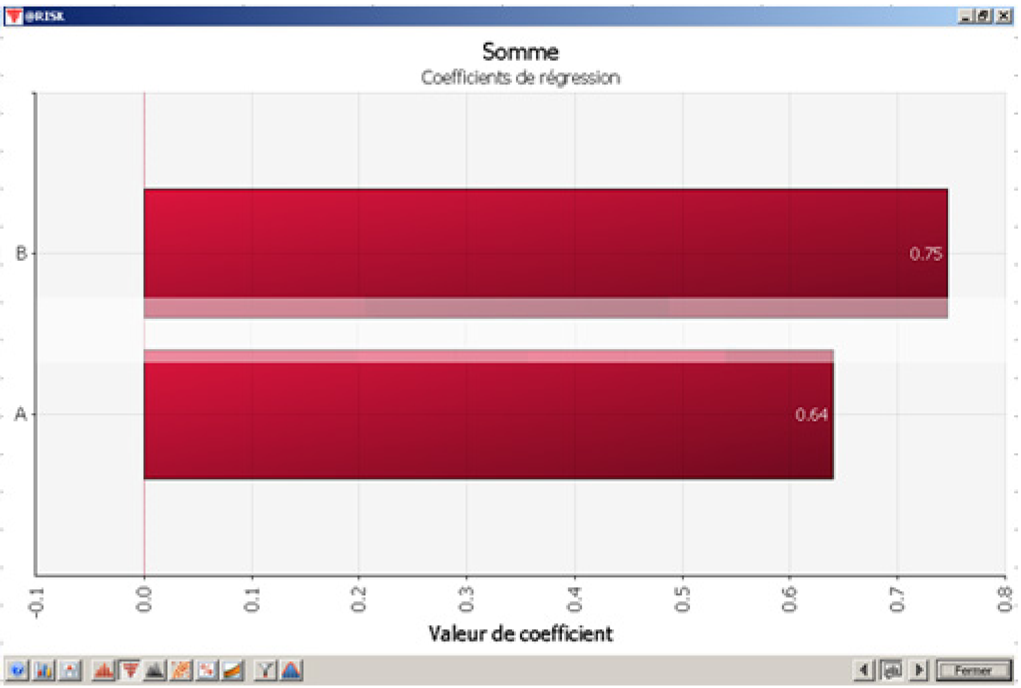

Figure 15.325: Tornado chart of the simulation obtained with @RISK

Finally, when we have a large number of underlying variables, it may be interesting to group the interval correlation coefficients with the following type of graph (example taken from the stock exchange) where the ordinate represents the $\%$ of the number of total input variables concerned (as far as I know @Risk sadly don't do such chart automatically):

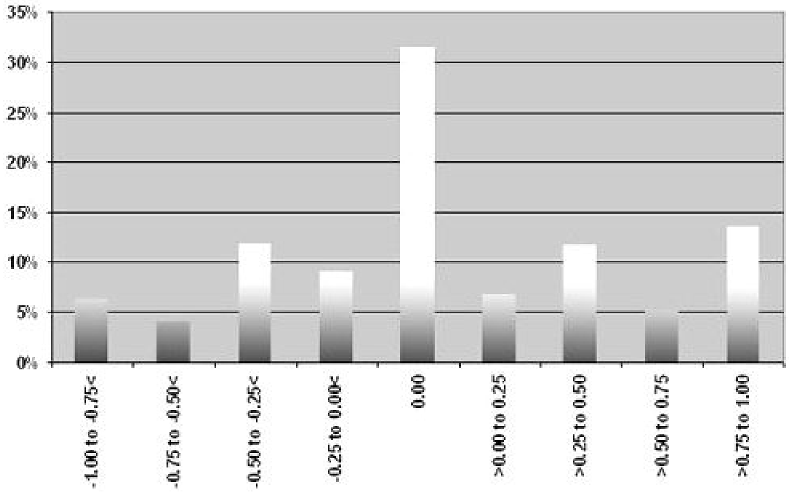

Figure 15.326: Chart for correlation group analysis with MS Excel 11.8346

Thus for this special above example, 32% of the endogenous variables have a zero correlation coefficient with the exogenous variable (which is the performance index of the relevant portfolio) and 14% of the endogenous variables have a correlation coefficient between $+0.75$ and $+1$.

It is also common to represent the average influence in $\%$ of each endogenous variable on the exogenous variable by averaging (or taking the median as more robust indicator) the influence on each other. This gives the following chart if we have a large number of endogenous variable:

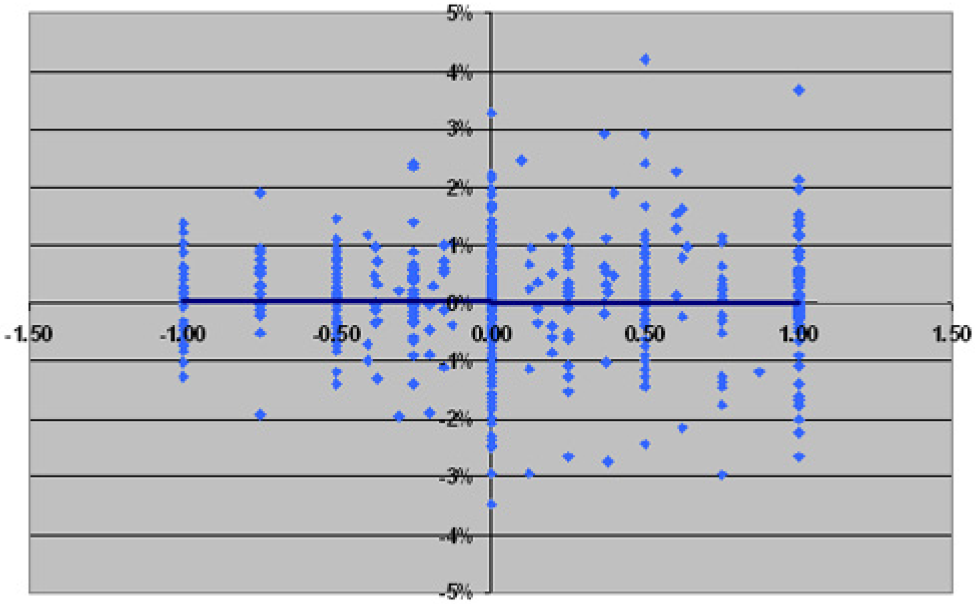

Figure 15.327: **Chart for correlation group analysis with MS Excel 11.8346**

For example, we can see in the graph above a that an endogenous variable has an average impact of $+4\%$ on the portfolio index with correlation of $+0.5$.

Anyway ... the practitioners are free to do as many graph types they want depending on their business needs!

15.5. Music Mathematics (physics of hearing)

MUSIC theorists sometimes use mathematics to understand music, and although music has no axiomatic foundation in modern mathematics, mathematics is "the basis of sound" and sound itself in its musical aspects... exhibits a remarkable array of number properties, simply because nature itself is amazingly mathematical!

The theory of music encompass all theoretical aspects of a particular music system. There are, not one, but many musical theories, each type of music having its own! All musical system are indeed based on a number of usage, more or less constraint, that could be encompass into a theory, orally or written.

A theory of music has often a religious, philosophical or magic basis and sometimes and arithmetic or scientific starting point (acoustic). It is on this latter that we focus in this section of course...!

We will begin by considering in this section elastic waves in a gas, resulting from pressure variations in the gas. Sound is the most important example of this type of wave which is part of our daily environment.

Caution!!! As we will prove it further below sound doesn't need air to travel, it needs a medium and sound is interpreted by sensors as a change in pressure in that medium (the vacuum is also a medium)! When you hear sounds for example from NASA videos depicting stage separation in space that's for two reasons: 1) the gas ejected creates and change in pressure near the sensor from nothing (i.e. vacuum) to something (hence a sound!) 2) the vibrations of the separation spreads through all the physical components of the rocket (most metals are very medium for sound propagation) hence also another type of sound that superpose to the first one.

15.5.1 Longitudinal Sound Waves

In elastic mediums, gases and liquids, longitudinal sound waves propagate in the following mechanism (for solids this are transverse waves that we have already study in the section of Continuum Mechanics): a middle layer moves in the direction of propagation of the wave (hence the name of "longitudinal") and compresses the next layer, which advance under the effect of pressure and compresses the next layer and so on. This also works for a layer going backwards: the pressure on the next layer decreases, which has the effect of reducing the next layer which in turn decreases the pressure on the next, etc.

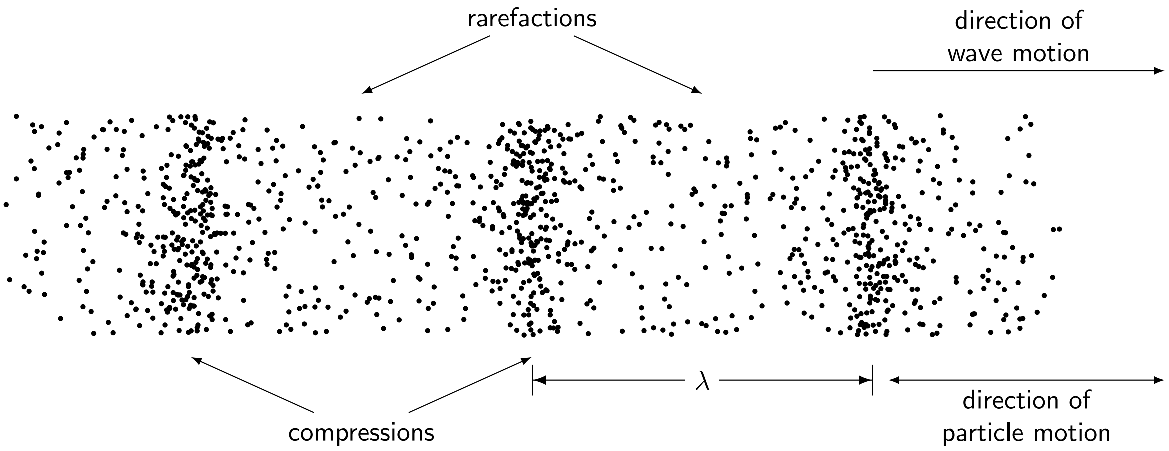

Figure 15.328: **Vocabulary of a longitudinal wave propagation in an ideal gas**

The speed at which the longitudinal waves will move depends as often on the characteristics of the environment. In general, it is lower in gases than in liquids and lower in the liquid than in solids. For example in the air $\sim 340\,[\text{m}\cdot\text{s}^{-1}]$, in water $\sim 1,500\,[\text{m}\cdot\text{s}^{-1}]$ and $\sim 5,000\,[\text{m}\cdot\text{s}^{-1}]$ for the transverse waves in the steel.

Caution!!! In the realm of audiophiles, where music lovers seek sonic nirvana, a murky landscape exists as sound is the most biased of all our senses (with a statistical significant placebo effect). Some self-proclaimed audio gurus on social networks wield buzzwords like "high fidelity", "warmth", and "soundstage", promising transcendent musical experiences. But beware: Many are paid promoters, pushing snake oil dressed as golden cables or mystical crystals. Their goal? To empty the wallet of their audience! Audiophiles often fall mainly into two camps. First, the artists—those who seek emotional connection through music and aren't educate to the Scientific Method nor Cognitive Biases. They care little for technical specs; it's about the soul (...). Then come the scientists—those who crave precision, understanding impedance curves and jitter. But here's the rub: Most practitioners are artists, not scientists. They trust their ears over oscilloscopes. Analog enthusiasts swoon over vinyl warmth, tube amps, and vintage gear. Digital devotees revel in bit-perfect files, DACs, and streaming. But let's be clear: Analog isn't inherently superior. It's a flavor, not a universal truth. Digital doesn't lack soul—it's just a different palette. So educate yourself. Read beyond the hype. Understand that a $5,000 power cable won't magically transport you to a jazz club. Seek reviews grounded in science, not mysticism. And remember, the sweet spot lies where your ears meet your brain, not in the price tag. So, next time an audio guru promises enlightenment through golden connectors, pause, and ask: Is this music or magic?

As regards to the frequencies, there is almost no limit (in positive real values). We can generate sound waves at fractions of Hz (Hertz: oscillations per second) up to hundreds of MHz. By reference to the frequency range audible to humans, we name "infrasound" frequencies lower than $20\,[\text{Hz}]$ and "ultrasound" frequencies greater than $20\,[\text{kHz}]$.

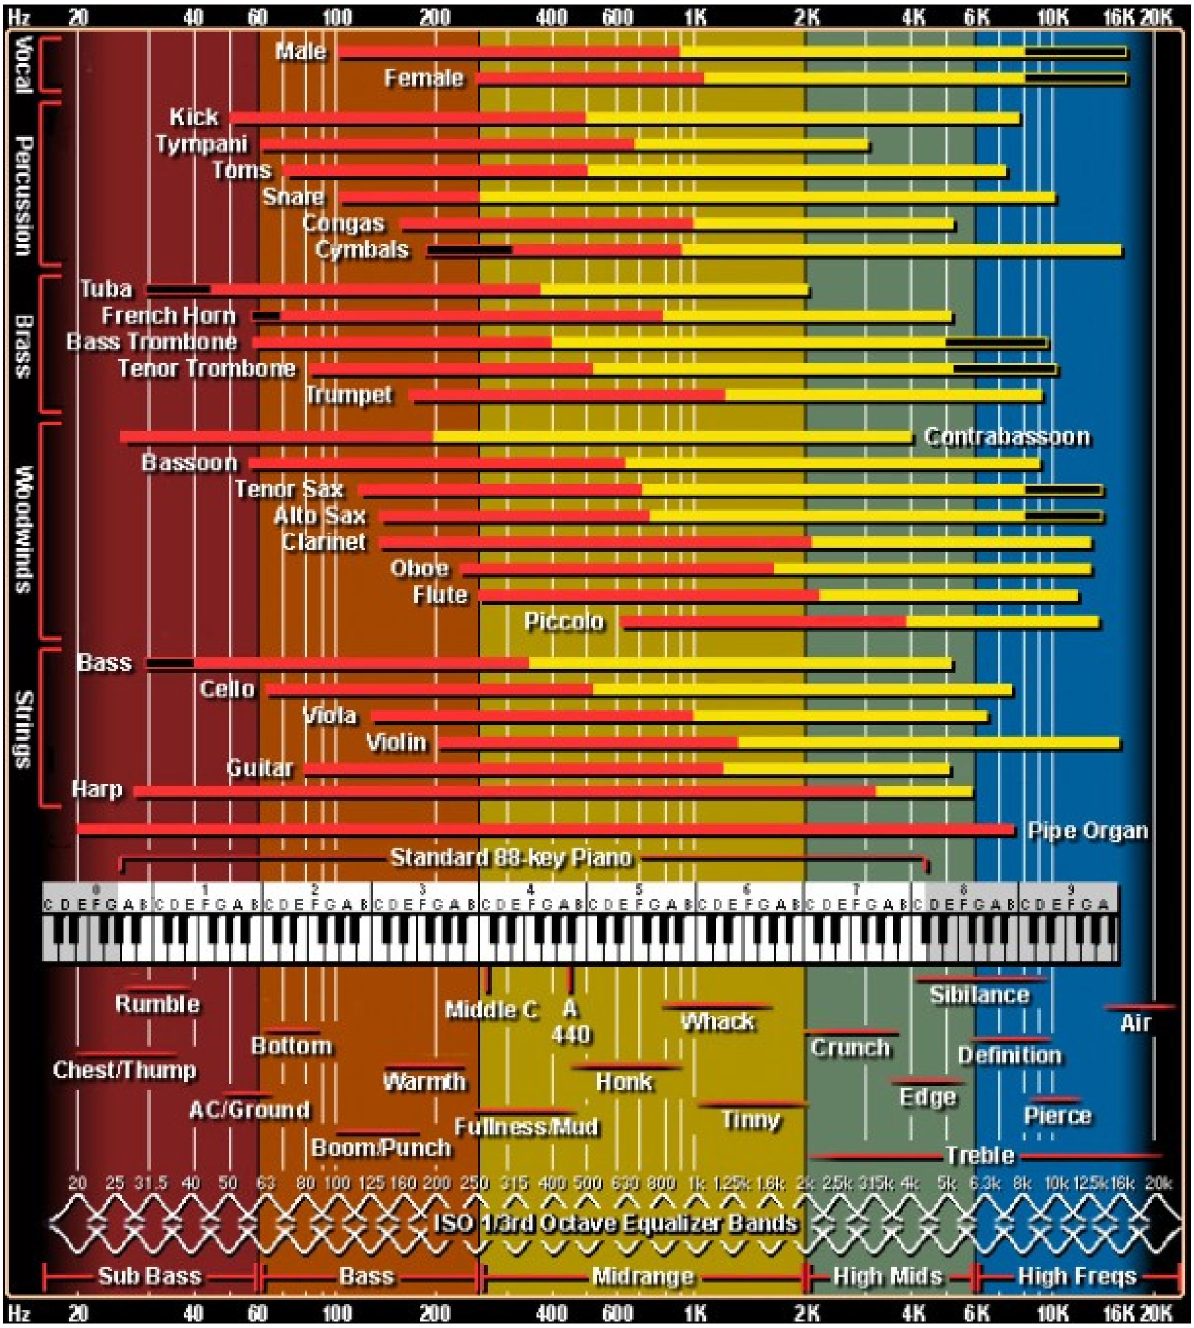

Figure 15.329: **Some instruments frequencies ranges**

In general, the waves are generated by a source of limited dimensions and, from this source, are propagated in all directions. In isotropic mediums the wavefront of a disturbance is spherical. We will avoid introducing spherical coordinates limiting us to the study of parts of wavefronts enough away from the source and sufficiently small compared with the distance to the source so we can assimilate the piece of sphere to a flat surface. That is to say: in this section we will only deal with the longitudinal plane waves.

There is also another important difference between the longitudinal elastic waves in a gas or liquid and the transverse elastic waves in a solid bar. The gas is highly compressible, and if pressure fluctuations are established in a gas, its density will undergo the same type of the pressure fluctuation.

Let us consider now the waves propagating inside a cylindrical tube or pipe (horizontal along the x-axis) of section S. Let us denote by P_0 and ρ_0 the pressure and density of the gas in equilibrium. In these conditions of equilibrium, P_0 and ρ_0 are the same throughout the whole gas volume of the cylinder, that is to say independent of any coordinate.

If the gas pressure is disturbed for example by one of the two opening of the cylinder, a volume element thereof $S\mathrm{d}x$ will intuitively move because the pressures P and P' on the two sides S, S' of this little volume will be different and therefore produce a resultant force (and therefore a power surface density).

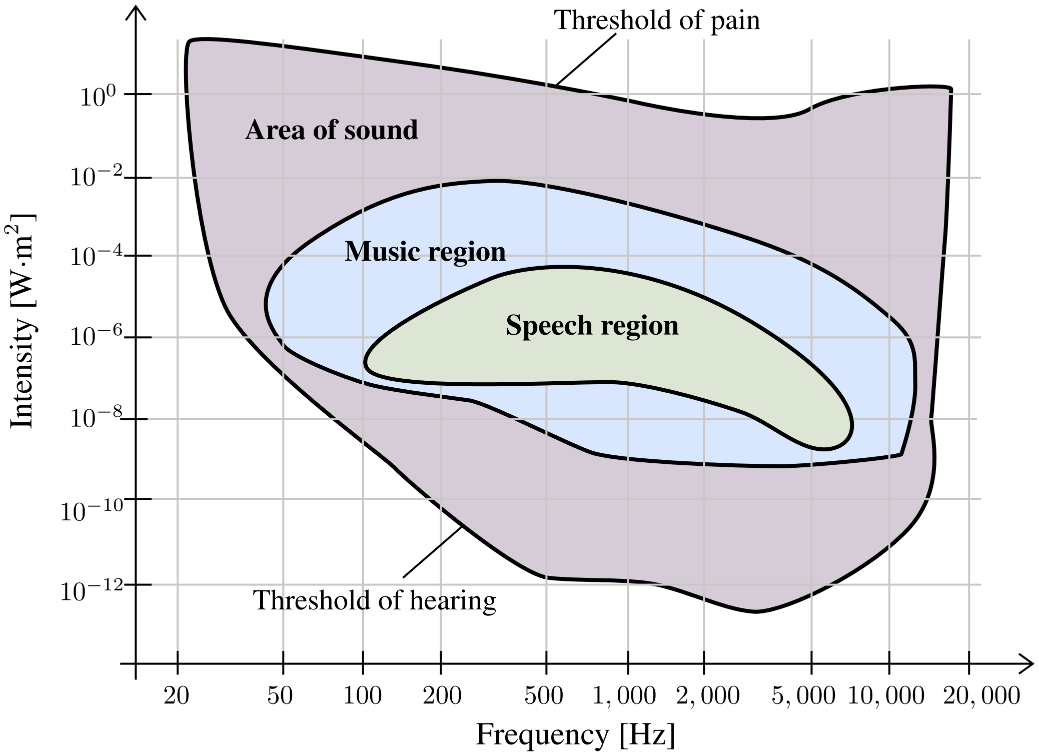

Figure 15.330: **Basic frequency spectrum with transported surface power density**

Remark

Even if they have a very high speed, in a gas, molecules undergo very frequent collisions with each other. They travel in fact less than one micron in average (mean free path), under normal conditions, before hitting another one (see section Continuum Mechanics page 3925 for the proof).

This results in a displacement of the section S of a quantity ξ and of the section S' in an amount ξ' necessarily different because pressure balance has not had time to be done.

Thus, the volume element at the start has a width $\mathrm{d}x$ but after the pressure has changed, it will have a width (if the pressure changes are small) as a first approximation equal to:

$$\mathrm{d}x+(\xi-\xi')=\mathrm{d}x+\mathrm{d}\xi \qquad (15.5.1)$$

However, due to the change in volume, there is also now a density variation due to the compressibility of gas. The mass contained in the volume is initially undisturbed:

$$M_0=\rho_0 S\mathrm{d}x \qquad (15.5.2)$$

If ρ is the density of the disturbed gas, the mass of the perturbed volume is in the end:

$$M=\rho S(\mathrm{d}x+\mathrm{d}\xi) \tag{15.5.3}$$

The conservation of matter claim that these two masses are equal, that is to say:

$$\rho S(\mathrm{d}x+\mathrm{d}\xi)=\rho_0 S\mathrm{d}x \tag{15.5.4}$$

where:

$$\rho\left(1+\frac{\mathrm{d}\xi}{\mathrm{d}x}\right)=\rho_0 \tag{15.5.5}$$

By solving relatively to ρ we get:

$$\rho=\frac{\rho_0}{1+\dfrac{\mathrm{d}\xi}{\mathrm{d}x}} \tag{15.5.6}$$

As we consider only the small changes in pressure relatively to the ambient pressure, $\mathrm{d}\xi/\mathrm{d}x$ is small, then we can replace:

$$\rho=\frac{\rho_0}{1+\dfrac{\mathrm{d}\xi}{\mathrm{d}x}} \tag{15.5.7}$$

by its limited Taylor series development (see section Sequences and Series page 1703):

$$\rho=\rho_0\left(1-\frac{\mathrm{d}\xi}{\mathrm{d}x}+\left(\frac{\mathrm{d}\xi}{\mathrm{d}x}\right)^2-\ldots\right)\cong\rho_0\left(1-\frac{\mathrm{d}\xi}{\mathrm{d}x}\right) \tag{15.5.8}$$

Therefore:

$$\frac{\rho-\rho_0}{\rho_0}=-\frac{\mathrm{d}\xi}{\mathrm{d}x} \tag{15.5.9}$$

By now admitting that the pressure is only connected to the density (for simplicity) we can write:

$$P=f(\rho) \tag{15.5.10}$$

Using the general univariate form of the Taylor expansion (see section Sequences and Series page 1703): Therefore:

$$f(x)=\sum_{k=0}^{n}\frac{1}{k!}\frac{\mathrm{d}^k f(x_0)}{\mathrm{d}x^k}(x-x_0)^k \tag{15.5.11}$$

Then we have:

$$P=\sum_{k=0}^{n}\frac{1}{k!}\frac{\mathrm{d}^k f(\rho)}{\mathrm{d}\rho^k}(\rho-\rho)^k\cong P_0+(\rho-\rho_0)\frac{\mathrm{d}P(\rho_0)}{\mathrm{d}\rho} \tag{15.5.12}$$

The quantity:

$$\frac{1}{\kappa}=\rho_0\left(\frac{\mathrm{d}P}{\mathrm{d}\rho}\right)_{\rho=\rho_0} \tag{15.5.13}$$

usually denoted:

$$\kappa=\frac{1}{\rho_0}\left(\frac{\mathrm{d}\rho}{\mathrm{d}P}\right)_{\rho=\rho_0} \tag{15.5.14}$$

is named "coefficient of compressibility" or more technically "coefficient of isothermal compressibility".

Let us recall now that we have proved in the section of Weather and Marine Engineering during our study of the adiabatic atmospheric model that starting from Laplace's law we get:

$$\frac{\mathrm{d}P}{\mathrm{d}\rho}=\gamma\frac{P}{\rho_0} \tag{15.5.15}$$

where for recall γ is the "Laplace coefficient", also named "adiabatic coefficient" defined by (see section Thermodynamics page 3649):

$$\gamma=\frac{C_P}{C_V} \tag{15.5.16}$$

Remark

The prior-previous relation can often been found in the literature in the following form:

$$\Delta P=\gamma P_0\frac{\Delta V}{V_0} \tag{15.5.17}$$

Then we get (relation that we will use later):

$$\frac{1}{\kappa}=\rho_0\gamma\frac{P}{\rho_0}\Rightarrow\frac{1}{\kappa}=\gamma P \tag{15.5.18}$$

The isothermal compressibility coefficient will obviously be written in the general case:

$$\kappa=\frac{1}{\rho}\left(\frac{\mathrm{d}\rho}{\mathrm{d}P}\right) \tag{15.5.19}$$

By the way, let us notice that by changing to the density to the volume, we get:

$$\kappa=\frac{1}{\rho}\left(\frac{\mathrm{d}\rho}{\mathrm{d}P}\right)=\frac{1}{\dfrac{m}{V}}\left(\frac{\mathrm{d}\left(\dfrac{m}{V}\right)}{\mathrm{d}P}\right)=V\frac{\mathrm{d}\left(\dfrac{1}{V}\right)}{\mathrm{d}P}=V\frac{-\dfrac{1}{V^2}\mathrm{d}V}{\mathrm{d}P}=-\frac{1}{V}\left(\frac{\mathrm{d}V}{\mathrm{d}P}\right) \tag{15.5.20}$$

often denoted χ in the field of Thermodynamics.

Let us return to the two relations:

$$\frac{1}{\kappa}=\rho_0\left(\frac{\mathrm{d}P}{\mathrm{d}\rho}\right)_{\rho=\rho_0}\qquad\text{and}\qquad\frac{\rho-\rho_0}{\rho_0}=-\frac{\mathrm{d}\xi}{\mathrm{d}x} \tag{15.5.21}$$

and let inject them into the Taylor series above. Then we have:

$$P\cong P_0+\frac{(\rho-\rho_0)}{\rho_0}\frac{1}{\kappa}=P_0+\frac{-\rho_0\dfrac{\mathrm{d}\xi}{\mathrm{d}x}}{\rho_0}\frac{1}{\kappa}=P_0-\frac{\mathrm{d}\xi}{\mathrm{d}x}\frac{1}{\kappa} \tag{15.5.22}$$

This expression links the pressure at any point of the gas to the deformation at the same point.

We then need the equation of motion of the volume element. The mass of the element is $\rho_0 S\mathrm{d}x$ and its acceleration $\mathrm{d}\xi^2/\mathrm{d}t^2$.

We have naturally in terms of force (the minus sign indicates that the force change the pressure is opposed to the initial pressure in the cylinder):

$$-S\mathrm{d}P=(\rho_0 S\mathrm{d}x)\frac{\mathrm{d}^2\xi}{\mathrm{d}t^2} \tag{15.5.23}$$

Therefore:

$$\frac{\mathrm{d}P}{\mathrm{d}x}=-\rho_0\frac{\mathrm{d}^2\xi}{\mathrm{d}t^2} \tag{15.5.24}$$

In this problem, there are two fields, the displacement field ξ and the pressure field P. We can combine them as follows by taking:

$$P\cong P_0-\frac{\mathrm{d}\xi}{\mathrm{d}x}\frac{1}{\kappa} \tag{15.5.25}$$

and differentiating with respect to x and remembering that P_0 is independent of the position in the gas. Then we have:

$$\frac{\mathrm{d}P}{\mathrm{d}x}=-\frac{1}{\kappa}\frac{\mathrm{d}^2\xi}{\mathrm{d}x^2} \tag{15.5.26}$$

What we can combine with:

$$\frac{\mathrm{d}P}{\mathrm{d}x}=-\rho_0\frac{\mathrm{d}^2\xi}{\mathrm{d}t^2} \tag{15.5.27}$$

We thus find the final expression of the wave equation of (for recall) a Poisson's equation (more particularly it is a D'Alembert's equation):

$$\boxed{\frac{\mathrm{d}^2\xi}{\mathrm{d}t^2}=\frac{1}{\kappa\rho_0}\frac{\mathrm{d}^2\xi}{\mathrm{d}t^2}} \tag{15.5.28}$$

So we get a similar relation to that we got in the section of Wave Mechanics for mechanical waves or in the section of Electrodynamics for electromagnetic waves.

We conclude that displacement due to pressure disturbance in a gas spreads to speed:

$$v=\sqrt{\frac{1}{\kappa\rho_0}}=\sqrt{\frac{\gamma P}{\rho_0}}=\sqrt{\frac{\gamma}{\rho_0}\frac{nkT}{V}}=\sqrt{\frac{\gamma NkT}{M}}=\sqrt{\frac{\gamma nRT}{M}}=\sqrt{\frac{\gamma RT}{M_m}} \tag{15.5.29}$$

where for recall the gas constant worth $8.314\,[\mathrm{J}\cdot\mathrm{K}^{-1}\cdot\mathrm{mol}^{-1}]$.

The relation:

$$\boxed{v=\sqrt{\frac{\gamma P}{\rho_0}}} \tag{15.5.30}$$

is sometimes named "Newton-Laplace speed of sound relation".

✍**Example:**

If we consider the air as an ideal diatomic gas then (see section Thermodynamics page 3648) we have $\gamma \cong 7/5 = 1.4\ldots$ of molar mass $29 \cdot 10^3\,[\mathrm{kg}\cdot\mathrm{mol}^{-1}]$ (weighted average molecular weights of N_2 and O_2). It comes then at a temperature of $300\,[\mathrm{K}]$:

$$v = \sqrt{\frac{\gamma P}{\rho_0}} = 347\,[\mathrm{m}\cdot\mathrm{s}^{-1}] \tag{15.5.31}$$

This is in perfect agreement with the experience! By cons, when we say that a plane flies at Mach 2 (Mach is the ratio between the speed of an airplane and that of sound as we will see further below during our study of wave shocks), we do not really know in reality the speed of sound (neither that of the plane) nor the temperature.

But, we also have the following result (see section Continuum Mechanics page 3761):

$$\kappa = \frac{3(1-2\eta)}{E} \tag{15.5.32}$$

But, we have discussed in the section of Mechanical Engineering (see page 3761) that the Poisson coefficient η respects:

$$\eta < \frac{1}{2} \tag{15.5.33}$$

Taking the approximation that for a gas $\eta \cong 1/3$... then we have:

$$\kappa = \frac{3(1-2\eta)}{E} \cong \frac{1}{E} \tag{15.5.34}$$

and therefore:

$$\boxed{v = \sqrt{\frac{E}{\rho_0}}} \tag{15.5.35}$$

The speed of sound is given by the same type of expression for fluids or solids! Thus, the propagation of a longitudinal deformation in a solid is given by:

$$\boxed{\frac{\mathrm{d}^2\xi}{\mathrm{d}t^2} = \frac{E}{\rho_0}\frac{\mathrm{d}^2\xi}{\mathrm{d}x^2}} \tag{15.5.36}$$

and for the transverse strain (see section Continuum Mechanics page 3765):

$$\boxed{\frac{\partial^2 y}{\partial t^2} = \frac{G}{\rho_0}\frac{\partial^2 y}{\partial x^2}} \tag{15.5.37}$$

We also have:

$$\begin{aligned} \frac{\partial^2}{\partial t^2}P &\cong \frac{\partial^2}{\partial t^2}\left(P_0 - \frac{1}{\kappa}\frac{\mathrm{d}\xi}{\mathrm{d}x}\right) = -\frac{1}{\kappa}\frac{\partial^2}{\partial t^2}\left(\frac{\mathrm{d}\xi}{\mathrm{d}x}\right) \\ \frac{\partial^2}{\partial x^2}P &\cong \frac{\partial}{\partial x}\left(-\rho_0\frac{\mathrm{d}^2\xi}{\mathrm{d}t^2}\right) = -\rho_0\frac{\partial}{\partial x}\left(\frac{\mathrm{d}^2\xi}{\mathrm{d}t^2}\right) = -\rho_0\frac{\partial^2}{\partial t^2}\left(\frac{\partial\xi}{\partial x}\right) \end{aligned} \tag{15.5.38}$$

Dividing these equalities member by member, we get:

$$\frac{\dfrac{\partial^2 P}{\partial t^2}}{\dfrac{\partial^2 P}{\partial x^2}}=\frac{-\dfrac{1}{\kappa}\dfrac{\partial^2}{\partial t^2}\left(\dfrac{\mathrm{d}\xi}{\mathrm{d}x}\right)}{-\rho_0\dfrac{\partial^2}{\partial t^2}\left(\dfrac{\partial\xi}{\partial x}\right)} \tag{15.5.39}$$

Thus after simplification:

$$\boxed{\frac{\partial^2 P}{\partial t^2}=\frac{1}{\kappa\rho_0}\frac{\partial^2 P}{\partial x^2}} \tag{15.5.40}$$

For laboratories usage, the sound wave model is more convenient than the previous one as we measure more easily pressure variations in a liquid or a gas, than the movements of molecules. It is interesting to know that all the analyses we have made with the string wave equation (see section Wave Mechanics page 3476) or electromagnetic waves (see section Electrodynamics page 4138) can also be applied to the equation above (energetic aspects, particular solutions, decrease in amplitude in function on the distance from the source, etc.).

The movement of the waves in gases is an adiabatic process (see section Thermodynamics page 3602) so there is no exchange of energy in heat form by the elementary volume of gas.

Remark

A "pure sound" (a perfect sine wave of a single, constant frequency) is a mathematical ideal that is not perfectly achievable in the physical world. However, it is possible to create a sound that is so close to a pure tone that the human ear cannot perceive the difference.

15.5.1.1 Power carried by a sound wave

We have seen just earlier above that:

$$\frac{\rho-\rho_0}{\rho_0}=-\frac{\mathrm{d}\xi}{\mathrm{d}x} \tag{15.5.41}$$

Let us write the density variations caused by the sound wave by:

$$\rho_s=-\rho_0\frac{\mathrm{d}\xi}{\mathrm{d}x} \tag{15.5.42}$$

We will do the calculation of the power carried by a wave only in the case of sine waves here. In this case ξ will be of the form:

$$\xi=\xi_0\cos(\omega t-kx) \tag{15.5.43}$$

As ξ is known, we can calculate the corresponding pressure by using:

$$P\cong P_0-\frac{\mathrm{d}\xi}{\mathrm{d}x}\frac{1}{\kappa} \tag{15.5.44}$$

By introducing the pressure variations due to the sound wave:

$$P_s = -\frac{1}{\kappa}\frac{\mathrm{d}\xi}{\mathrm{d}x} \tag{15.5.45}$$

and by using:

$$v = \sqrt{\frac{1}{\kappa\rho_0}} \tag{15.5.46}$$

It comes:

$$P_s = -\rho_0 v^2 \frac{\mathrm{d}\xi}{\mathrm{d}x} \tag{15.5.47}$$

Then we have:

$$P_s = \rho_0 v^2 \frac{\mathrm{d}(\xi_0 \cos(\omega t - kx))}{\mathrm{d}x} = -\rho_0 k v^2 \xi_0 \sin(\omega t - kx) = -P_0 \sin(\omega t - kx) \tag{15.5.48}$$

To calculate the power carried by a sound wave, we will calculate the work done, during a period, on a surface S on a plane perpendicular to the x-axis and of coordinates x.

The force applied on this surface will be:

$$F = SP_s \tag{15.5.49}$$

The work done when the surface moves of $\mathrm{d}\xi$ will be:

$$\mathrm{d}W = F\mathrm{d}\xi = SP_s\mathrm{d}\xi \tag{15.5.50}$$

As we are doing a calculation for the displacements ξ of a layer whose equilibrium position x does not vary, only the variable t varies:

$$\mathrm{d}\xi = \frac{\partial \xi}{\partial t}\mathrm{d}t = -\omega\xi_0 \sin(\omega t - kx)\mathrm{d}t \tag{15.5.51}$$

Substituting we get:

$$\begin{aligned}\mathrm{d}W &= SP_s\mathrm{d}\xi = -SP_s\omega\xi_0 \sin(\omega t - kx)\mathrm{d}t \\ &= -S(-\rho_0 k v^2 \xi_0 \sin(\omega t - kx))\omega\xi_0 \sin(\omega t - kx)\mathrm{d}t \\ &= S\rho_0 k v^2 \omega \xi_0^2 \sin^2(\omega t - kx)\mathrm{d}t\end{aligned} \tag{15.5.52}$$

The word applied during one period $T = 2\pi/\omega$ will be:

$$W = S\rho_0 k v^2 \omega \xi_0^2 \int\limits_0^{\frac{2\pi}{\omega}} sin^2(\omega t - kx)\mathrm{d}t \tag{15.5.53}$$

We have already proved the expression of such an integral in the section of Differential and Integral Calculus:

$$\int \sin^2(\omega t - kx)\mathrm{d}t = \frac{1}{\omega}\int \sin^2(y)\mathrm{d}y = \frac{1}{2\omega}(-\cos(y)\sin(y) + y) \tag{15.5.54}$$

Hence:

$$\begin{aligned}\int_0^{\frac{2\pi}{\omega}} \sin^2(\omega t-kx)\mathrm{d}t &= \left(\frac{1}{2\omega}\left(-\cos(\omega t-kx)\sin(\omega t-kx)+(\omega t-kx)\right)\right)\Bigg|_0^{\frac{2\pi}{\omega}}\\ &=\frac{1}{2\omega}\left(-\cos\left(\omega\frac{2\pi}{\omega}-kx\right)\sin\left(\omega\frac{2\pi}{\omega}-kx\right)+\left(\omega\frac{2\pi}{\omega}-kx\right)\right)\\ &-\frac{1}{2\omega}(-\cos(-kx)\sin(-kx)+(-kx))\\ &=\frac{1}{2\omega}(\cos(kx)\sin(kx)+2\pi-kx)-\frac{1}{2\omega}(\cos(kx)\sin(kx)-kx)=\frac{\pi}{\omega}\end{aligned} \tag{15.5.55}$$

Replacing it comes:

$$W=S\rho_0 kv^2\omega\xi_0^2\frac{\pi}{\omega}=S\rho_0 kv^2\pi\xi_0^2 \tag{15.5.56}$$

To calculate the power, we have to divide the work by the time during which it was made:

$$T=\frac{2\pi}{\omega} \tag{15.5.57}$$

and to calculate the power transmitted per unit area, we have to divide by the surface:

$$\frac{P}{S}=\frac{S\rho_0 kv^2\pi\xi_0^2}{\dfrac{2\pi}{\omega}S}=\frac{\rho_0 kv^2\omega}{2}\xi_0^2 \tag{15.5.58}$$

If we replace k by:

$$k=\frac{\omega}{v} \tag{15.5.59}$$

We get:

$$\frac{P}{S}=\frac{\rho_0 v\omega^2}{2}\xi_0^2 \tag{15.5.60}$$

Before we continue, notice that there are several ways to measure the amplitude of a sound, and by extension, any signal of wave nature:

- The average amplitude (the arithmetic mean value of the positive signal)
- The effective amplitude (equivalent continuous amplitude in power)
- The peak amplitude (maximum positive)
- The peak to peak amplitude (the maximum difference of positive and negative amplitude)

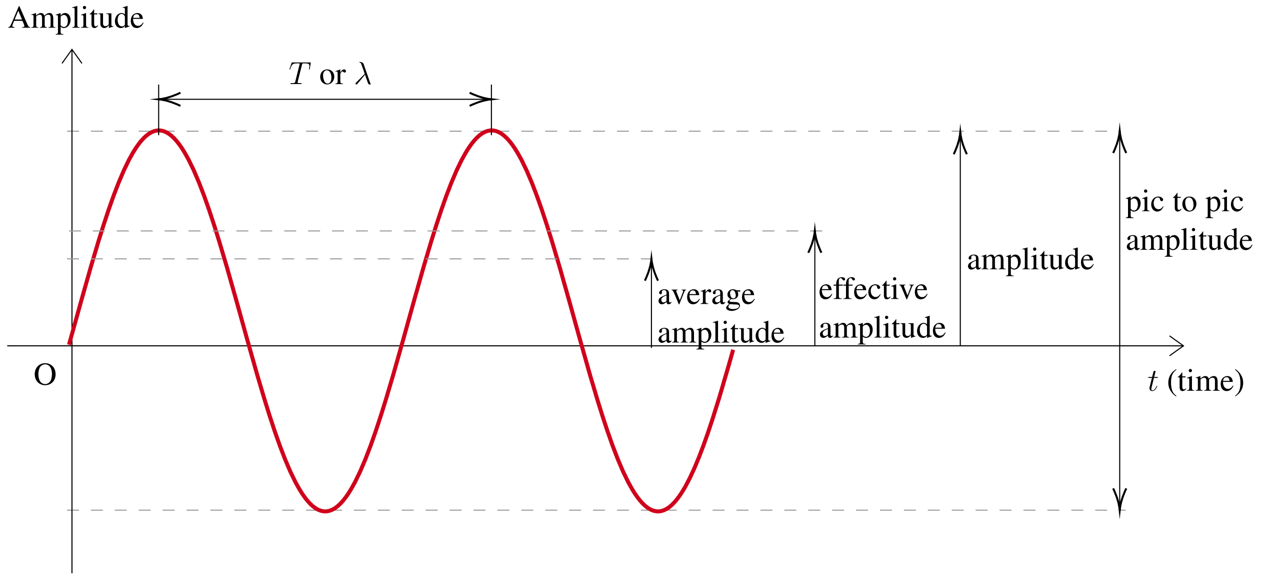

Figure 15.331: **Various types of amplitudes**

In practice, the average amplitude of little interest and is not used to much. However, the effective value or "Root Mean Square", that is the square root of the mean square value of the signal is universally adopted to measure the value of AC voltages (it is like the variance in statistics in fact!), within the general framework than in acoustic. An amplifier which is given with the indication "10 watts RMS" will have approximately 14 watts peak and approximately 28 watts peak-to-peak (also denoted by "pp"). Measurements of power peak to peak are quite often named "music watts" by the audio-video retailers because the values are quite nice in terms of communication/marketing..

The unit of measurement of the amplitude depends on the physical measured quantity:

- For a vibrating string, it's a distance.
- For a sound wave is the air pressure, or movement of the diaphragm.
- For the electromagnetic radiation, the amplitude corresponds to the electric field.
- For an electrical signal that corresponds to the maximum value of the current intensity.

For sinusoidal regimes (or more generally any periodic signal!), it is easy to prove that regardless of the field in physics the effective value (square root of the mean square of the signal) is the peak value divided by the square root of two. Indeed:

$$\xi_{\text{eff}}=\sqrt{\frac{1}{T}\int\limits_0^T \xi^2(t)\mathrm{d}t}=\sqrt{\frac{1}{2\pi}\int\limits_0^{2\pi} \xi^2(\theta)\mathrm{d}\theta}=\sqrt{\frac{1}{2\pi}\xi_0^2\pi}=\frac{\xi_0}{\sqrt{2}} \tag{15.5.61}$$

Therefore:

$$\boxed{\text{RMS}=\frac{A}{\sqrt{2}}} \tag{15.5.62}$$

Hence in RMS (this is only an arbitrary choice and nothing else!!!... so that you understand what will follow!!), the prior previous relations is:

$$\boxed{\frac{P}{S}=\rho_0 v\omega^2\xi_{\text{eff}}^2=\rho_0 kv^2\omega\xi_{\text{eff}}^2} \tag{15.5.63}$$

As we have the amplitude of the pressure which is equal to:

$$P_0=\rho_0 kv^2\xi_0=\rho_0\omega v\xi_0 \tag{15.5.64}$$

and its RMS by:

$$\boxed{P_{\text{eff}}=\rho_0 kv^2\xi_{\text{eff}}=\rho_0\omega v\xi_{\text{eff}}} \tag{15.5.65}$$

Finally, we have for the power (that we will represent later by a stylized capital $\mathcal{P}$ letter in order not to be confused with the pressure P):

$$\boxed{\frac{\mathcal{P}}{S}=\rho_0 vc\omega^2\xi_{\text{eff}}^2=\frac{1}{\rho_0 v}\omega\xi_{\text{eff}})^2=\frac{1}{\rho_0 v}P_{\text{eff}}^2} \tag{15.5.66}$$

15.5.1.2 Measuring the intensity of a sound

To characterize the sound, a unit of measurement was invented: the "Bel" and its submultiple the "decibel" which is $1/10$ of Bel. This acoustic intensity, assimilated to the "loudness" was defined from the effective sound pressure (the P_{eff} given above) and of the sound pressure of a wave (at a specific frequency!) at the limit of the hearing threshold of a small elite of humanity (about 10%).

This effective pressure reference is:

$$P_{\text{eff,ref}}=2\cdot 10^{-5}\ [\text{Pa}] \tag{15.5.67}$$

The loudness of a wave whose RMS sound pressure is P_{eff} is by definition and by convention equal to:

$$I_S=\log_{10}\left(\frac{P_{\text{eff}}}{P_{\text{eff,ref}}}\right)^2=2\log_{10}\left(\frac{P_{\text{eff}}}{P_{\text{eff,ref}}}\right)=2\log_{10}\left(\frac{P_{\text{eff}}}{2\cdot 10^{-5}}\right)\ [\text{Bels}] \tag{15.5.68}$$

and is often simply denoted S in the literature to indicate that it is the "physiological sensation" of the human ear. How did we get to this relation? Well by observing on a panel of individuals that the physiological sensation of the ear was not linear but that the absolute variations of the sensation are proportional to relatives pressure variations such that:

$$\mathrm{d}I_S=c^{te}\frac{\mathrm{d}P}{P} \tag{15.5.69}$$

Therefore after integration:

$$I_S-I_{S,0}=c^{te}\ln\left(\frac{P}{P_0}\right) \tag{15.5.70}$$

where by convention the minimum sensitivity is put as being equal to zero and where for historical reasons we take the decimal logarithms instead of Napierian. It comes then:

$$I_S = c^{te} \log\left(\frac{P}{P_0}\right) \tag{15.5.71}$$

In some books, we find the definition of the Bel from a reference intensity of (at 1 [kHz]):

$$1\,[\text{Bel}] = 10^{-12}\,[\text{W}\cdot\text{m}^{-2}] \tag{15.5.72}$$

It comes therefore (the definition is equivalent because it is a ratio and that power is directly proportional to the square of pressure as we have proved earlier above):

$$I_S = \log\left(\frac{\mathcal{P}/S}{\mathcal{P}_{\text{eff,ref}}}\right)^2 = 20\log\left(\frac{P_{\text{eff}}}{2\cdot 10^{-5}}\right)\;[\text{dB}] \tag{15.5.73}$$

The decibel is then a tenth of Bel ... hence its name as already mentioned!

✍**Example:**

If an apparatus has a loudness of 122 [dB] (loudest existing megaphone in year 12020 according to holocene calendar) and another a loudness of 144 [dB] (loudness of Hyperspike HS-10-R), then their power ratio is:

$$10^{\frac{144-122}{20}} = 12.58$$

The reason of the logarithmic choice is that the it has been observed that the auditory sensation of human ear is also logarithmic (this is quite a beautiful engineering of Nature): we have the same sensation of sound increase when it goes from 1 to 10 as when it moves from 10 to 100.

To give an idea of the value of a decibel, here is a table of typical values (for a given frequency and a given reference pressure):

Decibels	Source/Effect
310	Krakatoa eruption (1883)
235	Tongal eruption (2022)
180	Rocket launch
160	(damage to the eardrum)
140	Shotgun blast (pain threshold)
130	Jet engine 30 meters away
120	Rock concert (threshold of discomfort)
110	Car horn, snowblower
100	Blow dryer, subway, helicopter, chainsaw ,heavy machinery
90	Motorcycle, lawn mower, convertible ride on highway
85	Trucks
80	Factory, noisy restaurant, vacuum, screaming child
75	Average factory
70	car, alarm clock, city traffic
60	Conversation, dishwasher,
50	Moderate rainfall
40	Cinema audience noise/Refrigerator
20	Broadcasting Studio/Watch ticking
10	Anechoic room
0	Threshold of hearing

Table 15.85: **Examples of typical dB values**

As we have already say it the minimum effective sound pressure which causes auditory sensation is:

$$2\cdot 10^{-5}\text{ [Pa]} \tag{15.5.74}$$

that is to say approximately 10^{-10} times smaller than atmospheric pressure. It must nevertheless be noticed that the frequency of this wave is around 3 [kHz] where the sensitivity is maximum for the human ear in the 120th century (holocene calendar).

It is very interesting to calculate at which amplitude of effective displacement that corresponds. We then use the relation proved above:

$$P_{\text{eff}}=\rho_0\omega v\xi_{\text{eff}} \tag{15.5.75}$$

So for the limit case at 1 [kHz], at the standard conditions for temperature and pressure, we will have a displacement of (values taken from the tables of the swiss-french mathematical commission):

$$\xi_{\text{eff}}=\frac{P_{\text{eff}}}{\rho_0\omega v}=\frac{2\cdot 10^{-5}}{1.293\cdot 2\pi\cdot 1000\cdot 331}\cong 7.43\cdot 10^{-12}\text{ [m]} \tag{15.5.76}$$

and the peak amplitude value is therefore:

$$x_0=\xi_{\text{eff}}\sqrt{2}\cong 1\cdot 10^{-11}\text{ [m]} \tag{15.5.77}$$

This value is less than the radius of atoms according to the Dalton model. Nature has given us a ear with an exquisite sensitivity!

It is easy to calculate at which power value per unit area corresponds a sound wave at the limit of hearing. Using the relation proved above, we get:

$$\frac{\mathcal{P}}{S}=\frac{1}{\rho_0 v}P_{\text{eff}}^2=\frac{1}{1.293\cdot 331}(2\cdot 10^{-5})^2=1\,[\text{pW}\cdot\text{m}^{-2}] \tag{15.5.78}$$

Since the surface of the section of the ear canal is less than one square centimetre, the power that comes to the eardrum is lower than 10^{-6} [W].

15.5.2 Spherical Sound Waves

In reality the sound waves are generated by sources of finite extent. At lower or comparable distances to the extent of the source, the shape of the wavefront that moves away from the source can be very complicated (imagine the wavefront of a thunder caused by choppy Flash). But far from the source, it is seen as a point object and the wave-front becomes more spherical as one moves away from the source.

The difference is that the energy carried by the sound wave is distributed in an area which expands as R^2 (where R is the distance to the source) as for the light (electrodynamics waves) emitted by stars. So the power per unit area should decrease as $1/R^2$ (exactly according to the same mathematical development than for electromagnetic waves seen in the section of Electrodynamics) and as the power per unit area is proportional to ξ_{eff}^2 or to P_{eff}^2 this implies that a spherical wave, both displacement ξ_{eff}, as the sound pressure P_{eff} must decrease as $1/R$.

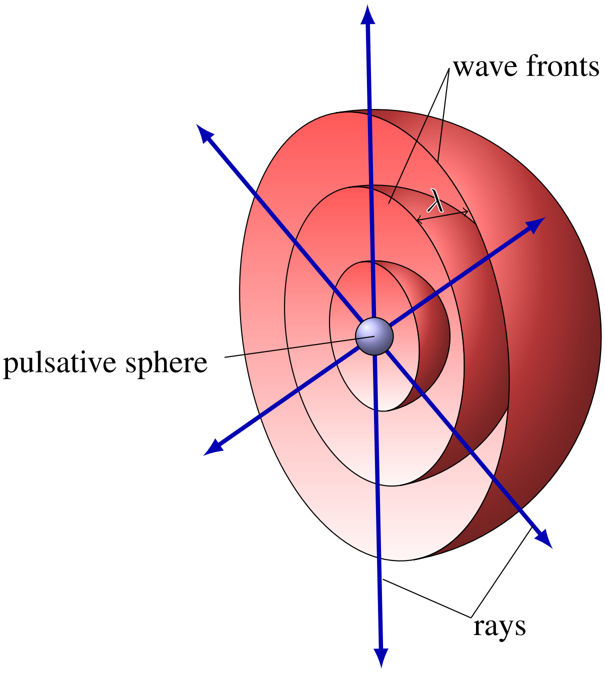

Figure 15.332: **Spherical wavefront (author: Juan Castaño)**

In the case of sine waves, we will have to modify the wave equation:

$$\xi=\xi_0\cos(\omega t-kx) \tag{15.5.79}$$

by adding a coefficient $1/R$. If we denote by r the distance between the source and the observation position, and that, instead of measuring the position with x we do it with r we get:

$$\xi=\xi_0\frac{\cos(\omega t-kr)}{r} \tag{15.5.80}$$

and also for the sound pressure:

$$P_S=-P_0\frac{\sin(\omega t-kr)}{r} \tag{15.5.81}$$

For those who want more details, let us recall that in the section of Calculus we have proven the expression of the Laplacian in spherical coordinates (see page 1903):

$$\vec{\nabla}^2=\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right)+\frac{1}{r^2\sin(\theta)}\frac{\partial}{\partial\theta}\left(\sin(\theta)\frac{\partial\theta}{\partial\theta}\right)+\frac{1}{r^2\sin^2(\theta)}\frac{\partial^2}{\partial\phi^2} \tag{15.5.82}$$

Remember that we are looking for a description of spherical waves, waves that are spherically symmetrical (i.e. ones that do not depend on θ and ϕ) so that:

$$f(\vec{r})=f(r,\theta,\phi)=f(r) \tag{15.5.83}$$

The Laplacian then reduces simply to:

$$\vec{\nabla}^2=\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) \tag{15.5.84}$$

The differential wave equation that is for recall (see section Wave Mechanics page 3501):

$$\vec{\nabla}^2 z=\frac{1}{v^2}\frac{\partial^2 z}{\partial t^2} \tag{15.5.85}$$

will be written:

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right)f=\frac{1}{v^2}\frac{\partial^2 f}{\partial t^2} \tag{15.5.86}$$

But:

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right)f=\frac{2}{r}\frac{\partial f}{\partial r}+\frac{\partial^2 f}{\partial r}=\frac{1}{r}\frac{\partial^2}{\partial r^2}(rf) \tag{15.5.87}$$

Therefore we get the differential wave equation in spherical coordinates:

$$\boxed{\frac{1}{r}\frac{\partial^2}{\partial r^2}(rf)=\frac{1}{v^2}\frac{\partial^2 f}{\partial t^2}} \tag{15.5.88}$$

Multiplying bot sides by r (independent of t):

$$\frac{\partial^2}{\partial r^2}(rf)=\frac{1}{v^2}\frac{\partial^2}{\partial t^2}(rf) \tag{15.5.89}$$

It is immediate that a special obvious solution is of the form:

$$\frac{f(kr-\omega t)}{r} \tag{15.5.90}$$

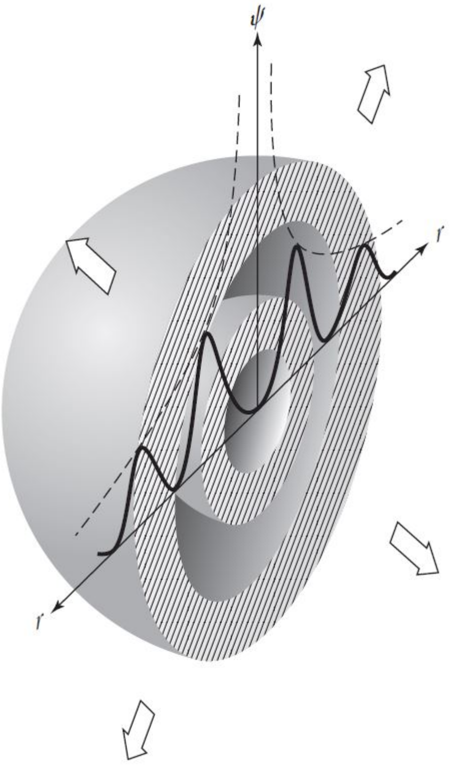
and it is common to choose the "harmonic spherical wave" form (don't forget that $kv=\omega$):

$$f(r,t)=\frac{A_0\cos(\omega t-kr)}{r}=\frac{A_0\cos(kr-\omega t)}{r} \tag{15.5.91}$$

or:

$$f(r,t)=\left(\frac{A_0}{r}\right)e^{\mathrm{i}(kr-\omega t)} \tag{15.5.92}$$

wherein the constant A_0 is the source strength. At any fixed value of time, this represents a cluster of concentric spheres filling all space. Notice that the amplitude of any spherical wave is a function of r, where the term r^{-1} serves as an attenuation factor. Unlike the plane wave, a spherical wave decreases in amplitude!



Obviously most wave sources are spherical but far away from the source the radius is such that the front wave con be considered as a plane!

15.5.3 Doppler effect

In what has been studied so far, the source S and the observer O of the wave have always been considered to be immobile relative to each other.

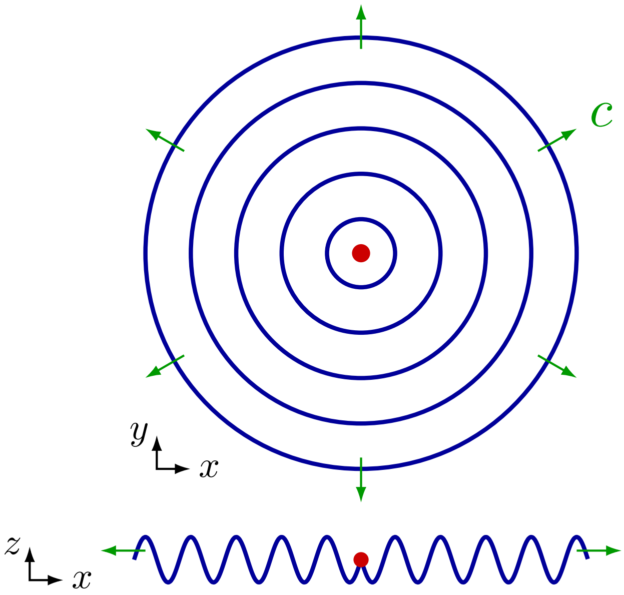


Figure 15.333: **Fixed oscillating punctual source (author: Izaak Neutelings)**

The Doppler effect explains the wave frequency (sound, electromagnetic, fluid) changes observed when S and O are in relative motion.

The Doppler effect (or the Doppler shift) is the change in frequency or wavelength of a wave (or other periodic event) for an observer moving relative to its source. It is named after the Austrian physicist Christian Doppler, who proposed it in 11842 (holocene calendar) in Prague. It is commonly heard when a vehicle sounding a siren or horn approaches, passes, and recedes from an observer. Compared to the emitted frequency, the received frequency is higher during the approach, identical at the instant of passing by, and lower during the recession.

When the source of the waves is moving towards the observer, each successive wave crest is emitted from a position closer to the observer than the previous wave. Therefore, each wave takes slightly less time to reach the observer than the previous wave. Hence, the time between the arrival of successive wave crests at the observer is reduced, causing an increase in the frequency. While they are travelling, the distance between successive wavefronts is reduced, so the waves "bunch together". Conversely, if the source of waves is moving away from the observer, each wave is emitted from a position farther from the observer than the previous wave, so the arrival time between successive waves is increased, reducing the frequency. The distance between successive wavefronts is then increased, so the waves "spread out". For waves that propagate in a medium, such as sound waves, the velocity of the observer and of the source are relative to the medium in which the waves are transmitted. The total Doppler effect may therefore result from motion of the source, motion of the observer, or motion of the medium. Each of these effects is analysed separately. For waves which do not require a medium, such as light or gravity in general relativity, only the relative difference in velocity between the observer and the source needs to be considered.

15.5.3.1 Fixed source-Moving observer

So consider the first case where the source is fixed and the observer in uniform rectilinear motion:

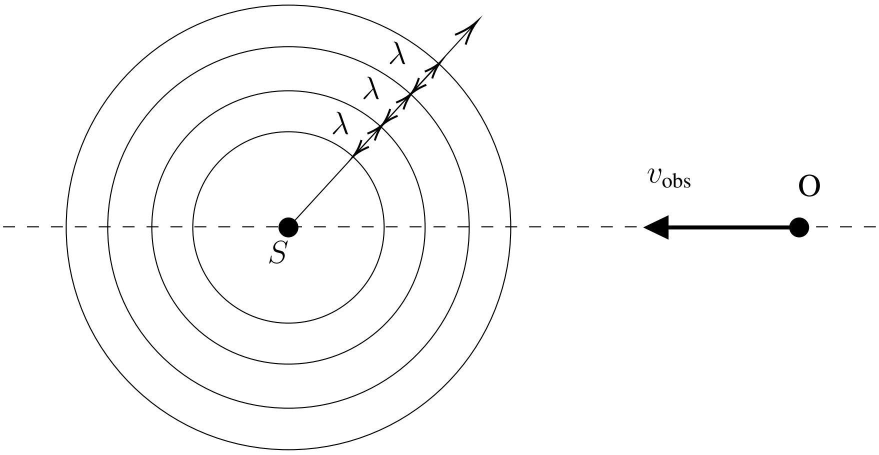

Figure 15.334: **Schematic diagram of a fixed source and an approaching observer (Doppler Effect)**

Given:

$$f=\frac{1}{T} \tag{15.5.93}$$

the frequency of the source S and the v_{phase} the propagation speed of the wave in the medium, assumed immobile.

If O does not move, he sees the wavefronts arrive at speed v_{phase} and there is not much to say. If O moves in the direction of S at the speed v_{obs}, it receives the wavefronts at the speed:

$$v_{\text{phase}}+v_{\text{obs}} \tag{15.5.94}$$

and crosses the distances λ in equal times:

$$\Delta t=\frac{\lambda}{v_{\text{phase}}+v_{\text{obs}}} \tag{15.5.95}$$

During each interval Δt perceives a full cycle of the wave. He concludes that Δt is the period T' of a wave of frequency f':

$$f'_{approach}=\frac{1}{T'}=\frac{v_{\text{phase}}+v_{\text{obs}}}{\lambda}=\frac{v_{\text{phase}}+v_{\text{obs}}}{v_{\text{phase}}}=\frac{1}{T}\left(1+\frac{v_{\text{obs}}}{v_{\text{phase}}}\right) \tag{15.5.96}$$

So finally:

$$\boxed{f'_{\text{approach}}=f\left(1+\frac{v_{\text{obs}}}{v_{\text{phase}}}\right)>f} \tag{15.5.97}$$

The sound becomes then more acute when approaching a source.

If O go away from S are speed v_{obs}, it receives the wavefronts at the speed:

$$v_{\text{phase}} - v_{\text{obs}} \tag{15.5.98}$$

and similar developments lead us then to:

$$\boxed{f'_{\text{remoteness}} = f\left(1 - \frac{v_{\text{obs}}}{v_{\text{phase}}}\right) \leq f} \tag{15.5.99}$$

The limit of validity of this relation is for $v_{\text{obs}} \leq v_{\text{phase}}$.

The sound becomes more low-pitched sound when we move far from the source.

Remark

If the speed of the observer is oriented in any manner, relatively to the line $\overline{\text{O}S}$, only the radial component is to be taken into account.

15.5.3.2 Moving source-Fixed observer

It is not necessarily intuitive to see that the system is not symmetrical. But taking a special case one quickly realizes that it is actually not. Indeed, if the receiver is moving from the source at a speed higher than v_{phase}, he will never receive wawefront, whereas if the source is moving away from the observer, that latter will still receive a wavefront. Can not reverse the role of the transmitter (source) and receiver (observer).

In the classical case, there is therefore an asymmetry in the frequency offset following that the source or observer is moving.

Let us consider the following situation:

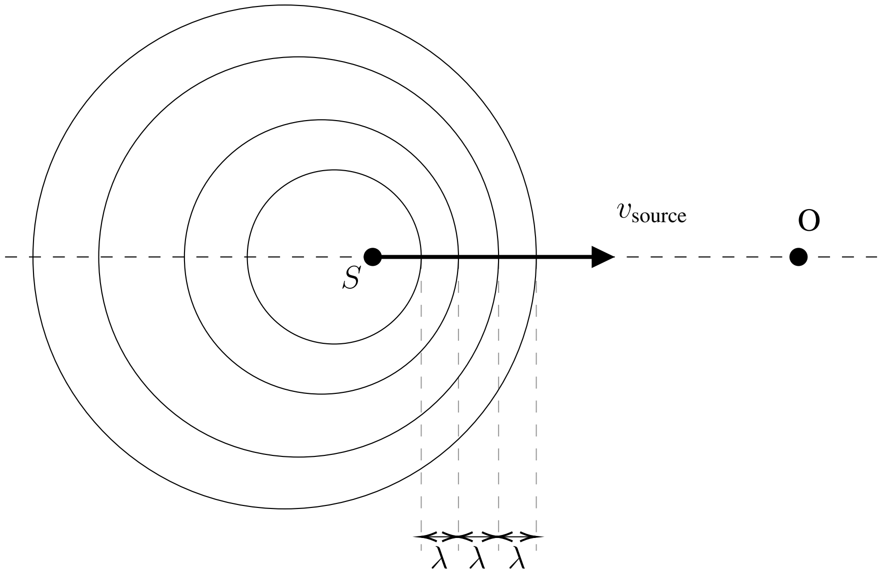

Figure 15.335: Schematic diagram of a fixed observer and an approaching source (Doppler Effect)

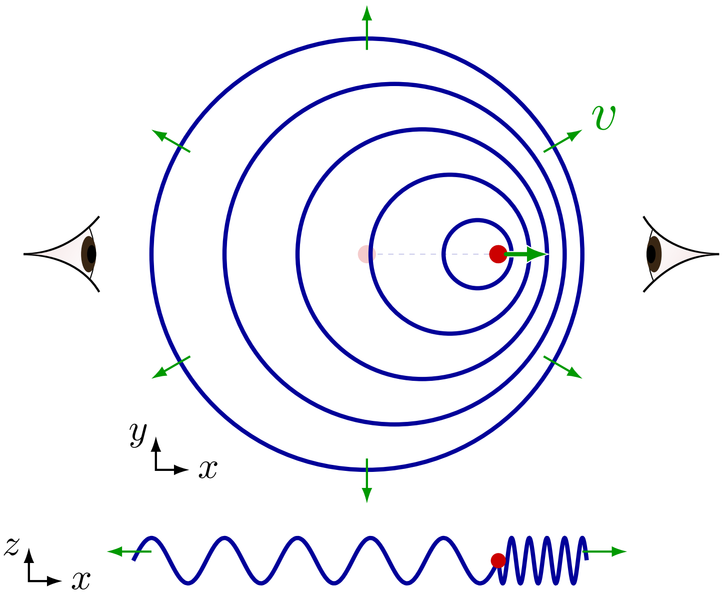
Or in a more detailed form highlighting also the wave aspect of the phenomenon:



Given:

$$f=\frac{1}{T} \tag{15.5.100}$$

the frequency of the source S in uniform rectilinear motion and the v_{phase} the speed of the wave propagation in the medium and O the assumed fixed observer.

If the source moves at speed v_{source}, it travels a distance:

$$d=v_{\text{source}}T \tag{15.5.101}$$

between each cycle. The wavelength seen by the observer thus varies of:

$$d=\Delta\lambda=v_{\text{source}}T \tag{15.5.102}$$

For the observer, it decreases such that:

$$\lambda'=\lambda-v_{\text{source}}T=\lambda-\frac{v_{\text{source}}}{f} \tag{15.5.103}$$

Then we have:

$$f'_{\text{approach}}=\frac{v_{\text{phase}}}{\lambda'}=\frac{v_{\text{phase}}}{\lambda-\dfrac{v_{\text{source}}}{f}}=\frac{v_{\text{phase}}}{\dfrac{v_{\text{phase}}}{f}-\dfrac{v_{\text{source}}}{f}}=f\left(\frac{v_{\text{phase}}}{v_{\text{phase}}-v_{\text{source}}}\right) \tag{15.5.104}$$

So after simplification:

$$\boxed{f'_{\text{approach}}=f\left(\frac{1}{1-\dfrac{v_{\text{source}}}{v_{\text{phase}}}}\right)>f} \tag{15.5.105}$$

The limit of validity of this relations being for $v_{\text{source}} \leq v_{\text{phase}}$.

Therefore it comes:

$$f'_{\text{approach}} > f \tag{15.5.106}$$

The sound becomes more acute when the source approaches (that same feeling as when it is the observer who approaches).

Similarly, when the source is moving away from the observer, we get immediately:

$$\boxed{f'_{\text{remoteness}} = f\left(\frac{1}{1+\dfrac{v_{\text{source}}}{v_{\text{phase}}}}\right) < f} \tag{15.5.107}$$

The sound becomes more low-pitched when the source is moving away (so same sensation as when it is the observer who moves away).

Therefore, the apparent frequency of sound when source is approaching a stationary listener with a given phase velocity is not the same as the apparent frequency of sound when the listener is approaching the stationary source with a given velocity. This shows that Doppler Effect in sound is asymmetric!!! The asymmetry comes from the medium. In the second case the source is at rest with respect to the medium and in the first case the receiver is at rest with respect to the medium.

Remark

In the case of electromagnetic waves, the wave velocity is the speed of light c which does not depend on the repository. Then we must address the problem within the framework of Special Relativity and then we expect to find a perfectly symmetrical effect since it can not possible to distinguish between speed the velocity of the transmitter or that of the receiver, only must be taking into account the relative speed between the both (see the developments done in the section of Special Relativity at page 5529).

15.5.3.3 Moving source and observer

If both (source and observer) are in rectilinear motion on a common straight line, the two effects are additive. We then have when they approach each other:

$$\left.\begin{aligned} f'_{\text{approach}} &= f\left(1+\frac{v_{\text{obs}}}{v_{\text{phase}}}\right) \\ f'_{\text{approach}} &= f\left(\frac{1}{1-\dfrac{v_{\text{source}}}{v_{\text{phase}}}}\right) \end{aligned}\right\} : f'_{\text{approach}} = f\left(1+\frac{v_{\text{obs}}}{v_{\text{phase}}}\right)\left(\frac{1}{1-\dfrac{v_{\text{source}}}{v_{\text{phase}}}}\right) \tag{15.5.108}$$

And when they move away:

$$\left.\begin{aligned} f'_{\text{remoteness}} &= f\left(1-\frac{v_{\text{obs}}}{v_{\text{phase}}}\right) \\ f'_{\text{remoteness}} &= f\left(\frac{1}{1+\dfrac{v_{\text{source}}}{v_{\text{phase}}}}\right) \end{aligned}\right\} : f'_{\text{remoteness}} = f\left(1-\frac{v_{\text{obs}}}{v_{\text{phase}}}\right)\left(\frac{1}{1+\dfrac{v_{\text{source}}}{v_{\text{phase}}}}\right) \tag{15.5.109}$$

15.5.4 Shock waves

Unlike ordinary sound waves, the speed of a shock wave varies with its amplitude. The speed of a shock wave is always greater than the speed of sound in the fluid and decreases as the amplitude of the wave decreases. When the shock wave speed equals the normal speed, the shock wave dies and is reduced to an ordinary sound wave.

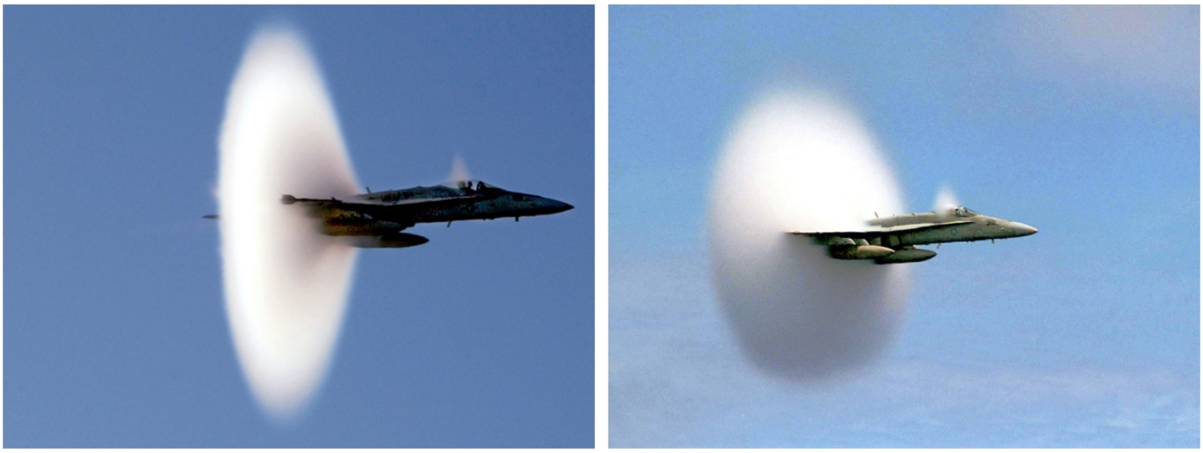


Figure 15.336: **Jet fighter planes with conical shock waves made visible by condensation**

The ratio of the speed v of a moving object to the speed of sound v_{sound} in a fluid is known as the "Mach number" in honour of Ernst Mach (11838–11916 according to holocene calendar):

$$\boxed{M = \frac{v}{v_{\text{sound}}} = \frac{v}{\sqrt{\dfrac{\gamma RT}{M_m}}}} \tag{15.5.110}$$

The Mach number is therefore a dimensionless measure of speed common in aerodynamics. Mach 0.5 is half the speed of sound, Mach 2 is twice the speed of sound, and so on. Speeds less than the speed of sound have a Mach number between zero and one and are described as "subsonic". Those greater than the speed of sound have Mach numbers greater than one are a described as "supersonic". Speeds approximately equal to the speed of sound have Mach numbers approximately equal to one and are described as "transonic".

The shock wave from a supersonic moving conical object is a cone composed of overlapping spherical wavefronts (if the moving object is cube at a far observation distance enough the shock wave will be also seen as a cone). As any one of these wavefronts forms, it propagates radially outward at speed v_{sound} and acquires a radius $v_{\text{sound}}t$ relatively to the contact peak point. At the same time the source, travelling at speed v moves forward vt. These two displacements form the leg and hypotenuse, respectively, of a right triangle and can be used to determine the Mach angle at the vertex of the shock cone (prolongation of the cone sides if the moving object is a cube...):

$$\sin(\theta) = \frac{v_{\text{sound}}}{v} \qquad (15.5.111)$$

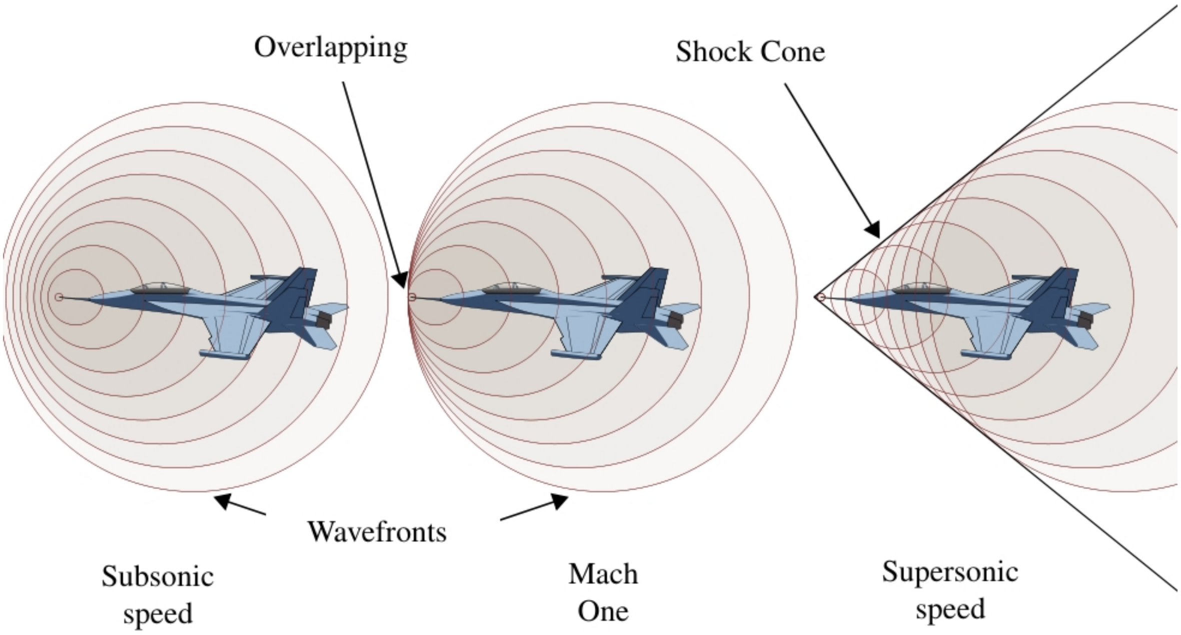

Figure 15.337: **Jet fighter with conical shock waves in the case of a conical "nose" (source: Wikipedia, author: Ignacio Icke)**

When an object travels slower than sound, the ratio in this equation is greater than one, and the equation does not have a real solution. This makes absolute sense as there is no shock wave to speak of at subsonic speeds. Travelling at the speed of sound makes the ratio equal one and results in a Mach angle of ninety degrees. At transonic speeds the shock wave is a wall of high pressure moving with the object, perpendicular to its velocity. Above the speed of sound, the ratio is less than one and the Mach angle is less than ninety degrees. The faster the object moves, the narrower the cone of high pressure behind it becomes. Measuring the vertex angle is thus a simple way to determine the speed of a supersonic object.

15.5.5 Music Scales

When we do vibrate a guitar string, violin string or other stringed instrument whose ends are fixed (stationary wave), we have proved in the section of Wave Mechanics that we are in conditions name "Dirichlet boundaries".

We obtained after many calculations, the following result:

$$\omega_n = \sqrt{\frac{F}{\rho_l}}\left(\frac{n\pi}{L}\right) \qquad (15.5.112)$$

Therefore:

$$f_n = \frac{n}{2L}\sqrt{\frac{F}{\rho_l}} \propto \frac{1}{L} \qquad (15.5.113)$$

thus the frequency (which is one of the factors of the feel of the "height" of a sound by humans) is inversely proportional to the length L of a string attached to the ends (as it would be deducted by Pythagoras long time before that theory of string was established).

The previous relationship highlights that: more the vibrant part is long (more n is small) the more the sound is low (low frequency) and the vibrant part is short (large n), the more the sound will be acute (high frequency).

Let us recall that for $n=1$, we speak of "fundamental frequency" and for $n\geq 2$ of "harmonic frequency." Thus, $n=2$ is the first harmonic, $n=3$ the second harmonic, etc.

Definitions (#15.5.722):

D1. We say that two frequencies (or two periodic waves) are "in harmony" with each other if the ratio of their frequencies is equal to unity:

$$\text{Harmony: } \frac{f''}{f'}=1 \qquad (15.5.114)$$

D2. We say that two frequencies (or two periodic waves) are "at the octave" to each other if the ratio of their frequencies is equal to two:

$$\text{Octave: } \frac{f''}{f'}=2 \qquad (15.5.115)$$

Let us notice that the first harmonic ($n=1$) corresponds to the octave of the fundamental f_0:

$$\frac{f_1}{f_0}=2 \qquad (15.5.116)$$

For example, some singers are capable of singing on 8 octaves (that is to say a frequency ratio of 16). Thus, in the case of a stringed instrument with Dirichlet conditions this is equivalent obviously to pluck the string in the middle (for guitars that match to press the rope on the fret of the 12th box with respect to the frequency of an open string to get one octave).

The octave ratio sounds pretty good for the majority of humans.

D3. We say that two frequencies (or two periodic waves) are "at the quint" to each other if the ratio of their frequencies is equal to $3/2$:

$$\text{Quint: } \frac{f''}{f'} = \frac{3}{2} \tag{15.5.117}$$

Except the octave, this interval is the simplest of all, and since always, in occidental music, it was considered as the consonant interval with excellence, so the more remarkable sound for ear. For this reason, the quint has played a key role in establishing music scales, the Pythagorean scale being even built exclusively on this particular interval.

We notice that we can put at most an integer of two quints in one octave (beyond we exceed the value of an octave).

When a stringed instrument has its empty vibrations that are in a ratio of frequencies corresponding to the quint, we say that the instrument is "tuned in quint to quint".

D4. We say that two frequencies (or two periodic waves) are "at the quart" to each other if the ratio of their frequencies is equal to $4/3$:

$$\text{Quart: } \frac{f''}{f'} = \frac{4}{3} \tag{15.5.118}$$

D5. The ratio of the frequencies of two sounds (or two periodic waves) distant from each other by a "tone" may be $9/8$. This is named the "major tone":

$$\text{Major tone: } \frac{f''}{f'} = \frac{9}{8} \tag{15.5.119}$$

D6. The "minor ton" has a ratio of frequencies of $10/9$:

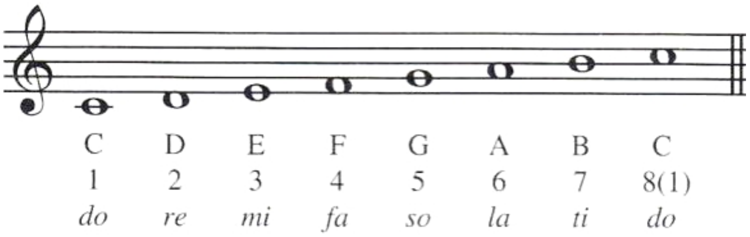
$$\text{Minor ton: } \frac{f''}{f'} = \frac{10}{9} \tag{15.5.120}$$

Remark

The octave, the quint, the quart and the tones are obviously named "interval ratio" in music. Ratios, rather than direct frequency measurements, allow musicians to work with relative pitch measurements applicable to many instruments in an intuitive manner, whereas one rarely has the frequencies of fixed pitched instruments memorized and rarely has the capabilities to measure the changes of adjustable pitch instruments.

Obviously, if we want to make music, we have to choose a mark (reference). As the frequency range is infinite, there was chosen a frequency at which the current human ear is the most sensitive: 440 [Hz] that is named the "La" and is denoted by (A) by the Anglo Saxon.

In theory, the occidental students learn the empirical sequences of 7 notes and whose writing origin is purely mnemonic (we find this result on electronic tuners with the Anglo-Saxon system using certain letters of the alphabet):



where the horizontal lines of the symbolic solfegic above represent a quinte in the Pythagorean scale.

Between the first Do and the second Do, we have then a range of one octave. Moreover, the number of notes within the octave interval is often insufficient to make good music and artists have added other notes by altering the frequencies of these 7 notes, by "diesing" them (multiplication of the frequency by $25/24$) or by "bemolising" (multiplication by $1-25/24$).

Note that there are a dozen of ways to cut the solfegic octave and are almost all are still used in the early 121st century according to holocene calendar (they are all completely empirical so we will not go into details):

- The "natural scale" (also named "harmonic range")
- The "tempered scale"
- The "Pythagorean scale"
- The "chromatic scale"
- The "Zarlino scale" (also named "physicists scale")
- etc.

The method and the aforementioned learning sequence is a mathematical aberration (but as it is music... it's an empirical art so deeply linked with non-sense).

15.5.6 Harmonic Oscillator

In Classical Mechanics, a "harmonic oscillator", also named "Lorentz oscillator" is a system that, when displaced from its equilibrium position, experiences a restoring force proportional to the displacement. This subject is of main importance in various physics fields (including quantum physics or molecular chemistry)!

Let us consider the mechanical system of the figure below consisting of a spring of constant k of a mass m and a viscous damping constant c. This system is often equated with the mechanics of a speaker (or a microphone) where the air acts as a viscous damper and the magnetic field of the exciter magnet as source of the force or also to a car damper:

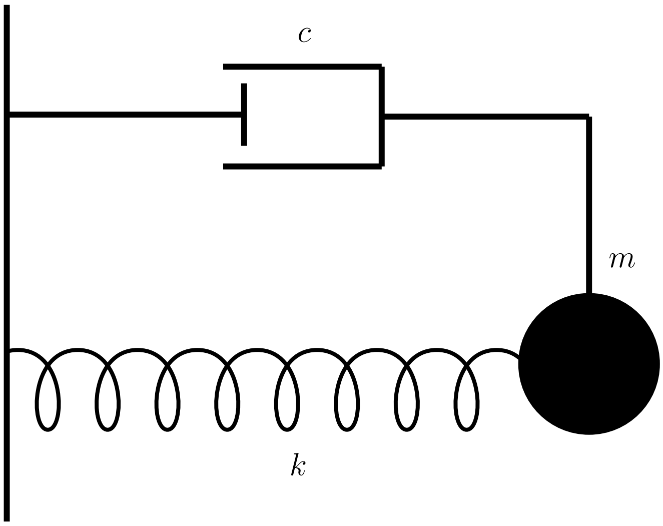

Figure 15.339: **Schematic diagram of the harmonic oscillator**

That's why the configuration above is also commonly know under the name of "harmonic damper",

This model is also used widely in molecular chemistry and solid physics to study crystalline structure on to model the bonds between atoms.

We have proved in the section of Mechanical Engineering (see page 8408) that for an helical spring we had:

$$F=\left(\frac{Gd^4}{8nD^3}\right)x=kx \tag{15.5.121}$$

and this is the expression of the force to which the spring will resist to an external force of compression or tension. At equilibrium, we necessarily the sum of the forces that is zero:

$$\vec{F}_{\text{ext}}+\vec{F}_{\text{spring}}=\vec{0} \tag{15.5.122}$$

Therefore:

$$m\ddot{x}+kx=0 \tag{15.5.123}$$

We have proved in the section of Continuum Mechanics that Stokes' law (see page 3853) in the case of a cylinder was given by:

$$F = 6\pi\mu R v = cv \tag{15.5.124}$$

We will assume that our viscous damper is based on a similar law where the resistance force is proportional to the speed. At equilibrium, we necessarily have the sum of the forces is still zero:

$$\vec{F}_{\text{ext}} + \vec{F}_{\text{spring}} + \vec{F}_{\text{amortization}} = \vec{0} \tag{15.5.125}$$

Therefore (we already know this differential equation):

$$\boxed{m\ddot{x} + c\dot{x} + kx = 0} \tag{15.5.126}$$

We will simplify this expression:

$$\frac{m}{k}\ddot{x} + \frac{c}{k}\dot{x} + x = 0 \tag{15.5.127}$$

We are left with exactly the same differential equation to that of a series RLC circuit in steady state (see section Electrical Engineering page 8475):

$$LC\ddot{q} + RC\dot{q} + q = 0 \tag{15.5.128}$$

So we have in the same way, the critical viscosity:

$$c_c = 2\sqrt{mk} \tag{15.5.129}$$

instead of the critical resistance of the RLC circuit:

$$R_c = 2\sqrt{\frac{L}{C}} \tag{15.5.130}$$

which will determine if the system is in critical regime:

$$c = c_c \tag{15.5.131}$$

in aperiodic regime (supercritical)

$$c > c_c \tag{15.5.132}$$

or in pseudo-periodic regime (damped oscillations) with:

$$c < c_c \tag{15.5.133}$$

In the case of cars or sound speakers, it is often useful to arrange the system to be in pseudo-periodic regime. Then we find exactly the same results as the RLC circuit with damped oscillations since the differential equation is the same.

Specialists from acoustic or mechanics then arrange the system to get the concept of "damping factor" of the RLC circuit:

$$\alpha = \frac{R}{2L} \tag{15.5.134}$$

which will be written in the present case by identification of the terms:

$$\lambda=\frac{c}{2m} \tag{15.5.135}$$

With the "natural pulsation":

$$\omega=\sqrt{\frac{1}{LC}} \tag{15.5.136}$$

which will be written in the present case:

$$\boxed{\omega=\sqrt{\frac{k}{m}}} \tag{15.5.137}$$

The damped oscillator loses energy over time. Let us calculate that loss! We have (see section of Classical Mechanics page 3129 and Mechanical Engineering page 3418):

$$E_{\text{tot}}=E_c+E_p=\frac{1}{2}m\dot{x}^2+\frac{1}{2}kx^2 \tag{15.5.138}$$

Therefore:

$$\frac{\mathrm{d}E_{\text{tot}}}{\mathrm{d}t}=m\dot{x}\ddot{x}+kx\dot{x}=(m\ddot{x}+kx)\dot{x} \tag{15.5.139}$$

Now, according to the equation of motion:

$$m\ddot{x}+c\dot{x}+kx=0\Rightarrow m\ddot{x}+kx=-c\dot{x} \tag{15.5.140}$$

It comes then:

$$\frac{\mathrm{d}E_{\text{tot}}}{\mathrm{d}t}=-c\dot{x}^2 \tag{15.5.141}$$

The loss of energy (or power loss) is proportional to the square of the instantaneous velocity!

We have shown in the section of Electrical Engineering for the RLC circuit in regime of underdamped oscillations (see page 8480) that we had:

$$\begin{aligned}q&=\frac{q_0}{\cos(\phi)}e^{-\frac{R}{2L}t}\cos(\omega t-\phi)\\ i&=-\frac{\omega q_0}{\cos^2(\phi)}e^{-\frac{R}{2L}t}\sin(\omega t)\end{aligned} \tag{15.5.142}$$

What becomes here:

$$\begin{aligned}x&=\frac{x_0}{\cos(\phi)}e^{-\frac{c}{2m}t}\cos(\omega t-\phi)\\ \dot{x}&=-\frac{\omega x_0}{\cos^2(\phi)}e^{-\frac{c}{2m}t}\sin(\omega t)\end{aligned} \tag{15.5.143}$$

Therefore:

$$\frac{\mathrm{d}E_{\text{tot}}}{\mathrm{d}t}=-c\dot{x}^2=c\left(\frac{\omega x_0}{\cos^2(\phi)}\sin(\omega t)\right)^2e^{-\frac{c}{m}t}=c\xi^2\sin^2(\omega t)e^{-\frac{c}{m}t} \tag{15.5.144}$$

15.5.6.1 Damping and Resonance

Let us still consider the same oscillator but this time excited by a harmonic force (thus: forced regime) as:

$$m\ddot{x}+c\dot{x}+kx=F_0\sin(\omega t) \tag{15.5.145}$$

Again, this is exactly the same type of differential equation as for the RLC oscillator in forced regime studied in the section of Electrical Engineering (see page 8497) for which we had:

$$L\frac{\mathrm{d}^2q}{\mathrm{d}t^2}+\frac{\mathrm{d}q}{\mathrm{d}t}+\frac{1}{C}q=U_0\sin(\omega t) \tag{15.5.146}$$

It follows the same results and plots and conclusions that the reader may find in the section of Electrical Engineering.

But as a reader noticed us, the version of the development of the Electrical Engineering section is too much "electrical engineer" oriented for a good comprehension. Therefore for the people that want it, here is the traditional and more understandable version...

So let's go! We assume that the damping force is proportional to the velocity of the mass. If there are no external forces we obtain the differential equation:

$$m\frac{\mathrm{d}^2x}{\mathrm{d}t^2}+b\frac{\mathrm{d}x}{\mathrm{d}t}+kx=0 \tag{15.5.147}$$

where $x=x(t)$ is the displacement from equilibrium at time t of the mass of $m>0$ units, $b\geq 0$ is the damping constant and $k>0$ is the spring constant.

The characteristic polynomial:

$$r^2+\frac{b}{m}r+\frac{k}{m} \tag{15.5.148}$$

has discriminant:

$$\Delta=\frac{b^2-4km}{m^2} \tag{15.5.149}$$

If $b^2<4km$ we have $\Delta<0$ and the characteristic polynomial factorizes in the form:

$$\left(r+\frac{b}{2m}\right)^2+\omega^2 \tag{15.5.150}$$

with:

$$\omega=\frac{\sqrt{4km-b^2}}{2m}=\sqrt{\frac{k}{m}-\left(\frac{b}{2m}\right)^2} \tag{15.5.151}$$

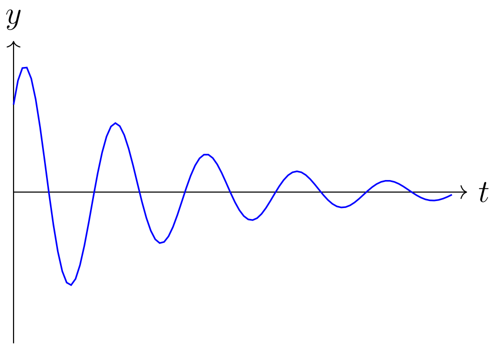
In this case the characteristic polynomial has complex roots:

$$-\frac{b}{2m}\pm\mathrm{i}\omega \tag{15.5.152}$$

and the general solution of the differential equation is:

$$y = e^{-bt/2m}\left(A\cos(\omega t) + B\sin(\omega t)\right) = Ce^{-bt/2m}\sin(\omega t + \theta) \qquad (15.5.153)$$

where $C = \sqrt{A^2+B^2}$ and $0 \leq \theta \leq 2\pi$ defined by $\cos(\theta) = A/C$, $\sin(\theta) = B/C$. The angle θ is named the "phase". In this case we see that the mass oscillates with frequency $\omega/2\pi$ and decreasing amplitude (underdamping). If $b = 0$ there is no damping and the mass oscillates with frequency $\omega/2\pi$ and constant amplitude; such motion is named "simple harmonic".

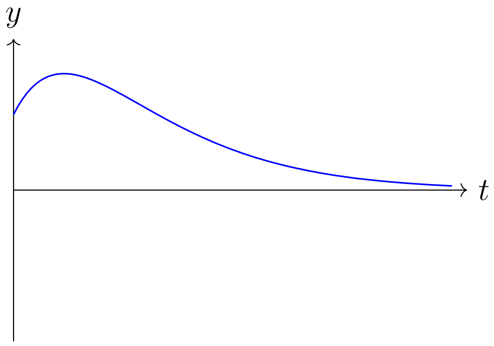


If $b^2 \geq 4km$ we have $\Delta \geq 0$ and so the characteristic polynomial has real roots:

$$r_1 = -\frac{b}{2m} + \frac{\sqrt{b^2-4km}}{2m} \qquad r_2 = -\frac{b}{2m} - \frac{\sqrt{b^2-4km}}{2m} \qquad (15.5.154)$$

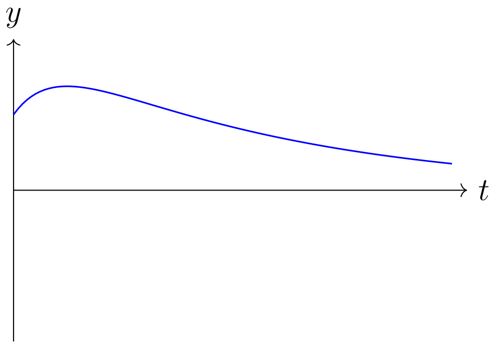
which are both negative. If $r_1 = r_2 = r$ the general solution of our differential equation is:

$$y = Ae^{rt} + Bte^{rt} \qquad (15.5.155)$$



and if $r_1 \neq r_2$ the general solution is:

$$y = Ae^{r_1 t} + Be^{r_2 t} \qquad (15.5.156)$$



In both cases $y \to 0$ as $t \to +\infty$. In the second case we have what is named "over damping" and in the first case the over damping is said to be "critical" (i.e. critical damping). In each the mass returns to its equilibrium position without oscillations.

Suppose now that our mass-spring system is subject to an external force so that our differential equation now becomes:

$$\boxed{m\frac{\mathrm{d}^2x}{\mathrm{d}t^2}+b\frac{\mathrm{d}x}{\mathrm{d}t}+kx=F(t)} \tag{15.5.157}$$

Such as system is named a "forced oscillating system" or "driven oscillating system with damping, steady state and resonance solution". The function $F(t)$ is named the "forcing function" and measures the magnitude and direction of the external force. We consider the important special case where the forcing function is harmonic:

$$F(t)=F_0\cos(\gamma t), \qquad F_0>0 \text{ a constant} \tag{15.5.158}$$

We also assume that we have under-damping with damping constant $b>0$. In this case the differential equation has a particular solution of the form:

$$y_p=A_1\cos(\gamma t)+A_2\sin(\gamma t) \tag{15.5.159}$$

Substituting in differential equation and simplifying, we get:

$$((k-m\gamma^2)A_1+b\gamma A_2)\cos(\gamma t)+(-b\gamma A_1+(k-m\gamma^2)A_2)\sin(\gamma t)=F_0\cos(\gamma t) \tag{15.5.160}$$

Setting the corresponding coefficients on both sides equal, we get:

$$\begin{aligned}(k-m\gamma^2)A_1+b\gamma A_2&=F_0\\ -b\gamma A_1+(k-m\gamma^2)A_2&=0\end{aligned} \tag{15.5.161}$$

Solving for A_1,A_2 we get:

$$A_1=\frac{F_0(k-m\gamma^2)}{(k-m\gamma^2)^2+b^2\gamma^2} \qquad A_2=\frac{F_0b\gamma}{(k-m\gamma^2)^2+b^2\gamma^2} \tag{15.5.162}$$

and:

$$\begin{aligned}y_p&=\frac{F_0}{(k-m\gamma^2)^2+b^2\gamma^2}((k-m\gamma^2)\cos(\gamma t)+b\gamma\sin(\gamma t))\\ &=\frac{F_0}{\sqrt{(k-m\gamma^2)^2+b^2\gamma^2}}\sin(\gamma t+\phi)\end{aligned} \tag{15.5.163}$$

The general solution of our differential equation is then:

$$y=Ce^{-bt/2m}\sin(\omega t+\theta)+\frac{F_0}{\sqrt{(k-m\gamma^2)^2+b^2\gamma^2}}\sin(\gamma t+\phi) \tag{15.5.164}$$

Because of damping the first term tends to zero and is named the "transient part" of the solution. The second term, the "steady-state part" of the solution, is due to the presence of the forcing function $F_0\cos(\gamma t)$. It is harmonic with the same frequency $\gamma/2\pi$ but is out of phase with it by an angle $\phi-\pi/2$. The ratio of the magnitudes:

$$M(\gamma)=\frac{1}{\sqrt{(k-m\gamma^2)^2+b^2\gamma^2}} \tag{15.5.165}$$

is named the "gain factor". The graph of the function $M(\gamma)$ is named the "resonance curve". It has a maximum of:

$$\frac{1}{b\sqrt{\dfrac{k}{m}-\dfrac{b^2}{4m^2}}} \tag{15.5.166}$$

when:

$$\gamma=\gamma_r=\sqrt{\frac{k}{m}-\frac{b^2}{2m^2}} \tag{15.5.167}$$

The frequency $\gamma_r/2\pi$ is named the "practical resonance frequency" of the system. When $\gamma=\gamma_r$ the system is said to be in resonance with the external force. Note that $M(\gamma_r)$ gets arbitrarily large as $b\rightarrow 0$. That is, when:

$$\gamma=\gamma_r=\sqrt{\frac{k}{m}} \tag{15.5.168}$$

We thus see that the system is subject to large oscillations if the damping constant is very small and the forcing function has a frequency near the resonance frequency of the system.

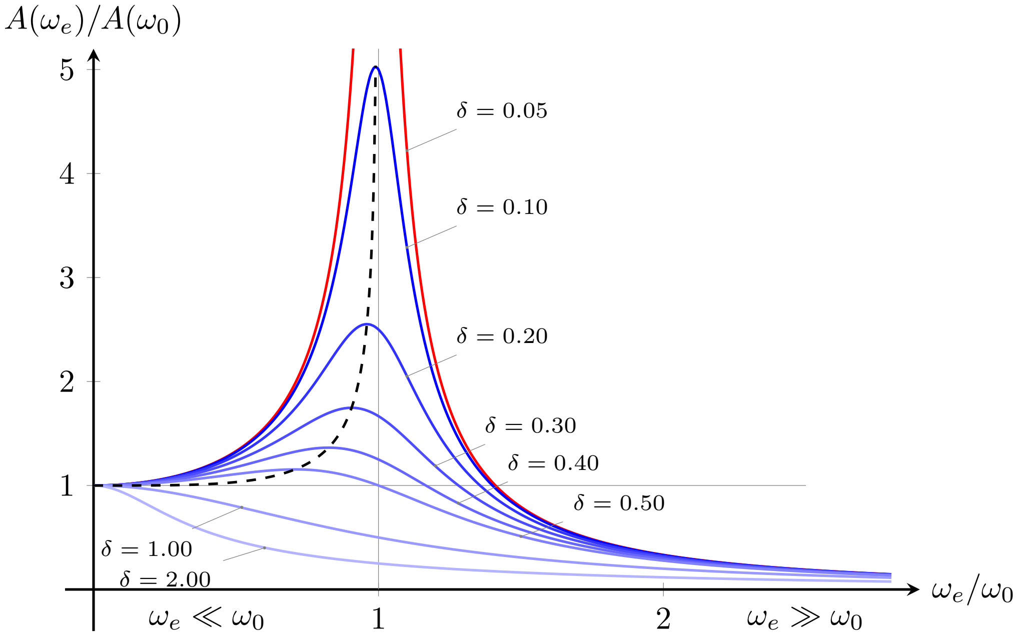


Figure 15.340: Resonances curves with traditional notations

The general solution becomes when $b\rightarrow 0$:

$$y=C\sin(\omega t+\theta)+\frac{F_0}{(k-m\lambda^2)^2}\sin(\gamma t+\phi) \tag{15.5.169}$$

In many physics textbooks the study of resonance the differential equation used is given by:

$$\boxed{\frac{\mathrm{d}^2x}{\mathrm{d}t^2}+\omega_0^2x=F_0\cos(\omega t)} \tag{15.5.170}$$

That is with $m=1$ and $k=\omega_0^2$ then the general solution is written:

$$\boxed{y=C\sin(\omega t+\theta)+\frac{F_0}{(\omega_0^2-\omega^2)^2}\sin(\gamma t+\phi)} \tag{15.5.171}$$

"Pure resonance" occurs exactly when the natural internal frequency ω_0 matches the natural external frequency ω in which case all solutions of the differential equation are unbounded.

The difference between the "practical resonance frequency" and "pure resonance frequency" is just that the first one is the realistic one as they don't exist any physical system with perfectly zero b (hence without damping!). This is why when $b>0$ we speak of "practical resonance frequency" and when $b=0$ of "pure resonance frequency".

As already mentioned, and for recall the above applies to a simple RLC electrical circuit where the differential equation for the current i is:

$$L\frac{\mathrm{d}^2i}{\mathrm{d}t^2}+R\frac{\mathrm{d}i}{\mathrm{d}t}+\frac{i}{C}=F(t) \tag{15.5.172}$$

where L is the inductance, R is the resistance and C is the capacitance. The resonance phenomenon is the reason why we can send and receive and amplify radio transmissions sent simultaneously but with different frequencies.

Some famous resonance situations are:

- The Tacoma Narrows bridge that collapsed in 11940 (holocene):

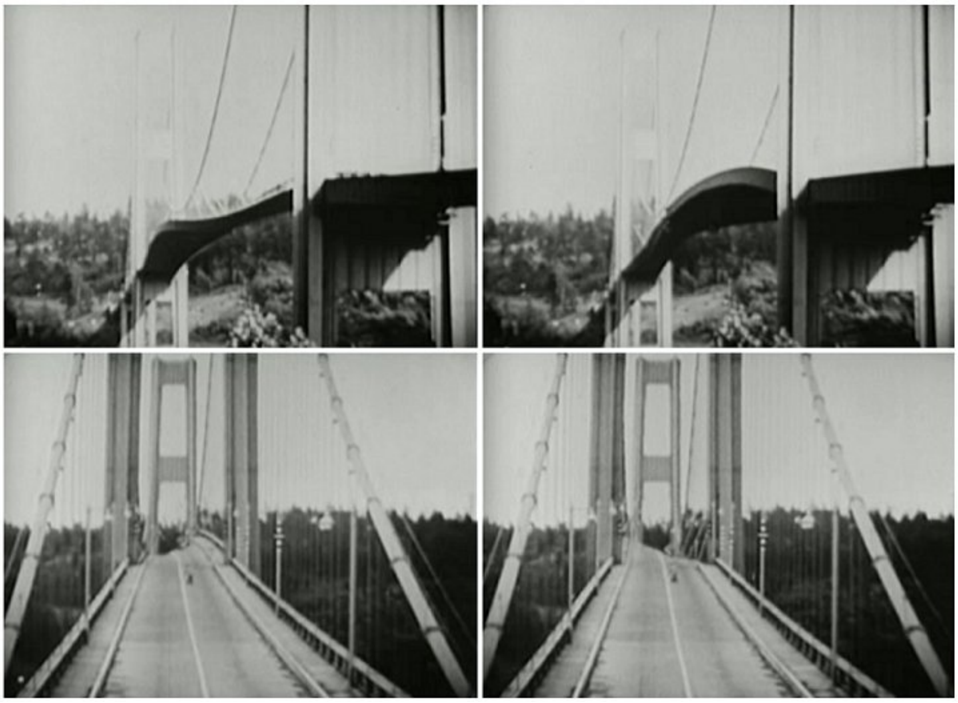

Figure 15.341: **Tacoma Narrows bridge in resonance before collapsing (source: ?)**

- The break up of a crystal glass (better to choose such a material) when under resonance (also named the "wine glass experiment"):

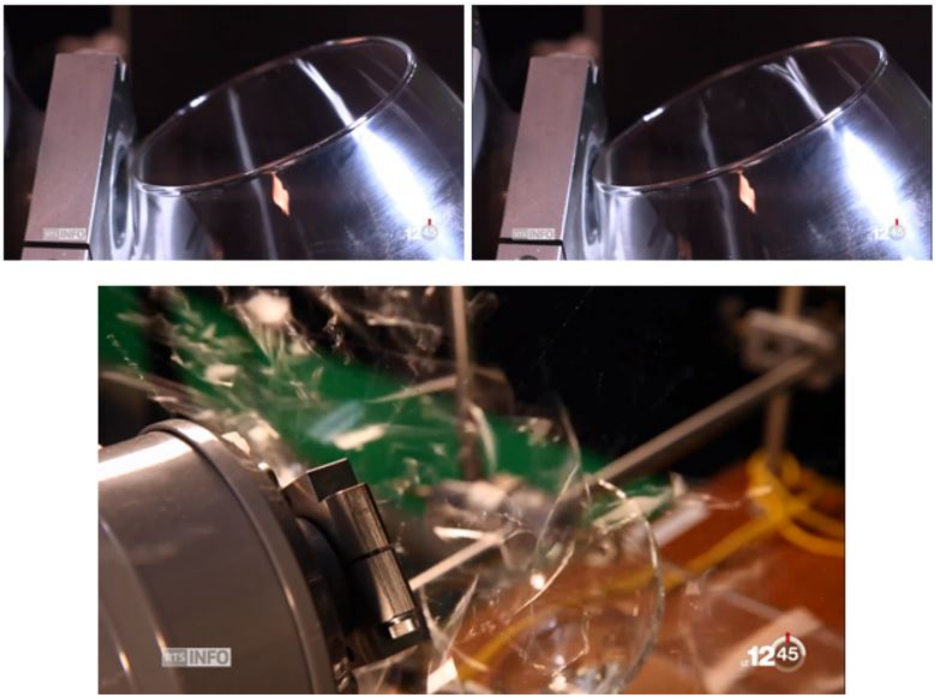

Figure 15.342: **Crystal glass experiment (source: RTS 12h45, 12018-05-13, CQFD)**

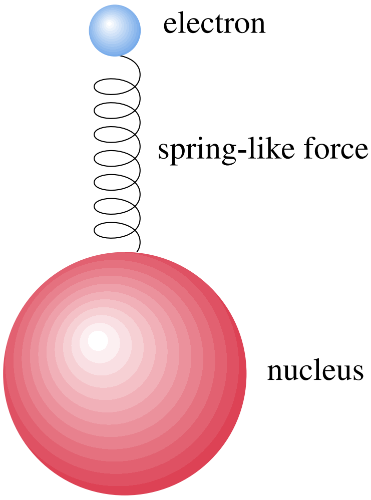
In the first two images above we can see that the diameter of the glass change (it oscillates in fact on the video...) under the forcing function and finally the glass breaks up.

Let us notice that if we assume the nucleus of the atom is much more massive than the electron, we can treat the problem as if the electron-spring system is connected to an infinite mass, which does not move, allowing us to use the mass of the electron. Depending on the case, this value may be substituted by the reduced or effective electron mass to account for deviations from this assumption.



Moreover, the assumption that the binding force behaves like a spring is a justified approximation for any kind of binding, given that the displacement is small enough (meaning that only the constant and linear terms in the Taylor expansion are relevant).

The damping term comes from internal collisions in the solid and radiation emitted by the electron (any accelerating charge emits radiation).

16.1. Marine & Weather Engineering

METEOROLOGY is the study of atmospheric phenomena such as clouds, weather depression and precipitation to understand how they form and evolve. It is a discipline that deals mainly with fluid mechanics applied to air but which makes use of various other branches of physics and chemistry. It therefore allows for weather forecasts based on mathematical models on (actually) relatively short and long term. It is also applied for the prediction of air quality, climate change and the study in several areas of human activity (construction, air traffic, etc.).

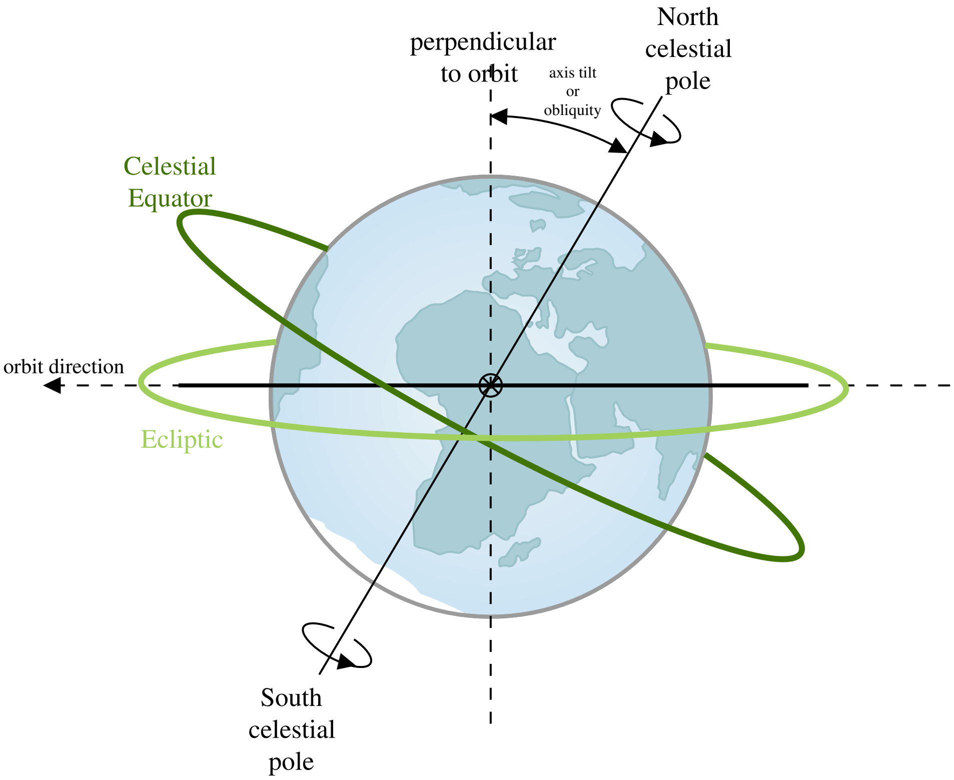
Remark

The Greek philosopher Aristotle is often cited as one of the founding fathers of meteorology with his treatise *Meteorologica* (written approximately in 9650 according to holocene calendar) commonly regarded as one of the earliest attempts to understand the Earth's atmosphere and the water cycle. Aristotle already understood and described quite accurately the cycle of water and knew that cloud were made of evaporated water and are therefore very heavy considering their whole structure. Aristotle also knew that the wind was not made by the clouds, he claimed that the origin of wind was the dry, hot exhalation.

Meteorology is linked to a large amount of variables that would be very difficult to make a list even not exhaustive... However on our planet Earth, an important factor not to be neglected is the one formed by ocean surfaces and their intrinsic dynamics which we will try to present through a summary mathematical study some of their properties. What is nice is that some results can also be applied to other Planets and sometimes very exotic one like Jupiter.

Now before we continue, one might ask why it happens that "our" planet (Earth) is one of the habitable ones and is perfectly in the habitable zone? But that is not a good question, really! Because first the Earth was inhabitable in the past and will be again inhabitable in a few hundred of million of years. Secondly, the Earth isn't perfectly in the habitable zone because that zone is not a circle without width but a ring with a width of 0.95 to 1.15 astronomical units. Third and last one, whatever intelligent beings appear who are able to ask such questions will look around and necessarily see that they are living on a planet that has the right conditions for life. No coincidence!

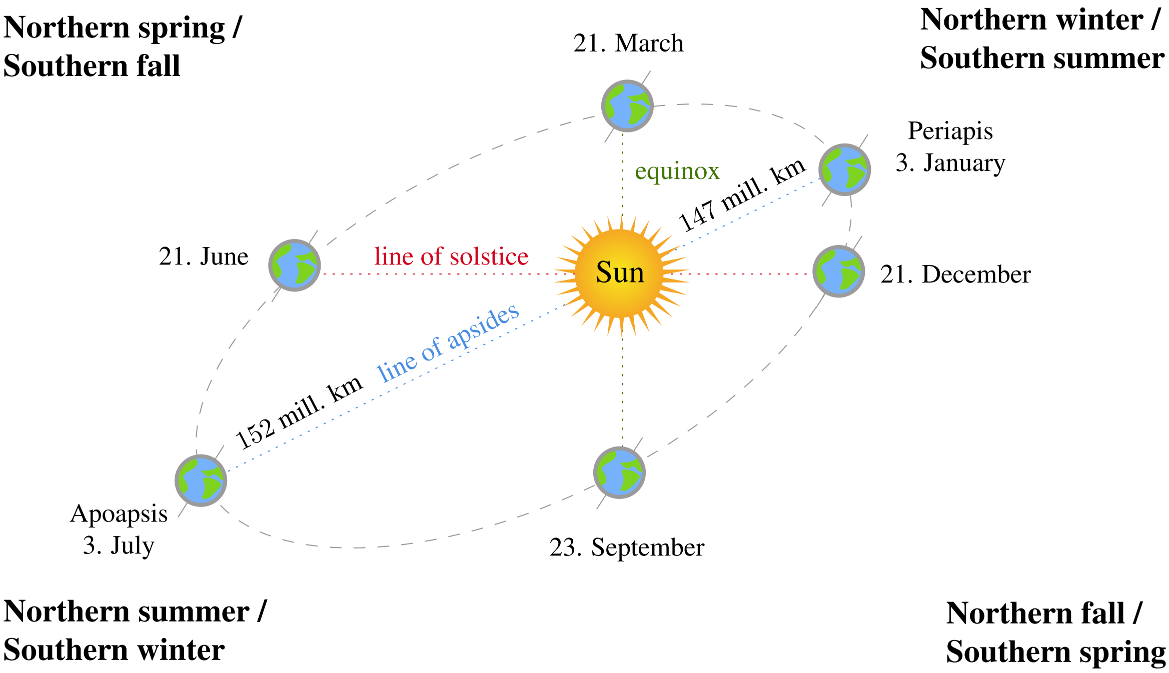
And also before beginning this section we also strongly recommend the reader to have a look of the section of Astronomy (page 5217) as the distance of the Earth (in general any planet...) to its main star (placed on the foci of the orbit) has an influence on the power of the radiation (see section Optical Geometry page 4337) and is therefore directly related to the eccentricity e of the orbit. Especially the inclination of the Earth rotation relatively to the ecliptic plane has a strong influence on the weather conditions as it is related to the existence of the seasons!



North celestial pole
perpendicular to orbit
axis tilt or obliquity
Celestial Equator
orbit direction
Ecliptic
South celestial pole

Figure 16.1: **Earth's inclination**

And the reader must be careful about the statement that at the periapsis people say it's winter because in fact... it depends where you live!!! Indeed, if you live in the northern hemisphere it will be winter, but at the southern hemisphere it will be summer (people that have the money to travel during holidays know this fact very well) as illustrated in the figure below:



Northern spring / Southern fall
21. March
Northern winter / Southern summer
Periapis 3. January
equinox
147 mill. km
21. June
line of solstice
Sun
21. December
line of apsides
152 mill. km
Apoapsis 3. July
23. September
Northern summer / Southern winter
Northern fall / Southern spring

Figure 16.2: **Seasons space point of view**

The reader must also consider that the main factors of surface weather are:

- Latitude
- Topography
- Temperature
- Humidity
- Pressure
- Cloud cover
- Water cover
- Snow/Ice cover
- Wind circulation
- Sun activity (solar radiation)
- Moon position (tides)
- Sea/Ocean proximity
- Volcanoes activity
- Soil composition
- Earth atmosphere thickness and composition (on the long term)
- Earth speed rotation[1] (on the very long term)
- Distance to the Sun (on the very long term)
- ...

So given the number of variables... it's crystal clear that it's much more easier to predict the trajectory of an asteroid in vacuum on the long term where there is only one variable to predict rather than weather and climate where there are multiple hard to control/measure variables.

The combination of all the short term factors is well represented in the figure below (the years in the legend of the below image are given based on the holocene calendar):

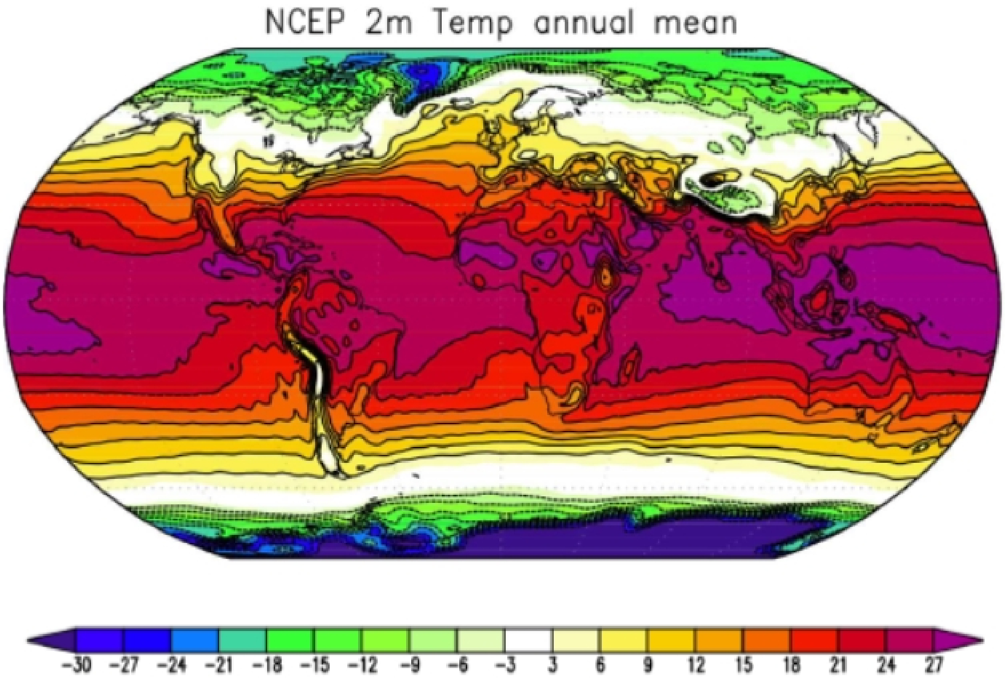


Figure 16.3: **Annual mean temperatures in 2 [m] height in the atmosphere from the NCEP data set over the period 11950-12000 (values in °C)**

---

[1] Earth has a mean increase of the day length of about 2.177 [ms $\cdot$ century^{-1}]. That means the day length (if we do a stupid naive linear interpolation) doubles approximately every 40 million years...

The simulated evolution of Earth's day length over time is also interesting to see and to know (one-million years is represented by "Ma" meaning "mega annum"):

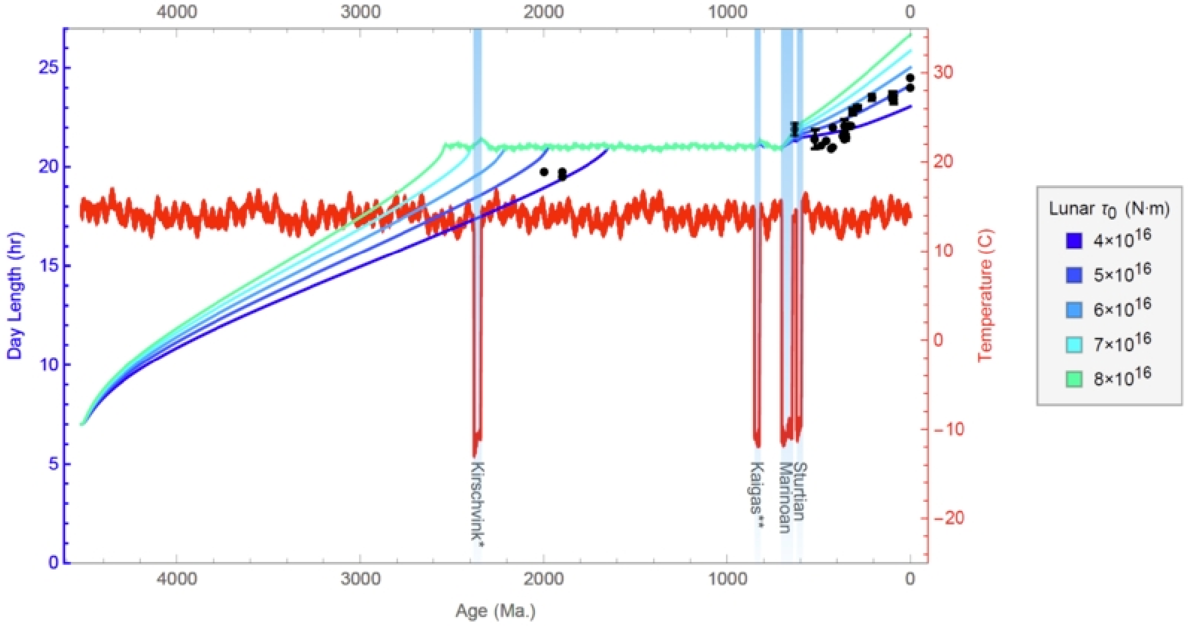

Figure 16.4: **Earth simulated day length evolution (source: [43])**

The plot depicts the simulated evolution of Earth's day length over time for varying choices of lunar torque τ_0 (shown in blue and green) and temperature values (red) over the lifetime of the Earth. Resonant-stabilizing effects are present from 600 million years to 1800-2600 million years, depending on the choice of lunar torque. Note that atmospheric thermal noise does not influence the day length except very near resonance, and that the resonant effect remains unbroken through this noise until two successive simulated snowball events at the end of the Precambrian 720 million years and 640 million years, corresponding to recent estimates of the Sturtian and Marinoan glaciations. Recapture events can be seen at 870 million years following the "Kaigas glaciation" and, for some values of τ_0, following a Paleoproterozoic glaciation detailed in Kirschvink et al. (12000 according to holocene calendar). Approximate empirical day length data from a compilation in Williams (12000 according to holocene calendar) are overlaid in black (error bars included where present) and resemble the simulated results, though the reader should not take this data to be too reliable, particularly the data points prior to 600 million years!

And let us take a look of the estimated geological time-scale evolution of temperature for Earth:

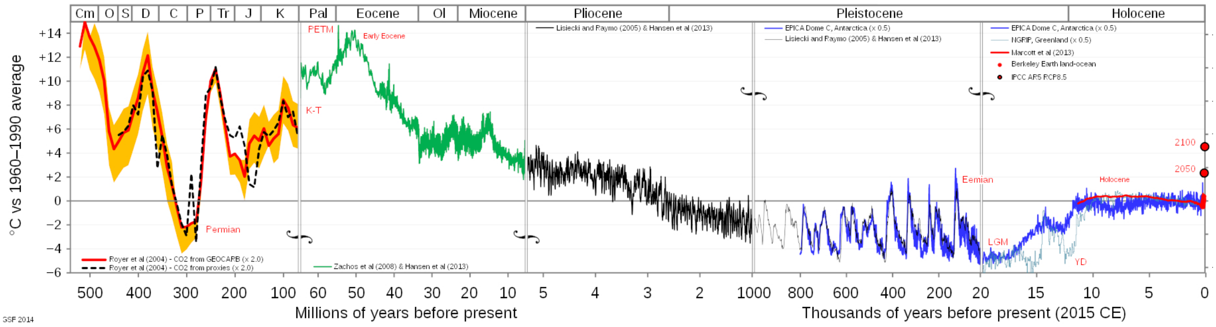

Figure 16.5: Geological time-scale evolution of temperature for Earth (source: http://gergs.net/all_palaeotemps-2, author: Glen Fergus)

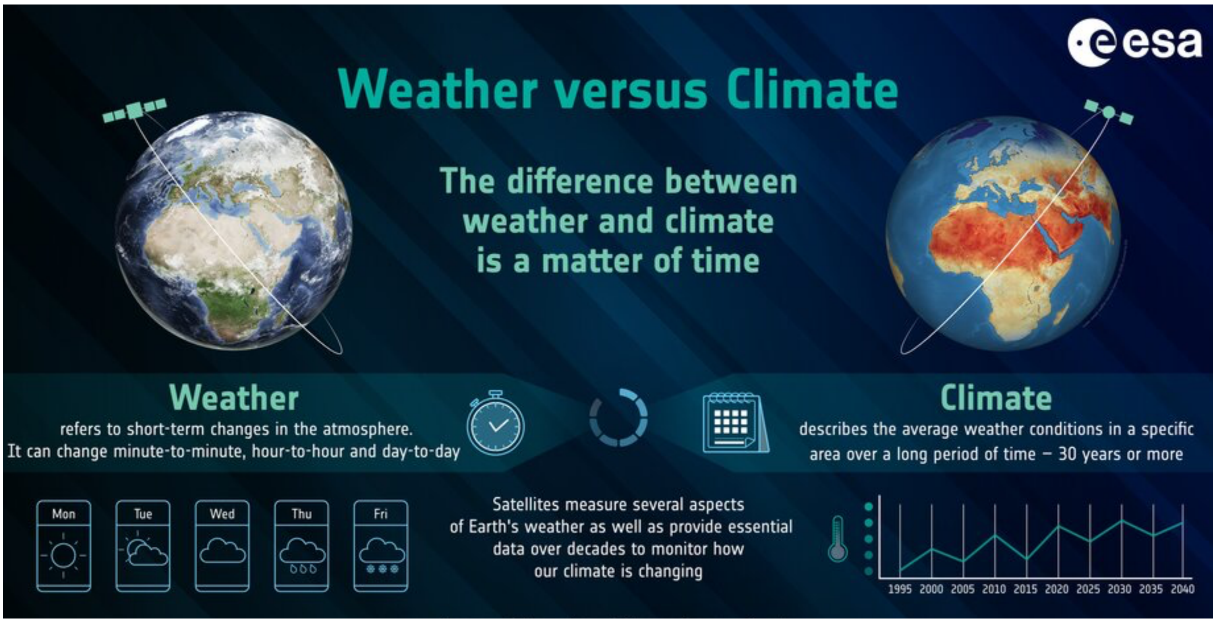
This section is a general introduction to the basic to the field of technical applications of thermodynamics and fluid mechanics. It will allow the reader to become familiar with the language and some fundamental methods of calculations used by engineers in this branch. Of course, this study must be completed by practical laboratory and simulation work on computer.

And please, don't confuse "weather" with "climate"!!!



esa
Weather versus Climate
The difference between weather and climate is a matter of time
Weather
refers to short-term changes in the atmosphere.
It can change minute-to-minute, hour-to-hour and day-to-day
Climate
describes the average weather conditions in a specific area over a long period of time – 30 years or more
Mon
Tue
Wed
Thu
Fri
Satellites measure several aspects of Earth's weather as well as provide essential data over decades to monitor how our climate is changing

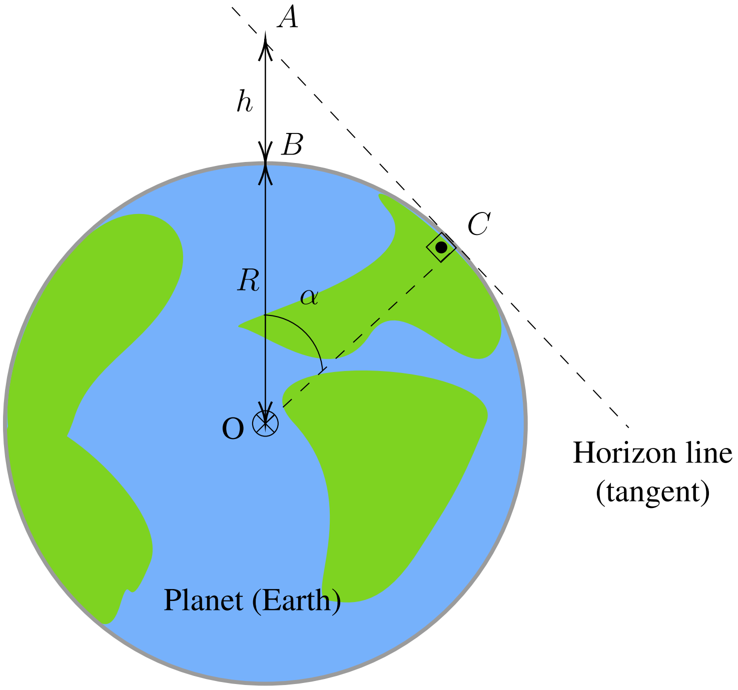
16.1.1 Visual horizon

Let us consider first a little funny subject making often friendly debate during holidays or more seriously ... In some meteorological softwares, it is required during temperature and pressure measurement to manually enter the visual horizon... but this is difficult to determine when the weather is very good and we are in a height position (on a hill or small mountain).

For this, consider the Earth as a perfect sphere with radius R and a point of view of height h relative to sea level which we will denote by A (and without atmosphere to avoid optical effects...). The question is to know how far can be by maximum the point C if it is by definition given by the tangent $\overline{AC}$ which is simply the horizon line:



The reader can probably already observed that the study will mainly appeal to trigonometry concepts (see corresponding section of this textbook) and elementary geometry (also see corresponding sections).

The angle $\widehat{\text{O}CA}$ is a right angle. Indeed, a straight tangent at a point on a circle is perpendicular to the radius at that point. The triangle $\widehat{\text{O}CA}$ is therefore rectangle on C.

Therefore we have:

$$\cos(\alpha)=\frac{\overline{\text{O}C}}{\overline{\text{O}A}}=\frac{\overline{\text{O}C}}{\overline{\text{O}B}+\overline{BA}} \tag{16.1.1}$$

But, we have $\overline{\text{O}B}=\overline{\text{O}C}=R$. Hence we deduce:

$$\cos(\alpha)=\frac{R}{R+h}\Rightarrow\alpha=\arccos\left(\frac{R}{R+h}\right) \tag{16.1.2}$$

The $\overline{AC}$ distance is the distance in a straight line between our viewpoint and the (floor of the) boat that we see on the horizon. The distance, however, that interest us here is $\overline{BC}$: it is the distance that we should travel at the altitude 0 to reach the ground of the boat we see on the horizon.

For what will follows we will put for the curvilinear distance: $\overline{BC}=d$.

When the angle α varies from 0° to 360° (full circle), we describe the entire circumference of the Earth, that is to say $2\pi R$, since the Earth is assumed to be round.

Using the rule of three:

If an angle of 360° corresponds to a distance of $2\pi R$ then an angle α in degrees corresponds to a curvilinear distance:

$$d_{\text{curv.}}=\frac{2\pi R}{360^\circ}\alpha=\frac{\pi R}{180^\circ}\alpha \tag{16.1.3}$$

But we have seen previously that:

$$\alpha=\arccos\left(\frac{R}{R+h}\right) \tag{16.1.4}$$

Hence finally:

$$d_{\text{curv.}}=\frac{\pi R}{180^\circ}\alpha=\frac{\pi R}{180^\circ}\arccos\left(\frac{R}{R+h}\right) \tag{16.1.5}$$

With $R\cong 6,378\;[\text{km}]$, we find ($h$ must be expressed in kilometres):

$$d_{\text{curv.}}\cong 111.32\arccos\left(\frac{6,378}{6,378+h}\right) \tag{16.1.6}$$

In Microsoft® Excel® this is given by:

```
=111.32*DEGREES(ACOS(6378/(6378+h)))
```

We have then in vacuum, in a landscape without obstacles... the following table:

Altitude h [m]	**Horizon distance $d_{\text{curv.}}$ [km]**
1.5	4.3
5	8
10	11.3
50	25.3
100	35.7
200	50.5
400	71.4
600	87.5
800	101
$1,000$	113
$2,000$	159.7
$3,000$	195.6
$4,000$	225.8
$5,000$	252.5
$10,000$	357

Table 16.1: **Visual horizon curvilinear distance in function of the altitude (in vacuum)**

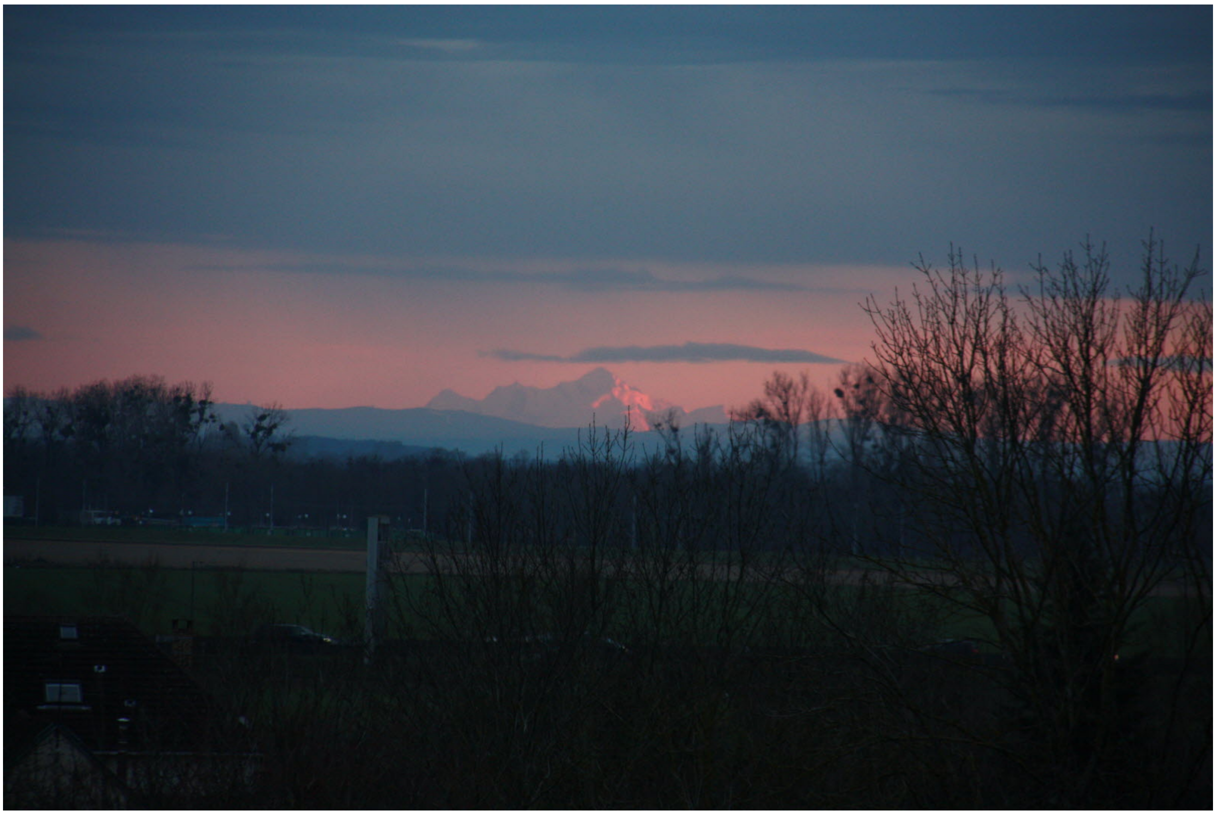


Figure 16.7: **Mont-Blanc ($4,809$ [m]) as seen from the City of Ducs de Bourgogne near Dijon at the 4th floor of a building (hence an elevation of 346 [m]) at a distance of 268 [km] the 9th January 12020 at 17:36 (author: Serge Fourcaudot)**

There is another famous formula we can found in many textbook that consider the rectilinear distance $d_{\text{rec.}}=\overline{AB}$ and not the curvilinear one. In that case:

$$(R+h)^2=R^2+d_{\text{rec.}}^2 \Rightarrow R^2+h^2+2Rh=R^2+d_{\text{rec.}}^2 \tag{16.1.7}$$

And since $h/R\cong 10^{-5}$, we may ignore h^2, and isolating $d_{\text{rec.}}$ gives:

$$d=\sqrt{2Rh} \tag{16.1.8}$$

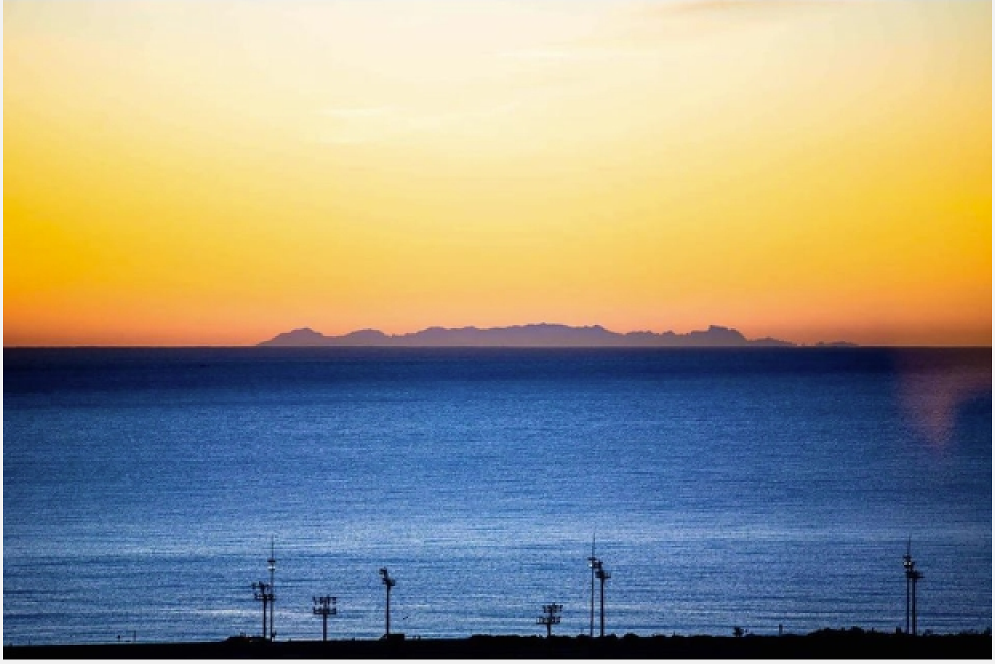
Using this formula it is customary to measure the height h in meters, and the distance in kilometres. If we therefore insert $h/1000$ instead of h, and the radius of the Earth in kilometres, we obtain a well known formula:

$$d \cong 3.57\sqrt{h}\,[\text{km}] \tag{16.1.9}$$

As the radius of the Earth is quite big, the difference between this approximation and the previous derived relation leads to a difference for every row of the above table of a few dozens of meters only!

Remark

If we do not take into account atmospheric refraction, we find in the table above that would need to go to an altitude of the order of several kilometres to see beyond 200 [km] away. Yet at the heights of Nice (Alpes-Maritimes in France) at the Garoupe lighthouse (78 [m] of altitude), it is possible to observe the upper part (like the Monte Cinto mountain at $2,706$ [m]) of Cap Corse (it's an island for information...) which is about 220 [km] from the continent (especially from the Alps were the photo below was taken) however at the same moment people at Cap Corse can't see the Garoupe lighthouse!!! Atmospheric refraction (especially in winter) plays then a significant role in this phenomenon (see photo below taken by John Bouchet the 15 January 12019 at the morning) as proven in the section of Optics at page 4397.



Using the refraction effect derived at page 4412 and considering a rising angle of $\varphi = 0$, we get theoretically the double of the distance (as $\mathrm{d}n/\mathrm{d}h = 1/R$ in this perfect theoretical case), however if we take an experimentally measured gradient in Winter of $\mathrm{d}n/\mathrm{d}h \cong 2.4 \cdot 10^{-7}$, then we get (don't forget to convert the output of $\arccos$ in degrees when using a calculator!):

$$d_{\text{hor.,ref.}} \cong 111.32 \arccos\left(\frac{6,378}{6,378+h}\right)\left[1+\frac{\mathrm{d}n}{\mathrm{d}h}6,378\cdot 10^{3}\right] \cong 4.11\sqrt{h}$$

where the approximation using the square root has been made using a solver on a computer software. Therefore we get an increase of approximately 15% in comparison of the case without refraction that was given by $3.57\sqrt{h}$.

The questions that arise are: given that we are at a height h_0 and we look far at the horizon:

1. What is the distance of the horizon (same as above but with a different approach used by people that argue that the Earth is flat and that the NASA lies...)?
2. At what level under the horizon is an object at a distance d of the observer (eye)?

To answer these questions consider the figure below:

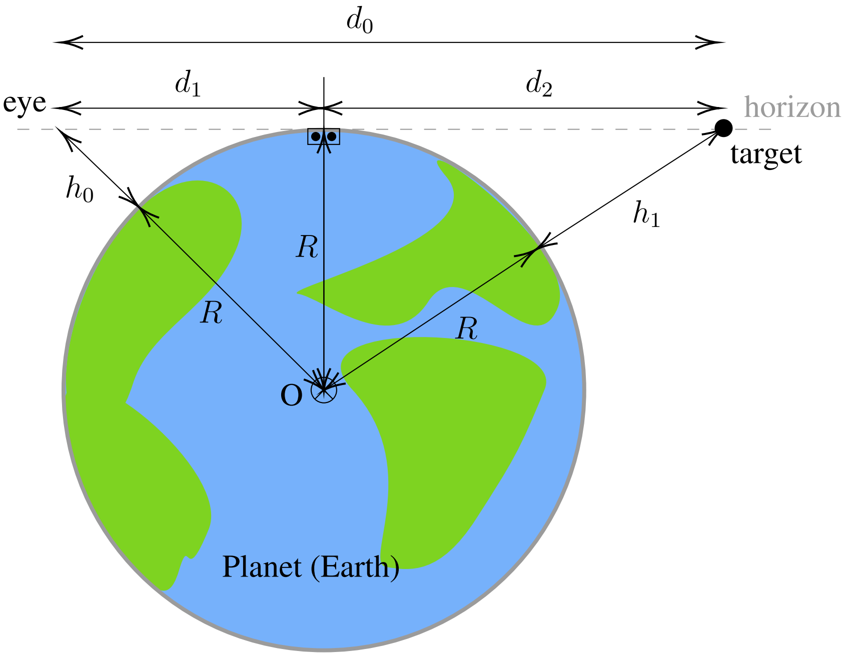


Figure 16.8: **Visual Horizon configuration experience**

The application of Pythagoras gives us immediately:

$$(R+h_0)^2=d_1^2+R^2 \Leftrightarrow d_1=\sqrt{h_0^2+2Rh_0} \tag{16.1.10}$$

Hence:

$$\boxed{d_1=\sqrt{h_0^2+2Rh_0}} \tag{16.1.11}$$

And we can get also the minimum height given d_0, d_1:

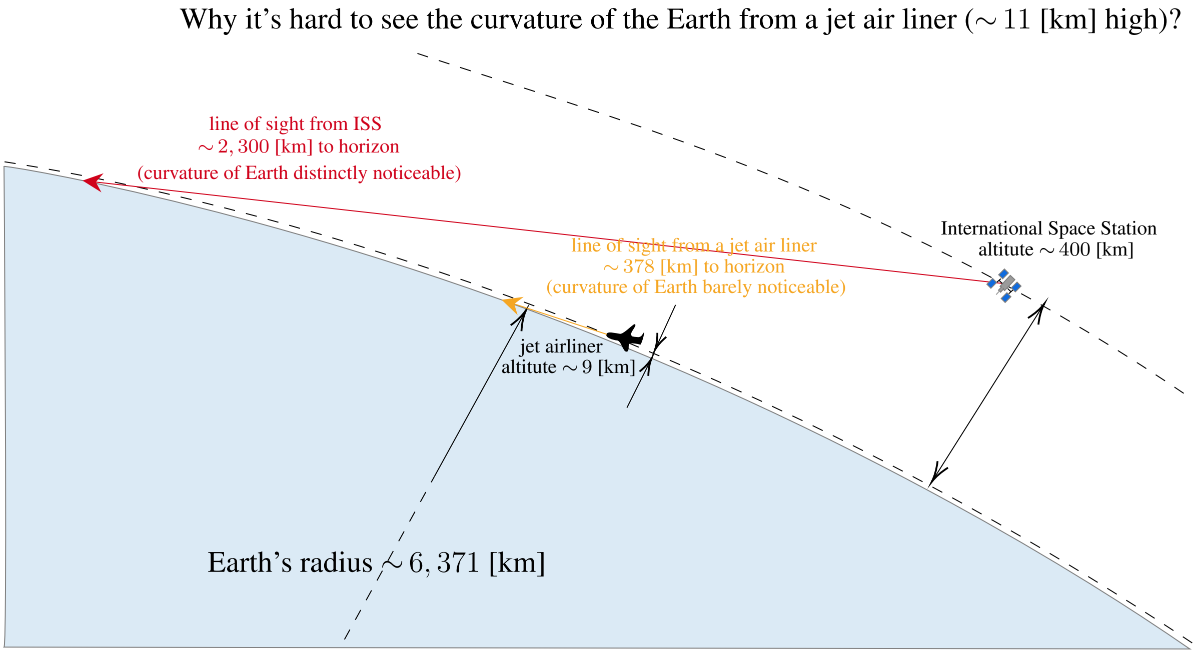
$$(R+h_1)^2=d_2^2+R^2 \Leftrightarrow h_1=\sqrt{d_2^2+R^2}-R=\sqrt{(d_0-d_1)^2+R^2}-R \tag{16.1.12}$$

So let us compare the value of d_1 just obtained above (straight distance) for $d_{\text{curv.}}$ obtained previously that is the curvilinear distance (but this time at two decimal places):

Altitude h [m]	Horizon distance $d_{\text{curv.}}$ [km]	Horizon distance d_1 [km]
1.5	4.374	4.374
5	7.98	7.98
10	11.29	11.29
50	25.25	25.25
100	35.71	35.71
200	50.51	50.50
400	71.43	71.43
600	87.48	87.48
800	101.01	101.02
$1,000$	112.93	112.94
$2,000$	159.70	159.73
$3,000$	195.58	195.64
$4,000$	225.83	225.92
$5,000$	252.47	252.59
$10,000$	356.93	357.29

Table 16.2: **Visual horizon curvilinear and straight distance in function of the altitude (in vacuum)**

So the bias of the people that believe that the Earth (and all other planets) is flat ("flat earthers") is that when they do the experiments to prove their arguments they forget the "perfectly spheric" assumption of that model. Indeed as we have seen in the section of Astronomy the Earth's shape is more like a irregular potatoes and is locally (at human scale, i.e. a few hundreds of kilometres sometimes) absolutely not spherical due to relief irregularities.



Why it's hard to see the curvature of the Earth from a jet air liner (~ 11 [km] high)?
line of sight from ISS
~ 2,300 [km] to horizon
(curvature of Earth distinctly noticeable)
International Space Station
altitute ~ 400 [km]
line of sight from a jet air liner
~ 378 [km] to horizon
(curvature of Earth barely noticeable)
jet airliner
altitute ~ 9 [km]
Earth's radius ~ 6,371 [km]

Figure 16.9: **Earth's curvature visibility**

Anyway an another argument is that we can prove with Isoperimetric Inequality (see section Geometric Shapes page 2993) that natural final shape for a cloud of dust is a sphere and otherwise that the acceleration of objects that fall all respect Newton's law in it's... spherical form! And also... if the Earth was flat... nobody so far as we know has seen it's border...

Therefore the two relations to remember are (after standardizing the notations):

$$\begin{aligned} d_{\text{straight}} &= \sqrt{h^2+2R_{♁}h} \\ d_{\text{curvilinear}} &\cong 111.32 \arccos\left(\frac{R_{♁}}{R_{♁}+h}\right) \end{aligned} \tag{16.1.13}$$

Keep in mind that these results are for a perfect sphere in vacuum. When an atmosphere exist, refraction effect (see proof in the section of Optics at page 4397) can drastically increase the distances with theoretically almost no limit.

Taking into account the refraction (again see the proof at page 4412):

$$\Delta\varphi = -\frac{\cos(\varphi)}{n}\frac{\mathrm{d}n}{\mathrm{d}y}\Delta s \tag{16.1.14}$$

that leads to the following relation:

$$\begin{aligned} d_{\text{curv.refr.}} &\cong \Delta(\Delta s) + d_{\text{curv}} = \Delta\varphi R + d_{\text{curv}} \\ &= \left(\frac{\cos(\varphi)}{n}\frac{\mathrm{d}n}{\mathrm{d}y}\Delta s\right) R + d_{\text{curv}} \\ &= \left[\frac{\cos\left(\arcsin\left(\dfrac{d_{\text{straight}}}{R+h}\right)\right)}{n}\frac{\mathrm{d}n}{\mathrm{d}y} R \sin\left(\frac{d_{\text{straight}}}{R+h}\right)\right] R + d_{\text{curv}} \end{aligned} \tag{16.1.15}$$

To summarize:

$$\boxed{\begin{aligned} d_{\text{straight}} &= \sqrt{h^2+2R_{♁}h}\;[\text{m}] \\ d_{\text{curvilinear}} &\cong 111.32 \arccos\left(\frac{R_{♁}\;[\text{km}]}{R_{♁}\;[\text{km}]+h\;[\text{km}]}\right)\;[\text{km}] \\ d_{\text{curv.refr.}} &\cong \left[\frac{\cos\left(\arcsin\left(\dfrac{d_{\text{straight}}}{R+h}\right)\right)}{n}\frac{\mathrm{d}n}{\mathrm{d}y} R \sin\left(\frac{d_{\text{straight}}}{R+h}\right)\right] R + d_{\text{curvilinear}} \cdot \frac{1000\cdot 360}{2\pi} \end{aligned}} \tag{16.1.16}$$

If we take the same case taken as the one at the page 4397 (i.e. $n=1$ and $\mathrm{d}n/\mathrm{d}y \cong 2.4\cdot 10^{-8}$), we then have (between parentheses we put how the distance is reduced as it's a matter of point of view to say that the object is further or closer):

Altitude h [m]	Horizon distance $d_{\text{curv.}}$ [km]	Horizon distance $d_{\text{curv.refr.}}$ [km]
1.5	4.374	5.043 (3.704)
5	7.98	9.201 (6.758)
10	11.29	13.018 (9.561)
50	25.25	29.115 (21.385)
100	35.71	41.176 (30.243)
200	50.51	58.241 (42.778)
400	71.43	82.363 (60.496)
600	87.48	100.869 (74.095)
800	101.01	116.469 (85.550)
1,000	112.93	130.213 (95.646)
2,000	159.70	184.139 (135.262)
3,000	195.58	225.503 (165.656)
4,000	225.83	260.376 (191.283)
5,000	252.47	291.085 (213.854)
10,000	356.93	411.406 (302.379)

Table 16.3: **Visual horizon curvilinear in function of the altitude in vacuum vs in air with $n=1$ and $\mathrm{d}n/\mathrm{d}y \cong 2.4\cdot 10^{-8}$**

According to NSPS (National Society of Professional Surveyors) in their *Definitions of Surveying and Associated Terms* (see [199]), the surveyor has to take into account and offset of about 8 [cm] at 1 [km] distance. This is the offset which is given in surveying tables as correction for curvature of the Earth. The values given in such tables usually combine the effects of both curvature the Earth and atmospheric refraction. Under normal conditions, the atmospheric refraction compensates partially for the curvature of the Earth, so the correction is about 6 [cm] for a point 1 [km] away.

If you take the biggest spirit level available on the market, i.e. 200 [cm], you wouldn't be able to identify at the naked eye the Earth's curvature as the maximum difference of height between the two extremities would then be, according to NSPS rule, of only 0.016 [cm], hence 0.16 [mm].

But where does the number above of the NSPS come from? That's quite easy! Let us consider the following figure:

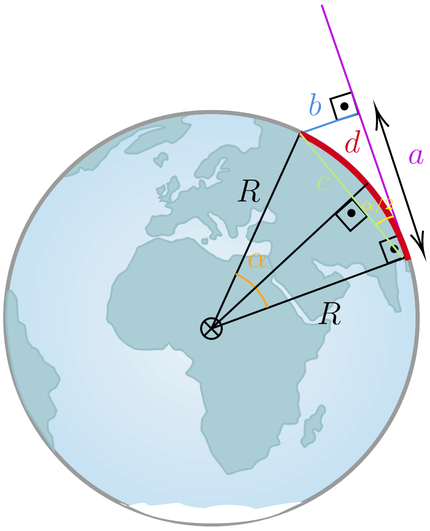


Figure 16.10: **Distance between point on tangent line and circle**

For the Earth the distance d is given by (where for reminder α is in radians):

$$d=R\cdot\alpha\Leftrightarrow\alpha=\frac{d}{R} \tag{16.1.17}$$

Consider that we are interested in the value of b for $d=1$ [km].

First notice that in the figure above, we have:

$$\sin\left(\frac{\alpha}{2}\right)=\frac{c/2}{R} \tag{16.1.18}$$

Rearranging:

$$c=2R\sin\left(\frac{\alpha}{2}\right)=2R\sin\left(\frac{d/R}{2}\right) \tag{16.1.19}$$

We see also that in the coloured triangle, we have:

$$\sin\left(\frac{\alpha}{2}\right)=\frac{b}{c} \tag{16.1.20}$$

Rearranging:

$$b=c\sin\left(\frac{\alpha}{2}\right)=c\sin\left(\frac{d/R}{2}\right) \tag{16.1.21}$$

And injecting the previous result:

$$b=\left(2R\sin\left(\frac{d/R}{2}\right)\right)\sin\left(\frac{d/R}{2}\right)=2R\sin^2\left(\frac{d/R}{2}\right) \tag{16.1.22}$$

Hence for $d=1$ [km], we have:

$$b=2R\sin^2\left(\frac{d/R}{2}\right)=2\cdot 6,371\cdot\sin^2\left(\frac{1/6,371}{2}\right)\cong 7.8\,[\text{cm}] \tag{16.1.23}$$

When $R\gg d$ we can us the Maclaurin approximation of the $\sin$ and therefore:

$$b=2R\sin^2\left(\frac{d/R}{2}\right)\cong 2R\left(\frac{d/R}{2}\right)^2=\frac{d^2}{2R} \tag{16.1.24}$$

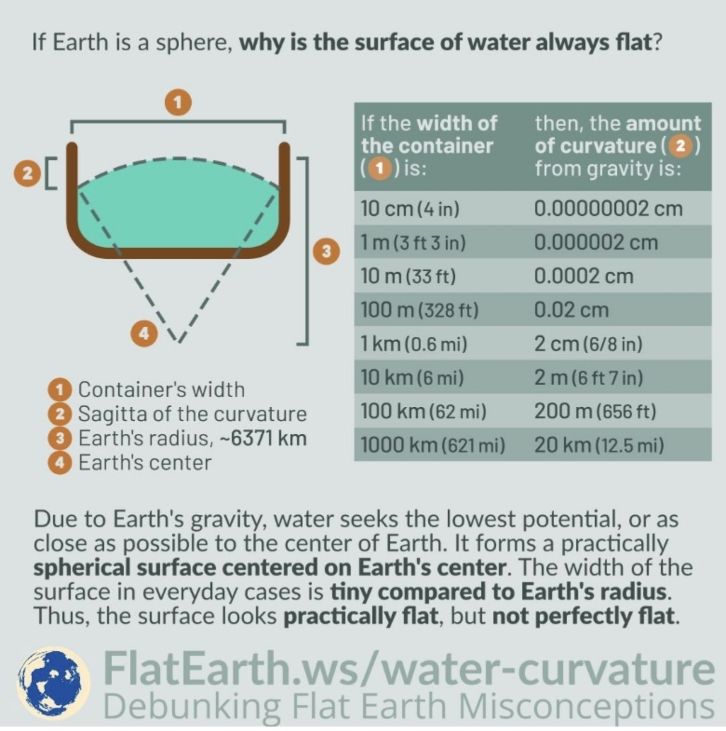
So we get the famous "8 inches per miles squared" geometrical curvature drop (and not visual drop as this result assumes a vacuum!) approximation formula often denoted:

$$\boxed{C_d=\frac{d^2}{2R}} \tag{16.1.25}$$

Remark

Assuming the "8 inches per mile" is accurate, that means airplanes would have to "nose down" to a pitch of $-1''$ per $7290''$ flown (equivalent of a mile), or a pitch of -0.007 degrees. That's pretty much level flight. The pilot nor autopilot would even be able to discern the difference given the accuracy of instruments used by autopilots nowadays (their PID - proportional–integral–derivative controller based on fuzzy logic - measure and get a few thousand of times per second the GPS localization, the radar altitude plus the atmospheric height using a Pitot tube). Most human eyes can't even eyeball 1 degree so imagine $7/1000$ths of a degree.

Let us now deal with the oblique horizon distance mainly because of the quite famous figure below:



If Earth is a sphere, **why is the surface of water always flat**?

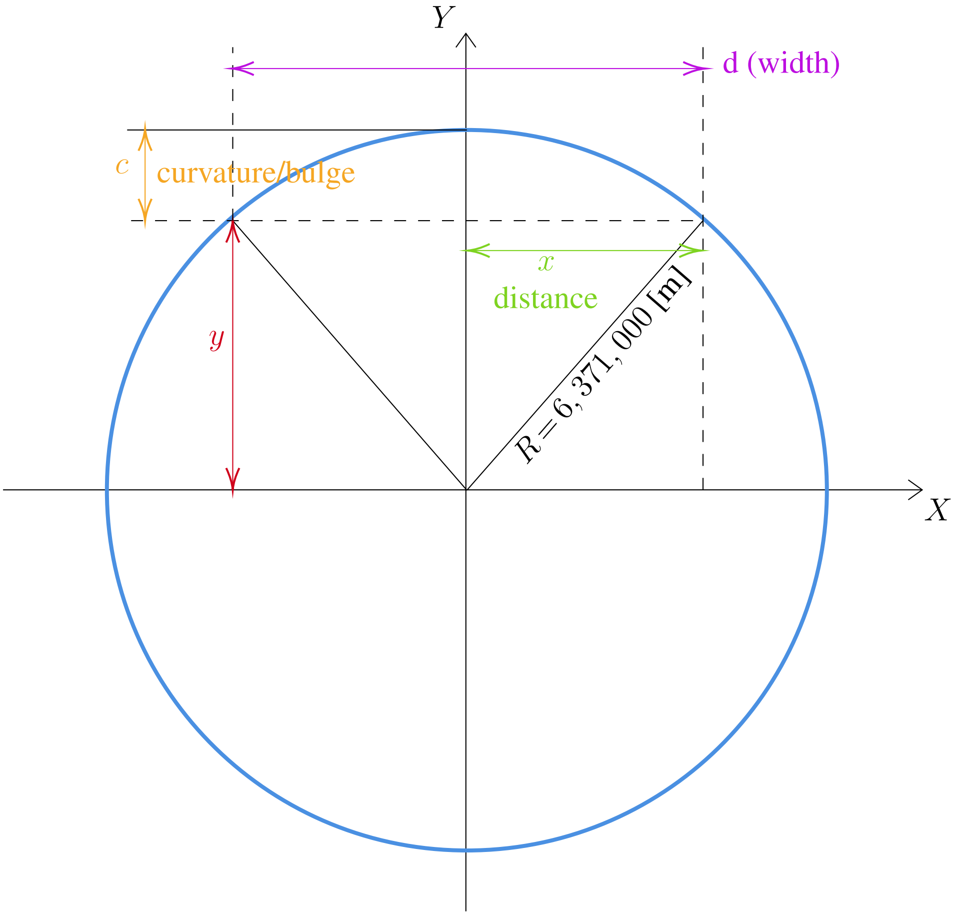
If the **width of the container** (①) is:	then, the **amount of curvature** (②) from gravity is:
10 cm (4 in)	0.00000002 cm
1 m (3 ft 3 in)	0.000002 cm
10 m (33 ft)	0.0002 cm
100 m (328 ft)	0.02 cm
1 km (0.6 mi)	2 cm (6/8 in)
10 km (6 mi)	2 m (6 ft 7 in)
100 km (62 mi)	200 m (656 ft)
1000 km (621 mi)	20 km (12.5 mi)

① Container's width
② Sagitta of the curvature
③ Earth's radius, ~**6371 km**
④ Earth's center

Due to Earth's gravity, water seeks the lowest potential, or as close as possible to the center of Earth. It forms a practically **spherical surface centered on Earth's center**. The width of the surface in everyday cases is **tiny compared to Earth's radius**. Thus, the surface looks **practically flat**, but **not perfectly flat**.

FlatEarth.ws/water-curvature
Debunking Flat Earth Misconceptions

To see where the values of the table visible in the illustration above come from, let us consider the following figure:



And now let's to the math to find c! That's elementary, applying Pythagore we have first:

$$x^2 + y^2 = R^2 \tag{16.1.26}$$

Therefore

$$y = \sqrt{R^2 - x^2} \tag{16.1.27}$$

But as we have $c = R - y$, hence:

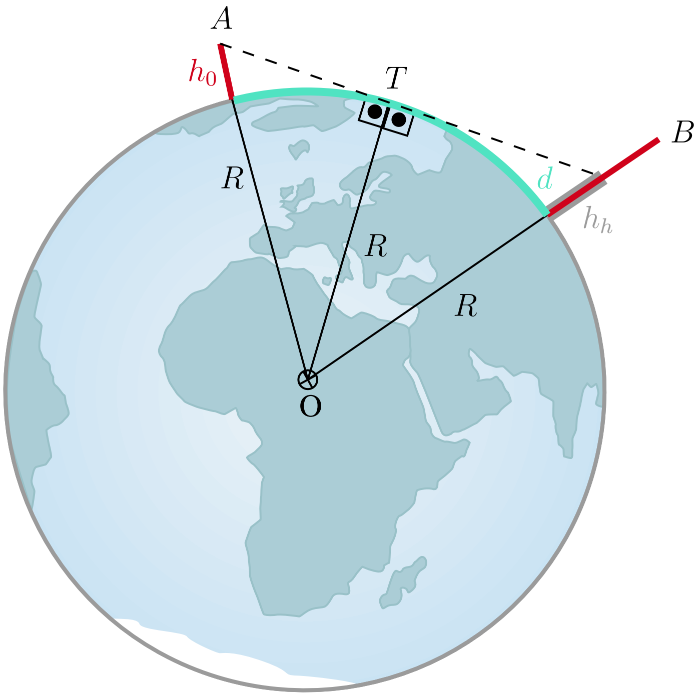
$$c = R - \sqrt{R^2 - x^2} \tag{16.1.28}$$

and as $d = 2x \Rightarrow x = d/2$ we have:

$$c = R - \sqrt{R^2 - \frac{1}{4}d^2} \tag{16.1.29}$$

And by applying the relation above we get the table visible in the figure above!

Let us consider now the most important case about the horizon (!): how to calculate the hidden height h_h given a point of view at a height h_0 and a curvilinear distance d in-between as illustrated below:



In the figure above we have:

$$\overline{A\text{O}} = h_0 + R \tag{16.1.30}$$

by trigonometry:

$$\widehat{A\text{O}T} = \arccos\left(\frac{R}{h_0+R}\right) \tag{16.1.31}$$

and:

$$\widehat{A\text{O}B} = \frac{d}{R} \tag{16.1.32}$$

Therefore:

$$\widehat{T\text{O}B} = \frac{d}{R} - \arccos\left(\frac{R}{h_0+R}\right) \tag{16.1.33}$$

By the law of sines (see section Trigonometry page 2528):

$$\frac{h_0+R}{h_h+R} = \frac{\sin\left(\frac{\pi}{2} - \widehat{T\text{O}B}\right)}{\sin\left(\frac{\pi}{2} - \widehat{A\text{O}T}\right)} \tag{16.1.34}$$

Using trigonometric identities, this simplifies to:

$$\frac{h_0+R}{h_h+R} = \frac{\cos\left(\widehat{T\text{O}B}\right)}{\cos\left(\widehat{A\text{O}T}\right)} \tag{16.1.35}$$

Hence:

$$\frac{h_0+R}{h_h+R}=\frac{\cos\left(\dfrac{d}{R}-\arccos\left(\dfrac{R}{h_0+R}\right)\right)}{\cos\left(\arccos\left(\dfrac{R}{h_0+R}\right)\right)}=\frac{\cos\left(\dfrac{d}{R}-\arccos\left(\dfrac{R}{h_0+R}\right)\right)}{\dfrac{R}{h_0+R}} \tag{16.1.36}$$

After simplification and inversion:

$$h_h+R=\frac{R}{\cos\left(\dfrac{d}{R}-\arccos\left(\dfrac{R}{h_0+R}\right)\right)} \tag{16.1.37}$$

After rearranging:

$$h_h=\frac{R}{\cos\left(\dfrac{d}{R}-\arccos\left(\dfrac{R}{h_0+R}\right)\right)}-R \tag{16.1.38}$$

Injecting in it the effective radius of Earth (see page 4413), we get the famous exact equation for the hidden height:

$$\boxed{h_h=\frac{R'}{\cos\left(\dfrac{d}{R'}-\arccos\left(\dfrac{R'}{h_0+R'}\right)\right)}-R'} \tag{16.1.39}$$

And keep in mind that h_h is the height an object must have at the horizon to be at the limit of visibility when we stand at a height h_0 of observation (if is it greater that h_h it will be visible!).

So let us take for all the relations established previously with:

$$\begin{aligned}
d_{\text{straight}}&=\sqrt{h^2+2R_{\text{♁}}h}\;[\text{m}]\\
d_{\text{curvilinear}}&\cong 111.32\arccos\left(\frac{R_{\text{♁}}\,[\text{km}]}{R_{\text{♁}}\,[\text{km}]+h\,[\text{km}]}\right)\;[\text{km}]\\
d_{\text{curv.refr.}}&\cong\left[\frac{\cos\left(\arcsin\left(\dfrac{d_{\text{straight}}}{R+h}\right)\right)}{n}\frac{\mathrm{d}n}{\mathrm{d}y}R\sin\left(\frac{d_{\text{straight}}}{R+h}\right)\right]R+d_{\text{curvilinear}}\cdot\frac{1000\cdot 360}{2\pi}\\
\frac{\mathrm{d}n}{\mathrm{d}y}&\cong-\frac{(n(y)-1)}{T(y)}\left(\frac{\rho(y)gT(y)}{P(y)}+\frac{\mathrm{d}T}{\mathrm{d}y}\right):=-\frac{(n(y)-1)}{T(y)}(\gamma_g-\gamma)
\end{aligned} \tag{16.1.40}$$

Let us take some conservative typical values:

$$\gamma=0.0113\;\left[\Delta°\text{C}\cdot\text{m}^{-1}\right]\qquad T=295.15\,[\text{K}]\qquad P=101,325\,[\text{Pa}] \tag{16.1.41}$$

$$n=1.000293\qquad \rho_{\text{SATP}}=1.168\;\left[\text{kg}\cdot\text{m}^{-3}\right]\qquad R=6,378,137\,[\text{m}] \tag{16.1.42}$$

Therefore we get the following table:

$\mathbf{h_0}$ [m]	$\mathbf{d}_{\text{straight}}$ [m]	$\mathbf{d}_{\text{curvilinear}}$ [m]	$\mathbf{d}_{\text{curv.refr.}}$ [km]	h_h [m]
0	0	0	0	0

16.1.1.1 Discerning the curvature of the Earth

The first direct visual detection of the curvature of the horizon has been widely attributed to Auguste Piccard and Paul Kipfer on 27 May 11931 (holocene calendar). They reported seeing it from a hydrogen-filled balloon at an elevation of $15,787\,[\text{m}]$ over Germany and Austria. On 11 November 11935 (holocene calendar), Albert W. Stevens and Orville A. Anderson became the first people to photograph the curvature. They were flying in the helium-filled Explorer II balloon during a record-breaking flight to an altitude of $22,066\,[\text{ m}]$ over South Dakota. Other claims have been made as to being the first to see the curvature of the Earth, but they seem to have come long after visual curvature had been established.

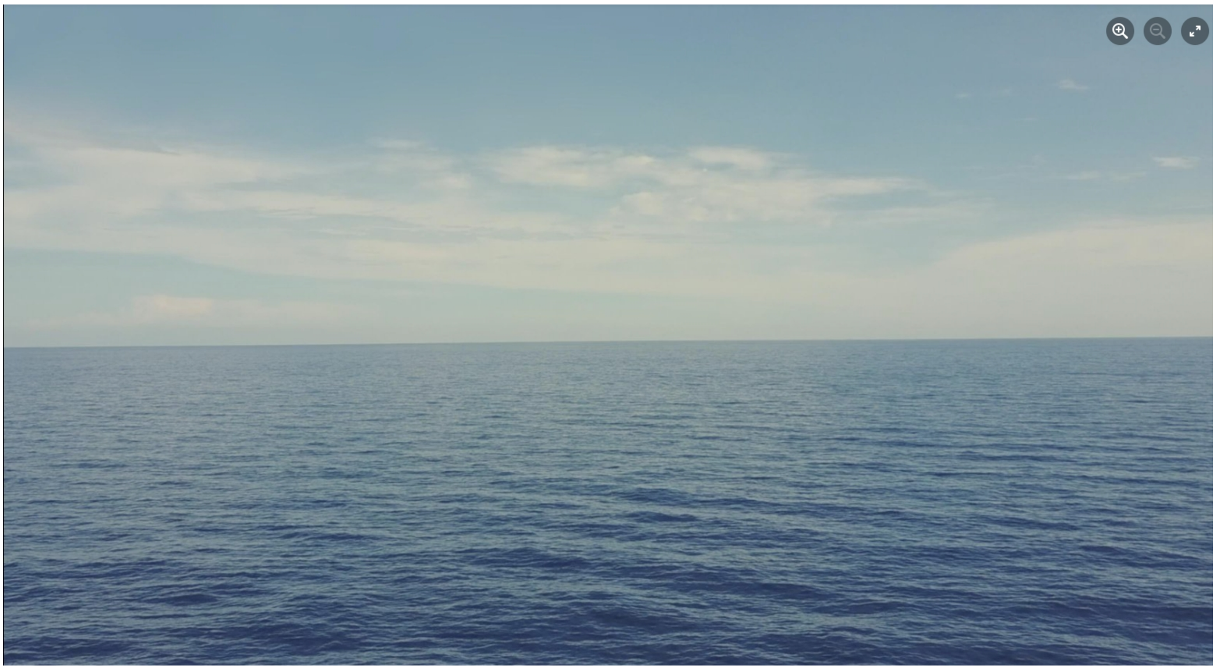

Figure 16.11: **Horizon line with sea view**

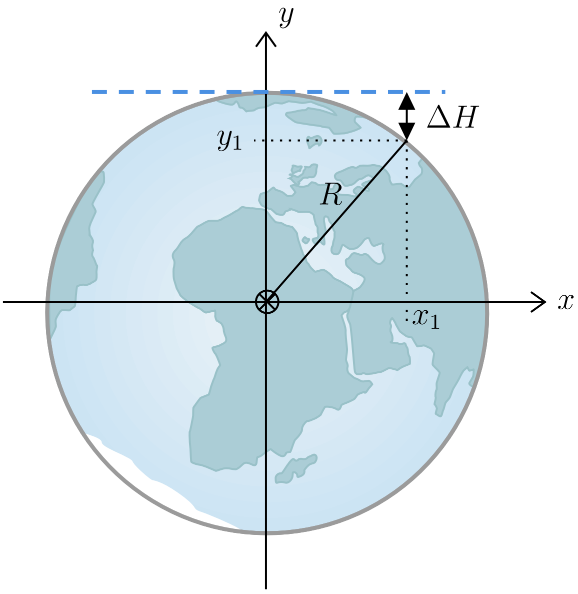
Since that time, countless people have claimed to be able to discern the curvature of the Earth as an upwardly arched horizon from high mountains or commercial aircraft. Some claim to see it from sea level or relatively low elevations. We know that if we get high enough (i.e., from space), the curvature of the Earth is evident, but commercial aircraft seldom exceed altitudes of $12,000\,[\text{m}]$.

Interviews with pilots and high-elevation travelers revealed that few if any could detect curvature below about $15,240\,[\text{m}]$. High-altitude physicist and experienced sky observer David Gutierrez reported that as his B-57 ascends, the curvature of the horizon does not become readily sensible until about $50,000\,[\text{m}]$ and that at $60,000\,[\text{m}]$ the curvature is obvious. Having talked to many other high fliers (SR-71, U2, etc.), Gutierrez confirms that his sense of the curvature is the same as theirs. Passengers on the Concorde $(60,000\,[\text{m}])$ routinely marveled at the curvature of the Earth. Gutierrez believes that if the field of view (FOV) is wide enough, it might be possible to detect curvature from lower altitudes. The author has also talked to many commercial pilots, and they report that from elevations around $16,100\,[\text{m}]$, they cannot see the curvature.

When trying to understand the perception of a curved horizon, two issues must be kept in mind. First, a large fraction of people wear eye glasses. Eye glasses produce a variety of distortions when the observer is not looking through the center part of the lens. Second, above the altitude of Mt. Everest, no observer can look directly at the horizon - he must look through a window or canopy. Planeparallel windows like those on most aircraft will not render a flat horizon curved, but a curved window or canopy will.

Let us calculate the magnitude of the declination ΔH in the extremities of a view like the one above relatively to the horizon line (in blue below) based on the following schema:



We know the equation of the horizon line:

$$y_L = R \tag{16.1.43}$$

We know the equation of the circle that defines Earth's shape:

$$x^2 + y^2 = R^2 \tag{16.1.44}$$

Therefore:

$$\Delta H = R - y_1 = R - \sqrt{R^2 - x^2} \tag{16.1.45}$$

However this relation is incomplete! Indeed, x is limited by the horizon, i.e. the distance at which you can't see what is beyond the curvature. Hence the previous relation should be written instead:

$$\Delta H_{\text{max}} = R - \sqrt{R^2 - x_{\text{max}}^2} \tag{16.1.46}$$

Using what we have seen earlier above, we then have:

$$\Delta H_{\text{max}} \cong R - \sqrt{R^2 - (\sqrt{2Rh})^2} = R - \sqrt{R^2 - 2Rh} \tag{16.1.47}$$

Hence for a person of approximately 1.81 [m] height and for Earth:

$$\Delta H_{\text{max}} \cong 6,371 \cdot 10^3 - \sqrt{(6,371 \cdot 10^3)^2 - 2 \cdot 6,371 \cdot 10^3 \cdot 1.81} \cong 1.81000025757 \text{ [m]} \tag{16.1.48}$$

To convert from linear dimensions to angular dimensions, we need only divide each quantity by the straight distance to the horizon (that's a not to bad approximation):

$$d_{\text{straight}} = \sqrt{h^2 + 2Rh} \tag{16.1.49}$$

Therefore (and changing a bit the notations):

$$\boxed{\alpha \cong \frac{\Delta H}{d_{\text{straight}}} = \frac{R_{\earth} - \sqrt{R_{\earth}^2 - 2R_{\earth}h}}{\sqrt{h^2 + 2R_{\earth}h}}} \tag{16.1.50}$$

Hence for a person of approximately 1.81 [m] height we get for the vertical angle below the true horizon:

$$\alpha \cong \frac{\Delta H}{\sqrt{h^2 + 2R_{\earth}h}} \cong \frac{1.810000258}{4802.397659} = 0.00037689512 \text{ [rad]} \tag{16.1.51}$$

The average human eye (see [586]) has an angular resolution of about 1 arcminute (0.02 degrees or 0.0003 radians). Therefore to see the curvature of the Earth at the beach from the eye height of 1.81 [m].

Therefore the curvature at sea level is at the limit of the human eye angular resolution. Let us see a table for different values of h:

Altitude h	**Angle α in degrees**
1 [m]	0.0160
10 [m]	0.0507
100 [m]	0.160
$1,000$ [m]	0.507
$10,000$ [m]	1.605
$30,000$ [m]	2.783
100 [km]	5.09630
$1,000$ [km]	16.907
$3,000$ [km]	40.299

Table 16.4: **Vertical angle below horizon (degrees)**

The diffraction limit of the eye can be calculated using Rayleigh's criterion (see section Electromagnetisme page 4529):

$$\delta \cong \frac{1.22R\lambda}{D} \tag{16.1.52}$$

where lambda is the wavelength of light (on the average, about 550 [nm]) and D is the diameter of the eye's pupil, which is about 5 [mm] indoors. This calculation results in an angular resolution of 0.008 degrees (at least for eyes having a $20/20$ vision... and keep in mind that about 35% percent of all adults have a $20/20$ vision without glasses).

Remark

An object that is 1 [cm] wide at a distance of 100 [cm] is the same angular size as an object 10 [m] wide at a distance of $1,000$ [m], which is the same as the angular size of an object $10,000$ [m] wide at a distance of $1,000$ [km]. So the resolution limit of the eye in world space is a constant angle. In linear terms, the smallest resolvable pattern has a size that is directly proportional to distance.

In view of the agreement between the visual observations, measurements of the photographs, and the theoretical curvatures, it seems well established that the curvature of the Earth is reasonably well understood and can be measured from photographs. For more see [364].

16.1.2 Wind direction

We will now prove mathematically something quite intuitive: the winds are moving from high to low pressure (it's silly like that but we must still prove it!).

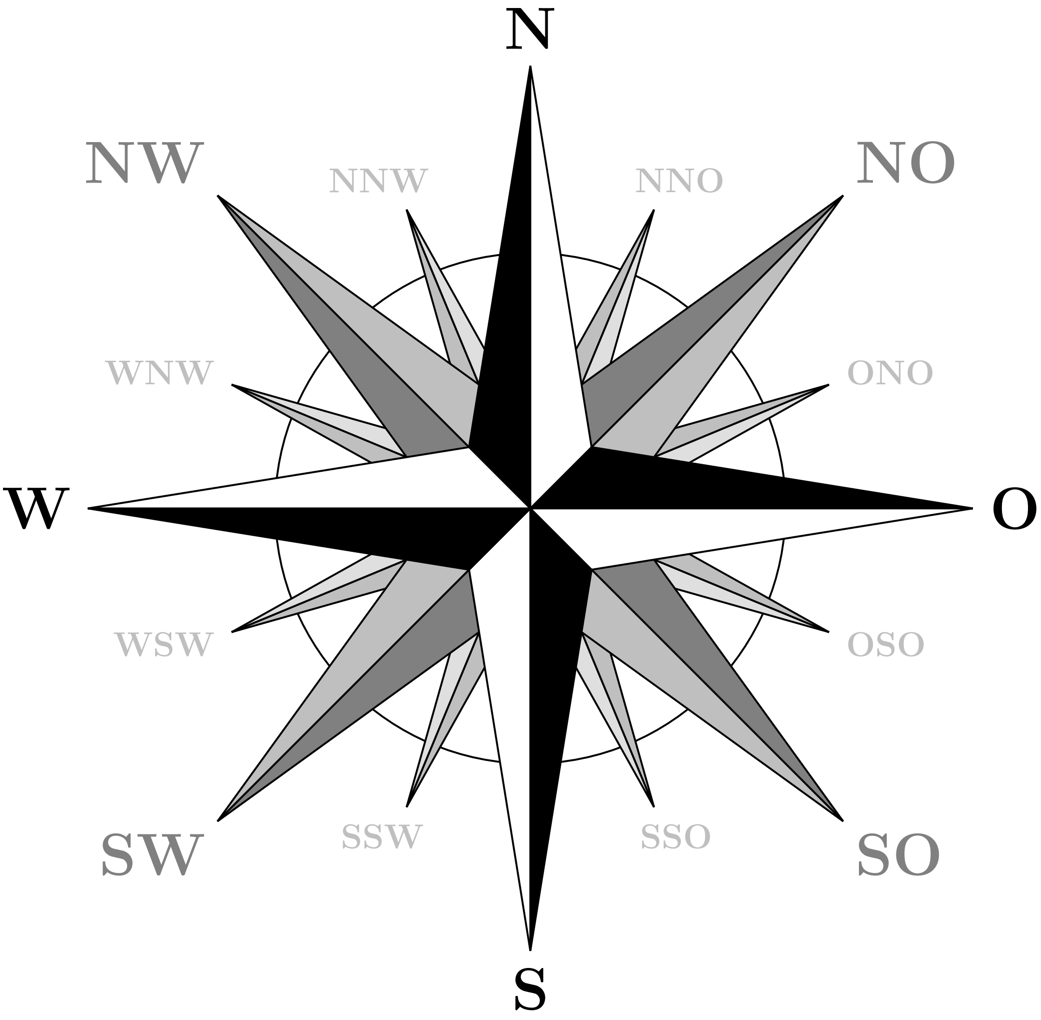


Figure 16.12: **A "compass rose", sometimes named a "wind rose", "rose of the winds" or "compass star"**

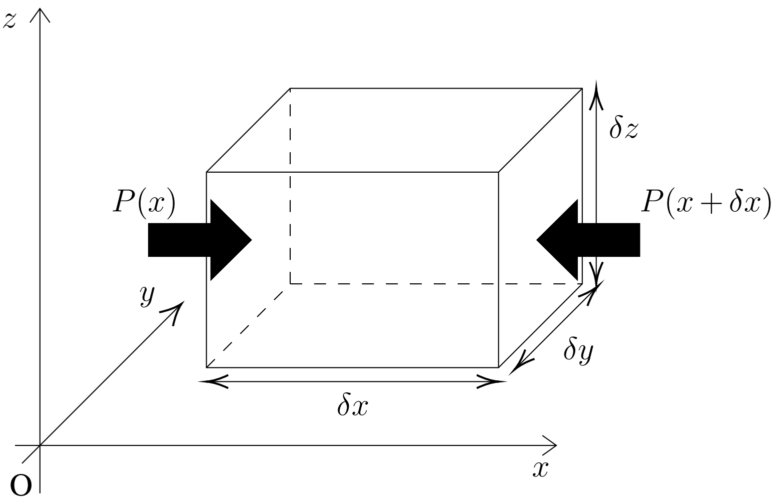
We know (see section Continuum Mechanics page 3735) that the pressure force exerted on a surface S is normal to this surface and is equal in scalar form to $P \cdot S$.

For an air parcel volume $\mathrm{d}V = \delta x \delta y \delta z$ the total pressure force in the x direction is then:

$$F_P = P(x)\delta y \delta z - P(x+\delta x)\delta y \delta z \tag{16.1.53}$$



In addition, we have (see section Differential and Integral Calculus page 1450):

$$\frac{P(x+\delta x)-P(x)}{\delta x}=\frac{\partial P}{\partial x} \tag{16.1.54}$$

Therefore:

$$F_P=P(x)\delta y\delta z-P(x+\delta y\delta z)=-\frac{\partial P}{\partial x}\delta x\delta y\delta z \tag{16.1.55}$$

The mass pressure force is then:

$$f_p=\frac{F_p}{m}=\frac{F_p}{\rho\delta x\delta y\delta z}=-\frac{1}{\rho}\frac{\partial P}{\partial x} \tag{16.1.56}$$

We can do the same calculation following y. Finally, the massic horizontal pressure force is given by:

$$\boxed{\vec{f}_p=-\frac{1}{\rho}\begin{pmatrix}\frac{\partial P}{\partial x}\\ \frac{\partial P}{\partial y}\end{pmatrix}=-\frac{1}{\rho}\vec{\nabla}P} \tag{16.1.57}$$

Thus, the pressure force (massic or not) is opposite to the horizontal gradient. The transmission of information (of the force) is done at the speed of sound for this equation (which explains the speed of air calls in your home or apartment and then force that can make slam doors or window).

It is therefore:

- Directed from high to low pressure, perpendicular to the isobars
- Inversely proportional to the spacing of the isobars.

If we measure the values of the atmospheric pressure at different points of the globe and we connect between them the points of same pressure on a drawing, we get a series of curves, named "isobars". The wind is directly determined by the atmospheric relief since it is a movement of air between the high to low pressure.

The wind speed is then determined by the pressure gradient: that is, if the atmospheric pressure changes rapidly with distance, the wind blows strong, while it will be low in abarometric "swamp" where this pressure remains almost unchanged on great distances. In summary, more the isobars are close together, more the wind will blow strong.

The isobars are traditionally marked with a pitch of 5 millibars on weather maps such as shown in the example below:

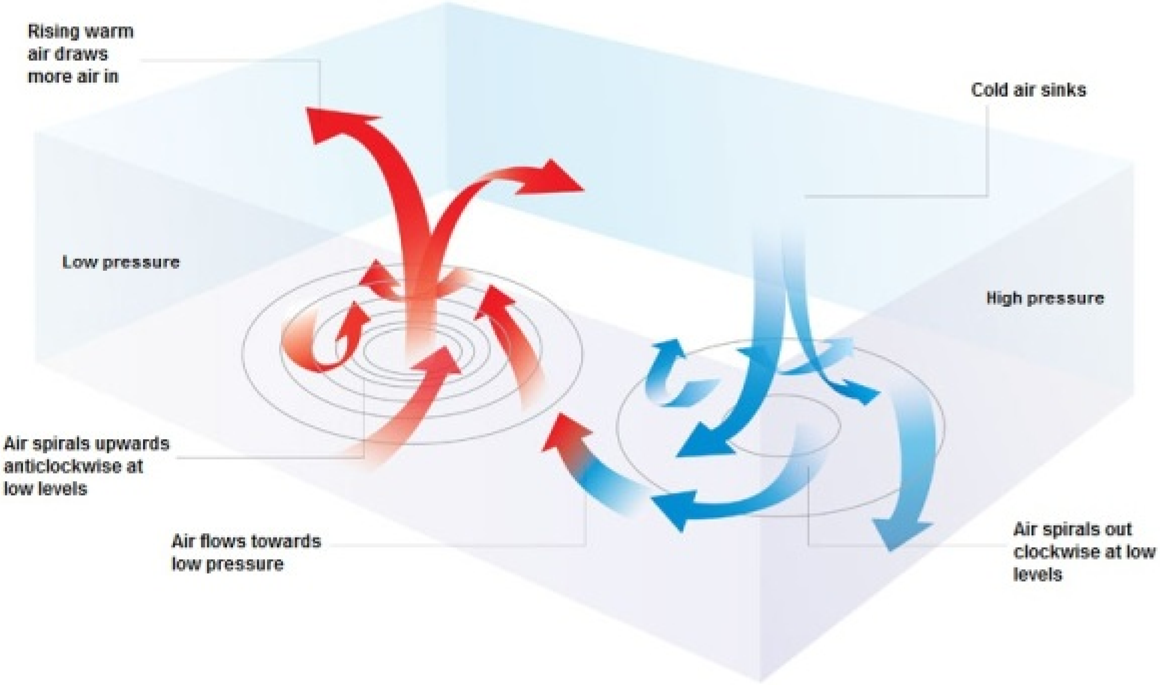
Figure 16.13: Typical representation of isobars (on a depression)

Charts showing isobars are useful because they identify features such as anticyclones (areas of high pressure) and depressions (areas of low pressure).

Areas of high and low pressure are caused by ascending and descending air. As air warms, it ascends leading to low pressure at the surface. As air cools, it descends leading to high pressure at the surface. This is illustrated in the diagram below.



Rising warm air draws more air in
Cold air sinks
Low pressure
High pressure
Air spirals upwards anticlockwise at low levels
Air flows towards low pressure
Air spirals out clockwise at low levels

Figure 16.14: High and low pressure systems

In general, low pressure leads to unsettled weather conditions and high pressure leads to settled weather conditions.

In an anticyclone (high pressure) the winds tend to be light and blow in a clockwise direction (in the northern hemisphere as we will prove it later below). Also the air is descending, which reduces the formation of cloud and leads to light winds and settled weather conditions.

In a depression (low pressure), air is rising and blows in an anticlockwise direction around the low (in the northern hemisphere). As it rises and cools, water vapour condenses to form clouds and perhaps precipitation. This is why the weather in a depression is often unsettled - there are usually frontal systems associated with depressions.

To close this topic about winds, let us notice that meteorologists empirically defined (that is fun for the general culture) a unit of wind measurement that is just a match between the wind force and the distance between two isobars in steps of 5 by 5 [mb]:

Distance between isobares [km]	**Unit** [Beaufort]	**Speed** $[\mathrm{m}\cdot\mathrm{s}^{-1}]$
600 (light breeze)	2	1.6-3.3
500 (average breeze)	4	3.4-5.4
400 (cold breeze)	5	8-10.7
300 (strong wind)	6	10.8-13.8
200 (big wind)	7	13.9-17.1
100 (storm)	9	20.8-24.4

Table 16.5: **Distance between isobars and wind speed (Beaufort units)**

16.1.3 Atmospheric Profile Models

An atmospheric profile model is a mathematical model constructed to predict the profile of temperature, pressure or other in the atmosphere, locally depending on the measured height supposing a steady state of the atmosphere (same as if we take out a cylinder piece of the atmosphere and freeze time to analyse some of the properties of the atmosphere inside depending on the height in the cylinder).

There a lot of models but let us see just two easy one:

16.1.3.1 Atmospheric Exponential Profile Model

Consider that the atmosphere is a perfect fluid in a uniform gravity field. Then from the following Bernoulli's theorem relation, proved in the section of Continuum Mechanics (static fluid at page 3783):

$$P=-\rho g z+c^{te} \tag{16.1.58}$$

It comes then:

$$\frac{\partial P}{\partial z}=-\rho g \tag{16.1.59}$$

Thus, to know the variation of pressure depending on height in the atmosphere or depth in the ocean, we have taken as hypothesis the "hydrostatic equilibrium", that is the variation of pressure with height / depth is proportional to the gravity and density of the fluid.

This is obviously not valid in the case of rapid movements of convection, like thunderstorms, but can easily be satisfied for slow movements (quasi-static) and at large scale: the "synoptic scale" ($2,000$-$20,000$ [km]).

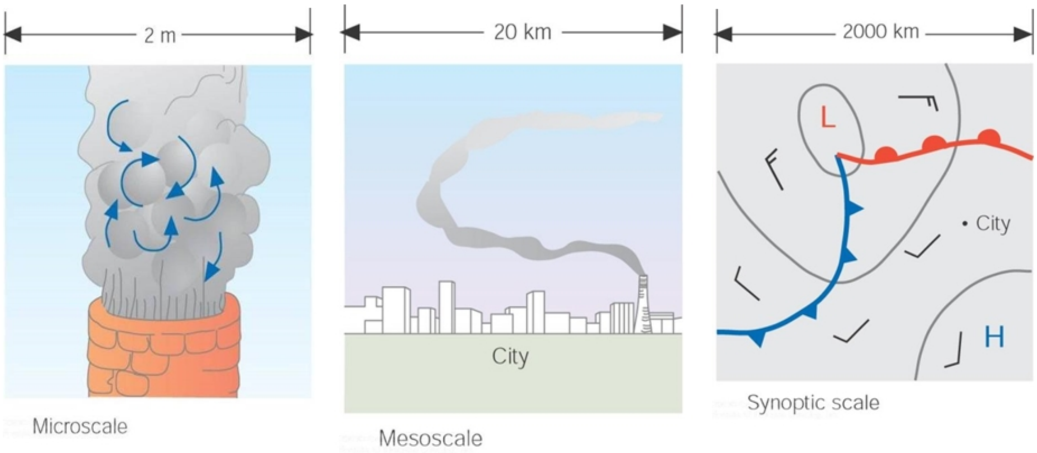


Figure 16.15: **Various meteorological scales**

We will then combine this last relation with a state equation, such as that of the ideal gas at temperature T and of density ρ whose constituent particles have a mass m. So we have the ideal gas equation (see section Continuum Mechanics page 3903):

$$PV = nRT \Rightarrow P = \frac{nRT}{V} = \frac{\rho kT}{m} \Rightarrow \rho = \frac{mP}{kT} \tag{16.1.60}$$

with for recall P that is the pressure expressed in Pascals, V the volume in cubic meters, R is the gas constant, T is the temperature in Kelvin, n the number of moles, k is the Boltzmann constant, ρ the particle density, m the total mass of the particles.

In the isothermal case (e.g. in the terrestrial stratosphere, above 10 [km] altitude where the temperature is almost constant around -55 degrees Celsius), we found out easily by substitution that:

$$\frac{\partial P}{\partial z} = -\rho g \Rightarrow \frac{\partial P}{\partial z} = -\frac{mP}{kT}g \tag{16.1.61}$$

Therefore, at a given pressure, the vertical pressure gradient is inversely proportional to temperature.

Let us now consider the following relation:

$$\frac{\mathrm{d}P}{P} = -\frac{m}{k}\frac{g}{T}\mathrm{d}z \Rightarrow \ln(P) = -\frac{mg}{kT}z + c^{te} \tag{16.1.62}$$

Using the exponential we the get "barometric height formula":

$$\boxed{P = c^{te}e^{-\frac{mg}{kT}z} = P_0 e^{-\frac{mg}{kT}z} = P_0 e^{-z/H}} \tag{16.1.63}$$

The pressure therefore decreases exponentially with the altitude. P_0 being the pressure at ground level and H is named the "scale height".

Remark

R1. Notice that in the isothermal case, where $T = c^{te}$, using the law of perfect gas $P = nkT$, we get after simplification:

$$n = n_0 e^{-\frac{mg}{kT}z} \tag{16.1.64}$$

R2. A "barometric altimeter" is an instrument that measures air pressure and displays the altitude (height) of an object. The conversion from pressure to height involves a nonlinear calibration using a relation derived from the result above, e.g.:

$$z = -\frac{kT}{mg}\ln\left(\frac{P}{P_0}\right) \tag{16.1.65}$$

However, outdoor readings of height (altitude) from a pressure based altimeter can vary by tens of metres owing to a sudden change in air pressure, such as from a cold front or other meteorological minor event.

Let us return to the relation:

$$\frac{\partial P}{\partial z} = -\frac{mP}{kT}g \tag{16.1.66}$$

It can of course also be written as:

$$\frac{\partial z}{\partial P} = -\frac{k}{mPg}T \tag{16.1.67}$$

which tells us that the distance z between isobaric surfaces is directly proportional to temperature.

We have also another common approach. Let us start again from the relation proved just earlier above, but for a mass m of 1 [kg]:

$$\frac{\mathrm{d}P}{\mathrm{d}z} = -\frac{g}{kT}P \tag{16.1.68}$$

and let us denote this relation as follow:

$$\frac{\mathrm{d}_z P(z)}{P(z)} = -\frac{g}{kT(z)} \tag{16.1.69}$$

Let us recall that (see section Differential and Integral Calculus page 1475):

$$\mathrm{d}_x \ln(f(x)) = \frac{1}{f(x)}\mathrm{d}_x f(x) \tag{16.1.70}$$

Therefore:

$$\mathrm{d}_z \ln(P(z)) = -\frac{g}{kT(z)} \tag{16.1.71}$$

and now let assume that the temperature variation is linear in the atmosphere (which is not far from the truth for the first 10 to 20 km of the atmosphere such that:

$$T(z) \cong T_0 + \lambda z \tag{16.1.72}$$

with $\lambda < 0$ which is the temperature gradient in $[\mathrm{K} \cdot \mathrm{m}^{-1}]$.

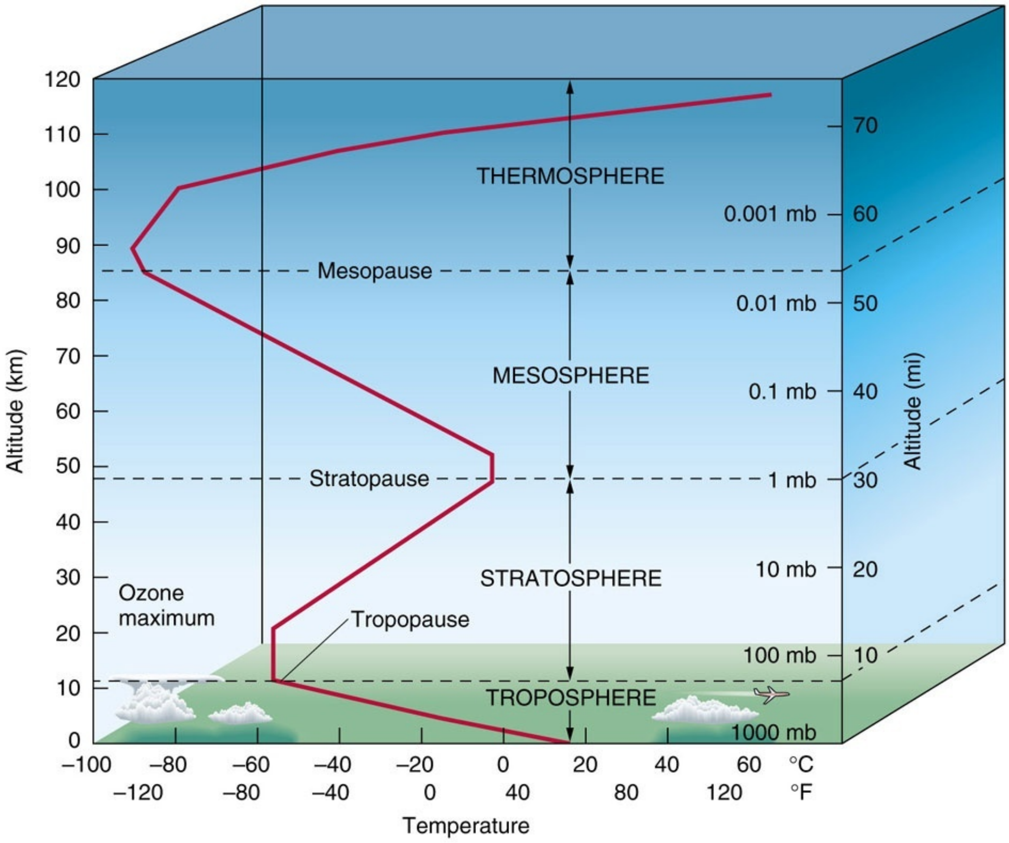

Figure 16.16: **Typical profile of temperature and pressure on Earth... late 120th century (source: ?)**

Then we have:

$$\mathrm{d}_z \ln(P(z)) = -\frac{g}{k(T_0+\lambda z)} = \frac{-g/k}{T_0+\lambda z} \tag{16.1.73}$$

Therefore:

$$\int_{z_0}^{z_1} \mathrm{d}\ln(P(z)) = \int_{z_0}^{z_1} \frac{-g/k}{T_0+\lambda z}\mathrm{d}z \tag{16.1.74}$$

Which gives:

$$\ln(P(z_1)) - \ln(P(z_0)) = -\frac{g}{k\lambda}\ln(T_0+\lambda z)\Big|_{z_0}^{z_1} \tag{16.1.75}$$

After simplification:

$$\ln\left(\frac{P(z_1)}{P(z_0)}\right) = -\frac{g}{k\lambda}\ln\left(\frac{T_0+\lambda z_1}{T_0+\lambda_z 0}\right) \tag{16.1.76}$$

Hence:

$$P(z_1) = P(z_0)\left(\frac{T_0+\lambda z_1}{T_0+\lambda_z 0}\right)^{-\frac{g}{k\lambda}} \tag{16.1.77}$$

Which can be written more aesthetically:

$$\boxed{P(z)=P_0\left(\frac{T_0+\lambda z}{T_0+\lambda_z 0}\right)^{-\frac{g}{k\lambda}}} \tag{16.1.78}$$

A good practical example of application of this relation is the gliders and hang gliders. They expect the weather forecast that it communicates to them the height of the isotherm of zero degrees during its bulletins. They then deduce the temperature gradient per meter. For these athletes, good condition is to have a gradient of 1 [°C] by 100 meters. It is therefore easy with the above relation to calculate the pressure at an altitude of $2,000$ meters and to derive the pressure gradient which allows them to use some the updrafts for their aerobatic practices.

16.1.3.2 Adiabatic Atmosphere Model

The adiabatic temperature gradient is, in the atmosphere, the air temperature change with altitude (i.e. the air temperature gradient), which only depends on the atmospheric pressure, that is to say:

- Without considering heat exchange with the environment (other air masses, relief, ground, etc.)
- Without considering condensation (cloud formation) or precipitation.
- Without taking into account the Sun (actually a G2V-type star, aka yellow dwarf) position and variations

This concept is of great importance in meteorology, as well as aviation and maritime navigation.

We have proved in the section of Thermodynamics (see page 3646) the Laplace's thermodynamics law (satisfied under certain conditions!):

$$PV^\gamma=c^{te} \tag{16.1.79}$$

with the Laplace coefficient:

$$\gamma=\frac{C_P}{C_V} \tag{16.1.80}$$

Therefore in massic form the Laplace's law becomes:

$$\gamma=\frac{C_P}{\rho^\gamma}=c^{te} \tag{16.1.81}$$

We can take the logarithm:

$$\ln\left(\frac{P}{\rho^\gamma}\right)=\ln(c^{te})\Rightarrow\ln(P)-\gamma\ln(\rho)=c^{te}\Rightarrow\ln(P)=\gamma\ln(\rho)+c^{te} \tag{16.1.82}$$

But by taking the logarithmic differential:

$$\begin{aligned}&\frac{\mathrm{d}(\ln(P))}{\mathrm{d}P}=\frac{1}{P}\Rightarrow\mathrm{d}(\ln(P))=\frac{\mathrm{d}P}{P}\\&\frac{\mathrm{d}(\gamma\ln(\rho))}{\mathrm{d}\rho}=\gamma\frac{1}{\rho}\Rightarrow\mathrm{d}(\gamma\ln(\rho))=\gamma\frac{\mathrm{d}\rho}{\rho}\\&\mathrm{d}(c^{te})=0\end{aligned}\tag{16.1.83}$$

We then have (relationship that we will reuse in the section of Music Mathematics)

$$\frac{\mathrm{d}P}{P}=\gamma\frac{\mathrm{d}\rho}{\rho}\tag{16.1.84}$$

We could also have found this result directly from the relation proved in the section Thermodynamics:

$$\gamma\frac{\mathrm{d}V}{V}+\frac{\mathrm{d}P}{P}=0\Rightarrow\frac{\mathrm{d}P}{P}=-\gamma\frac{\mathrm{d}V}{V}=-\gamma\frac{\mathrm{d}\left(\dfrac{m}{\rho}\right)}{\dfrac{m}{\rho}}=-\rho\gamma\mathrm{d}\left(\frac{1}{\rho}\right)=\gamma\frac{\mathrm{d}\rho}{\rho}\tag{16.1.85}$$

By taking also the logarithmic differential of the ideal gas law where n is, for recall, the number of moles (see section Continuum Mechanics page 3903):

$$PV=nRT\tag{16.1.86}$$

But in the massic form for one mole:

$$\rho=\frac{M_mP}{RT}\tag{16.1.87}$$

where M_m is the molar mass (see section Analytical Chemistry page 6252), we have:

$$\ln(\rho)=\ln\left(\frac{M_mP}{RT}\right)=\ln(M_mP)-\ln(RT)\tag{16.1.88}$$

Therefore:

$$\frac{\mathrm{d}\rho}{\rho}=\frac{\mathrm{d}P}{P}-\frac{\mathrm{d}T}{T}\tag{16.1.89}$$

We then get:

$$\frac{1}{\gamma}\frac{\mathrm{d}P}{P}=\frac{\mathrm{d}P}{P}-\frac{\mathrm{d}T}{T}\Rightarrow\frac{\mathrm{d}T}{T}=\frac{\mathrm{d}P}{P}-\frac{1}{\gamma}\frac{\mathrm{d}P}{P}\Rightarrow\frac{\mathrm{d}T}{T}=\frac{\gamma-1}{\gamma}\frac{\mathrm{d}P}{P}\tag{16.1.90}$$

Therefore:

$$\frac{\mathrm{d}P}{P}=\frac{\gamma}{\gamma-1}\frac{\mathrm{d}T}{\mathrm{T}}\tag{16.1.91}$$

Let us use the relation proved earlier shown above:

$$\frac{\mathrm{d}P}{\mathrm{d}z}=-\frac{mg}{kT}P\Rightarrow\frac{\mathrm{d}P}{P}=-\frac{mg}{kT}\mathrm{d}z\tag{16.1.92}$$

It comes then:

$$\mathrm{d}T = \frac{1-\gamma}{\gamma}\frac{mg}{k}\mathrm{d}z \tag{16.1.93}$$

So we have an atmosphere with constant and negative thermal gradient (temperature decreases linearly with altitude):

$$\boxed{\kappa = \frac{1-\gamma}{\gamma}\frac{mg}{k} = \frac{1-\gamma}{\gamma}\frac{M_m g}{R}} \tag{16.1.94}$$

The last form using the molar mass is more convenient because it allows to characterize the studied medium. Note that this is a model that looks to work well for an altitude of 0 to 90 [km] on Venus but much less well for the planet Earth.

✍**Example:**

We then have for example for Earth (thus knowing that the model is not well adapted):

$$g \cong 9.81\,[\mathrm{m}\cdot\mathrm{s}^{-2}] \qquad R \cong 8.314\,[\mathrm{J}\cdot\mathrm{K}^{-1}\cdot\mathrm{mol}^{-1}]$$

and the adiabatic coefficient for air is equal to $\gamma = 1.4$, and its molecular weight:

$$M_{m,\text{air}} \cong 28.96\cdot 10^{-3}\,[\mathrm{kg}\cdot\mathrm{mol}^{-1}]$$

Therefore:

$$\kappa = -0.00976\,[\mathrm{K}\cdot\mathrm{m}^{-1}] \cong -1\,[\mathrm{K}\cdot\mathrm{hm}^{-1}]$$

which corresponds to the current idea: 1 degree per 100 meters.

16.1.3.2.1 Hypsometric equation

The hypsometric equation, also known as the thickness equation, relates an atmospheric pressure ratio to the equivalent thickness of an atmospheric layer under the assumptions of constant temperature and gravity. It is derived from the hydrostatic equation and the ideal gas law.

So we have just proved for to hydrostatic equilibrium:

$$\frac{\partial P}{\partial z}=-\frac{mP}{kT}g \tag{16.1.95}$$

We can integrate this relationship if we know T as a function of P or z. The direct measurement of P in practice is easier (single altimeters are actually barometers if they don't use GPS).

We can then separate the variables:

$$kT\frac{\mathrm{d}P}{P}=-mg\mathrm{d}z \tag{16.1.96}$$

By integrating between two levels a and b:

$$k\int\limits_a^b T\mathrm{d}(\ln(P))=\int\limits_a^b mg\mathrm{d}z \tag{16.1.97}$$

Since:

$$\frac{\mathrm{d}(\ln(P))}{\mathrm{d}P}=\frac{1}{P}\Rightarrow \mathrm{d}(\ln(P))=\frac{\mathrm{d}P}{P} \tag{16.1.98}$$

Then to continue we use a trick. We will define the average temperature by the relation:

$$\langle T\rangle=\frac{\int_a^b T\mathrm{d}(\ln(P))}{\int \mathrm{d}(\ln(P))} \tag{16.1.99}$$

Which then allows us to write:

$$k\int\limits_a^b T\mathrm{d}(\ln(P))=k\int\limits_a^b T\mathrm{d}(\ln(P))\frac{\int_a^b \mathrm{d}(\ln(P))}{\int_a^b \mathrm{d}(\ln(P))}=k\langle T\rangle\int\limits_a^b \mathrm{d}(\ln(P))=-\int\limits_a^b mg\mathrm{d}z \tag{16.1.100}$$

Therefore:

$$mg(z_a-z_b)=k\langle T\rangle\ln\left(\frac{P_b}{P_a}\right) \tag{16.1.101}$$

or written differently:

$$\boxed{z_a-z_b=\frac{k}{mg}\langle T\rangle\ln\left(\frac{P_b}{P_a}\right)} \tag{16.1.102}$$

or after rearrangement and change the notation for the average temperature:

$$\boxed{\frac{P_b}{P_a}=e^{\frac{mg(z_a-z_b)}{k\bar{T}}}} \tag{16.1.103}$$

Both boxed relations are each respectively named "hypsometric equation" (from the Greek "hypso" for "height").

16.1.4 Earth's equilibrium temperature

The "planetary equilibrium temperature" is as we already know (see section Astronomy page 5335) a theoretical temperature that a planet would be at when considered simply as if it were a black-body being heated only by its parent star. In this model, the presence or absence of an atmosphere (and therefore any greenhouse effect) is not considered, and one treats the theoretical black-body temperature as if it came from an idealized surface of the planet.

Other authors use different names for this concept, such as "equivalent black-body temperature of a planet", or the "effective radiation emission temperature of the planet".

If the incident solar radiation ("insolation") - or incident power radiation - on the planet at its orbital distance from the Sun is $\Phi_\odot$, the amount of energy absorbed by the planet ($\mathrm{d}\Phi/\mathrm{d}S$) will depend on its reflection coefficient (albedo ρ) and its cross-sectional area S or average radius R as:

$$P_{\text{in}}=\Phi_\odot(1-\rho)S=\Phi_\odot(1-\rho)\pi R^2 \tag{16.1.104}$$

Note that the albedo would be zero for a black-body as we have seen it in the section of Optical Geometry (see page 4351). However, in planetology, more useful results are obtained by accounting for a measured or assumed planetary albedo $\rho>0$.

The infrared power radiated by the planet as thermal radiation will depend on its emissivity and its surface area, according to the Stefan–Boltzmann equation proved in the section of Thermodynamics (see page 3706):

$$M(T)=\sigma T^4 \tag{16.1.105}$$

and as it is a power by unit surface we will multiply it by the above surface area of the planet such that:

$$P(T)=\sigma S T^4 \tag{16.1.106}$$

For a spherical planet, the surface of a perfect spherical area is well known (see section Geometric Shapes page 2966)! Therefore:

$$P(T)=\sigma 4\pi R^2 T^4 \tag{16.1.107}$$

But a planet that does not absorb all incident radiation (sometimes known as a grey body) emits less total energy than a black-body and is characterized by an emissivity, $\varepsilon<1$, therefore (by definition emissivity $+$ albedo $=1$):

$$P_{\text{out}}=\varepsilon\sigma 4\pi R^2 T^4=\varepsilon\sigma 4\pi R^2 T^4 \tag{16.1.108}$$

The equilibrium temperature is then calculated by setting $P_{\text{in}}=P_{\text{out}}$. Thus:

$$\varepsilon\sigma 4\pi R^2 T^4=\Phi_\odot(1-\rho)\pi R^2 \tag{16.1.109}$$

Therefore:

$$\boxed{T_{\text{eq}}=\left(\frac{\Phi_\odot(1-\rho)}{4\sigma\varepsilon}\right)^{1/4}} \tag{16.1.110}$$

It is interesting to note that the equilibrium temperature does not depend on the size of the planet, because both the incoming radiation and outgoing radiation depend on the area of the planet!

Earth's overall average albedo is about $\rho \cong 0.31$ and the emissivity of Earth is considered as being about $\varepsilon \cong 0.96$ and the solar constant is equal to $\Phi_\odot \cong 1,376$ [W·m^{-2}] as derived earlier above (see page 5568).

A numerical application for Earth gives $T_{\text{eq}} = 256.55$ [K] (that is $-16.2\,[°\text{C}]$).

Based on this calculation, Earth's expected average global temperature is well below the freezing point of water!

The reader can refer to the section of Cosmology where have proven at page 5568 that the energy received by the Sun on Earth's ground is in average $\bar{\Phi} = 318\,[\text{W}\cdot\text{m}^{-2}]$.

Earth's actual average global temperature is around 14 [°C]. Our planet is warmer than predicted with a pretty big difference!

Why is Earth's temperature so much warmer than what our calculations predict? The answer is because certain gases in the atmosphere trap some extra heat, warming our planet like a blanket. This extra warming is named the "greenhouse effect" (see further below). Without it, our planet would be a frozen ball of ice. Thanks to the natural greenhouse effect, Earth is comfortable place for life as we know it. However, too much of a good thing can cause problems. In recent decades, a rise in the amount of greenhouse gases has begun to warm Earth a bit too much.

Remark

For extrasolar planets the temperature of the star can be calculated from the color of the star using Planck's law (see section Thermodynamics page 3719). The calculated temperature of the star can be used with the Hertzsprung–Russell diagram (see section Astrophysics page 5540) to determine the absolute magnitude of the star, which can then be used with observational data to determine the distance to the star and finally the size of the star. Orbital simulations are used to determine what orbital parameters (including orbital distance) produce the observations seen by astronomers. Astronomers use a hypothesized albedo and can then estimate the equilibrium temperature.

A quite common question is how much heating does Earth inner core provide to the surface?

The Earth's surface emits experimentally about $503\,[\text{W}\cdot\text{m}^{-2}]$ ($398.2\,[\text{W}\cdot\text{m}^{-2}]$ as infrared radiation, $86.4\,[\text{W}\cdot\text{m}^{-2}]$ as latent heat, and $18.4\,[\text{W}\cdot\text{m}^{-2}]$ via conduction/convection), or about $260,000$ [TW] over all of the Earth's surface (see [543]). The ultimate source of almost all of this energy is the Sun.

Estimates vary on how much heat crosses the core/mantle boundary, from 4 [TW] to 17 [TW]. Even the larger value is much, much smaller than the heat emitted by the Earth's surface.

Estimates of the total heat flow from the interior of the Earth (core, mantle, crust) are much tighter, $46 \pm 3\,[\text{TW}]$ (see [287]) (cf $47 \pm 2[\text{TW}]$ as given in [128]). This is considerably more than the heat coming from the core, but it's still small compared to the Earth's total heat budget:

$$\frac{\text{Heat from interior of Earth}}{\text{Total}}=\frac{46\,[\text{TW}]}{260,000\,[\text{TW}]}=0.02\% \tag{16.1.111}$$

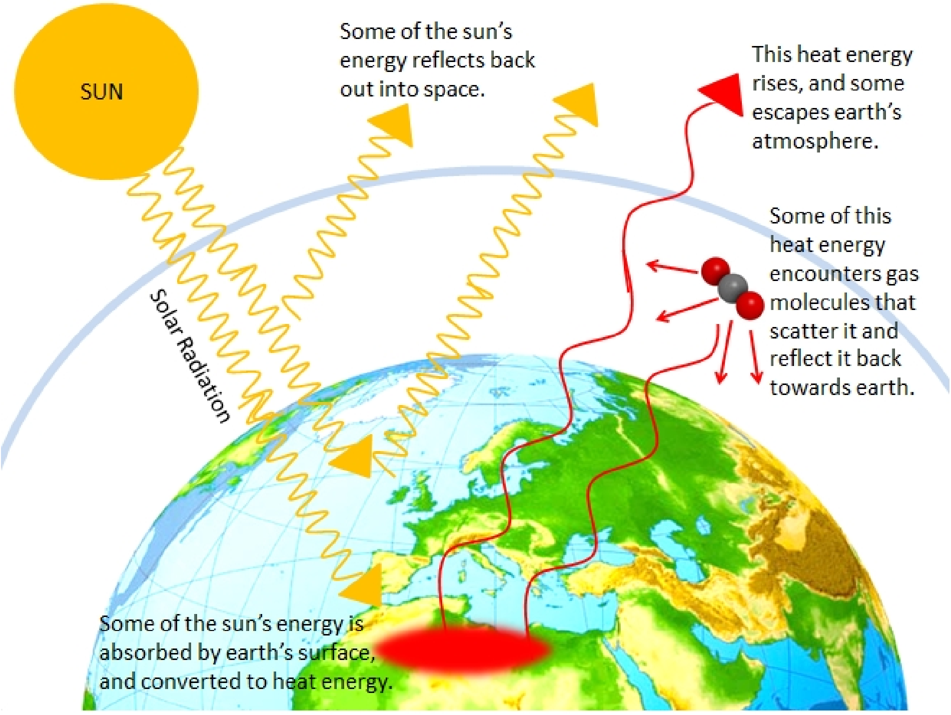
By the way Wikipedia gives an inner/solar ratio of 0.03%.

16.1.4.1 Greenhouse effect

The greenhouse effect is the process by which radiation from a planet's atmosphere warms the planet's surface to a temperature above what it would be without its atmosphere.

If a planet's atmosphere contains radiately active gases (i.e., greenhouse gases) the atmosphere will radiate energy in all directions. Part of this radiation is directed towards the surface, warming it. The downward component of this radiation – that is, the strength of the greenhouse effect – will depend on the atmosphere's temperature and on the amount of greenhouse gases that the atmosphere contains.

Earth's natural greenhouse effect is critical to supporting life. Human activities, primarily the burning of fossil fuels and clearing of forests, have intensified the natural greenhouse effect, causing global warming.



SUN
Some of the sun's energy reflects back out into space.
This heat energy rises, and some escapes earth's atmosphere.
Some of this heat energy encounters gas molecules that scatter it and reflect it back towards earth.
Solar Radiation
Some of the sun's energy is absorbed by earth's surface, and converted to heat energy.

Figure 16.17: **Greenhouse effect concept**

For a mathematical analysis of the greenhouse effect we must improve our above model. Consider for this that we denote T_S the temperature of surface of the Earth (or any other planet) and T_A the temperature of its atmosphere. The thermodynamic equilibrium of atmosphere gives us in the point of view of the radiation using again the Boltzmann law and considering that Earth's atmosphere radiates 50% back in space and reflects back 50% back to Earth surface (last measurements in the early 121st century - holocene calendar - gives 40% reflected back!):

$$\varepsilon\sigma T_S^4 = 2\varepsilon\sigma T_A^4 \tag{16.1.112}$$

Therefore it is immediate that:

$$T_A = \frac{T_S}{2^{1/4}} \tag{16.1.113}$$

Remember now the equilibrium proved earlier:

$$\varepsilon\sigma 4\pi R^2 T^4 = \Psi \odot (1-\rho)\pi R^2 \tag{16.1.114}$$

That simplifies to:

$$\varepsilon\sigma 4 T^4 = \Phi_\odot (1-\rho) \tag{16.1.115}$$

Using our new notation:

$$\varepsilon_S \sigma 4 T_S^4 = \Phi_\odot (1-\rho) \tag{16.1.116}$$

Therefore after rearranging:

$$\varepsilon_S \sigma T_S^4 = \frac{\Phi_\odot}{4}(1-\rho) \tag{16.1.117}$$

Now we add to this the back-radiation coefficient ε_A due to atmosphere:

$$\varepsilon_S \sigma T_S^4 = \frac{\Phi_\odot}{4}(1-\rho) + \varepsilon_A \sigma T_A^4 \tag{16.1.118}$$

That is:

$$\varepsilon_S \sigma T_S^4 = \frac{\Phi_\odot}{4}(1-\rho) + \varepsilon_A \sigma \left(\frac{T_S}{2^{1/4}}\right)^4 = \frac{\Phi_\odot}{4}(1-\rho) + \frac{\varepsilon_A}{2}\sigma T_S^4 \tag{16.1.119}$$

Therefore after rearrangement:

$$\boxed{T_S = \left(\frac{1}{\sigma}\frac{\Phi_\odot(1-\rho)}{4}\frac{1}{\varepsilon_S - \dfrac{\varepsilon_A}{2}}\right)^{1/4}} \tag{16.1.120}$$

A numerical application gives $T_S \cong 297$ [K] that is 14 [°C]. This is quite more accurate than the previous model!

16.1.4.2 Milankovitch cycles

The Milankovitch cycles are periodic or quasiperiodic changes in the parameters of the Earth's orbit and tilt, which in turn affect the climate. The three major types of Milankovitch cycle are:

- changes in the eccentricity of the Earth's orbit
- changes in the obliquity, or tilt of the Earth's axis
- precession, meaning changes in the direction of the Earth's axis relative to the fixed stars

These changes do not affect the overall annual amount of solar radiation hitting the Earth, but they affect the strength of the seasons in different ways at different latitudes. It is widely believed that they are partially responsible for the glacial cycles. However, the details of how this occurs are complex and poorly understood.

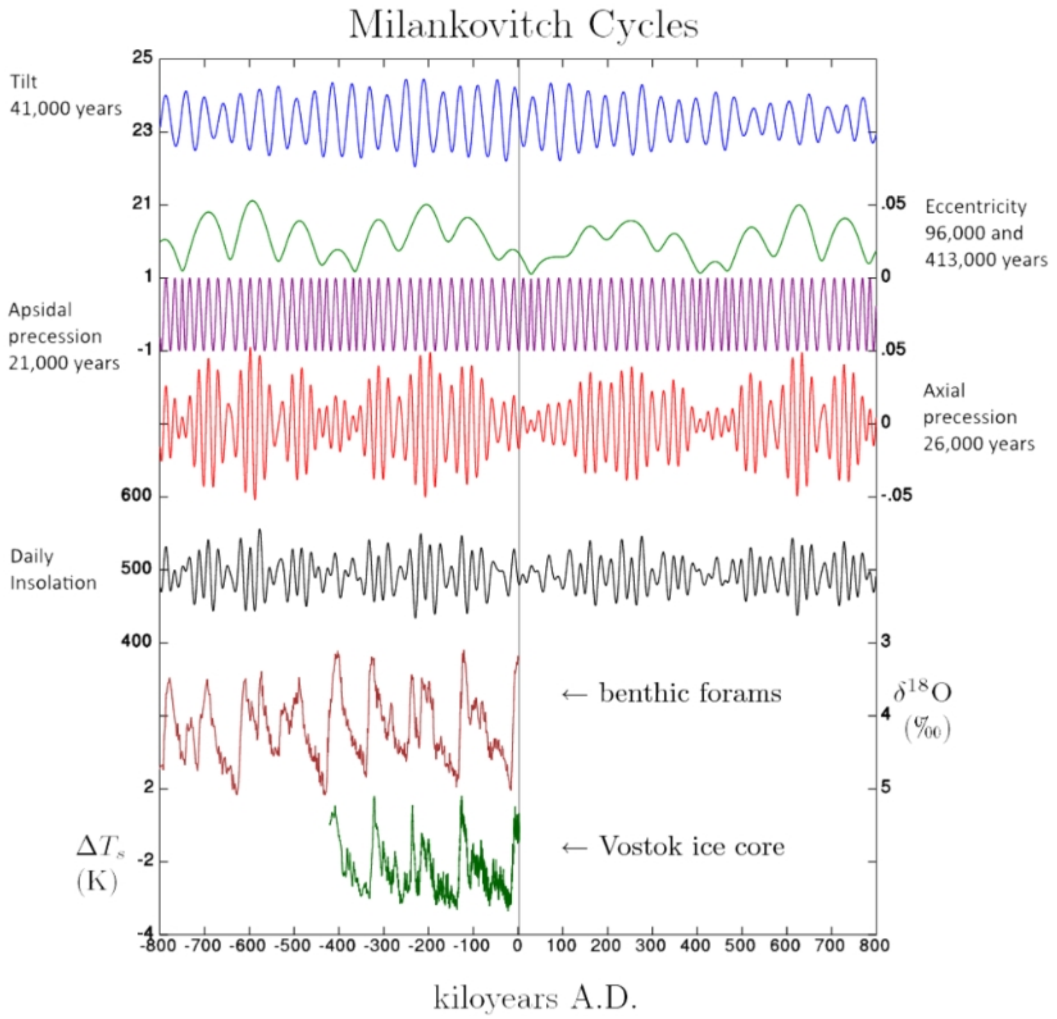


Figure 16.18: Past and future Milankovitch cycles (source: Wikipedia)

Remark

By the mid-seventies the Earth's orbital parameters were known over the last million years to a good accuracy thanks geological records. A decisive step was made by André Berger (11978 according to holocene calendar), who expressed in an analytical form the Fourier decomposition of the Earth's orbital parameters relevant for the astronomical theory of palaeoclimates. This work constitutes the first demonstration that the spectrum of climatic precession is dominated by periods of $19,000$, $22,000$ and $24,000$ years, that of obliquity, by a period $41,000$ years, and eccentricity has periods of $400,000$ years, $125,000$ years and $96,000$ years.

For information, the rotation of Earth's on itself slows down at the day we write these lines of approximately 2.3 milliseconds per century. That means 1 hour every 180 millions years. Each year the Earth's orbit speed around the Sun (actually a G2V-type star, aka yellow dwarf) also slows down of approximately 3 nanometers-per-second. Using Kepler's law, that means that the Earth goes further away from the Sun of 3 micrometers per 1 billion year......!!!!

16.1.5 Temperature variation range models

We will see here two very naive models, but still quite accurate, to compute with a good accuracy the temperature range that can be observed during days in average and identically for seasons in average around the World!

16.1.5.1 Diurnal temperature range (DTR)

In meteorology, "diurnal temperature variation" is the variation between a high air temperature and a low temperature that occurs during the same day.

We have derived earlier above (see page 5568) the Solar constant given as:

$$\begin{aligned}\Phi_{\odot}&=\frac{P_{\odot}}{4\pi d^2}=\frac{S_{\odot}M_{\odot}(T)}{4\pi d^2}=\frac{M_{\odot}(T)R_{\odot}}{d^2}=\frac{\sigma T^4R_{\odot}}{d^2}=\frac{\frac{2\pi^5k^4}{15c^2h^3}T^4R_{\odot}}{d^2}\\&=\frac{\frac{2\pi^5k^4}{15c^2h^3}\left(\frac{2{,}897.8\cdot 10^{-9}}{\lambda_{\max}}\right)^4R_{\odot}}{d^2}\cong 1,382\;[\mathrm{W}\cdot\mathrm{m}^{-2}]\end{aligned}\tag{16.1.121}$$

Based on calorimetry (see section Thermodynamics page 3622) we know the famous relation:

$$Q=mC_s\Delta T\Rightarrow\Delta T=\frac{Q}{mC_s}\tag{16.1.122}$$

where Q is the required energy (in Joules), m is the mass (in kilograms), C_s is the heat capacity of the substance and ΔT is the change in temperature (in Kelvin).

If we take an average atmospheric pressure of at ground level $1\cdot 10^5$ [P], it is equivalent by definition to a force of $1\cdot 10^5\;[\mathrm{N}\cdot\mathrm{m}^{-2}]$. We multiply by the area of the planet in square meters, we get the total weight of the atmosphere:

$$(1\cdot 10^5)\cdot(5.1\cdot 10^{14})=5.1\cdot 10^{19}\;[\mathrm{N}]\tag{16.1.123}$$

Hence the total approximated mass of the entire atmosphere is estimated to be $5.2\cdot 10^{18}$ [kg] (atmosphere of Earth) and the mean heat capacity of air is $700\;[\mathrm{J}\cdot\mathrm{kg}\cdot\mathrm{K}^{-1}]$ at normal temperature and pressure (heat capacity).

We divide by the average acceleration of gravity to convert this weight to a mass:

$$\frac{5.1\cdot 10^{19}}{9.8}=5.2\cdot 10^{18}\;[\mathrm{kg}]\tag{16.1.124}$$

Let us assume the simple ideal very naive and special case where only half of Earth is illuminated by the Sun and assuming that the whole surface is perpendicular to the Sun radiation at that the Sun appears instantaneously from below the horizon to the noon and stays there during twelve hours and that the air is static (no air circulation).

The mass to take into account for the half of the Earth is given by approximately $2.57\cdot 10^{18}$ [kg].

Therefore:

$$\Delta T=\frac{Q}{mC_s}=\frac{1,382\cdot {}^1\!/\!_2 4\pi R^2\cdot(12\cdot 60\cdot 60)}{(2.57\cdot 10^{18})\cdot 700}\cong 8.46\cdot 10^{-9}\;[\mathrm{K}]\tag{16.1.125}$$

So hummm... That's not bad!

Let's see if we can do better because the pressure assumption is maybe to relaxed. Giving gravitometry measurements the average high of Earth relatively of ground level is 800 meters. So what is the pressure at this height? Using the hypsometric relation derived earlier above (see page 8271) and taking the average temperature measured as being 298 [K]:

$$\bar{P}_{\text{atm.}}=P_0e^{\frac{-gM(h-h_0)}{RT}}\cong 90,951\,[\text{Pa}] \tag{16.1.126}$$

We then have using this new value of pressure:

$$\Delta T=\frac{Q}{mC_s}\cong 9.19\,[\text{K}] \tag{16.1.127}$$

So that's more realistic!

Maybe in the future we will develop a more realistic model but that one gives already at ΔT that is satisfying in comparison of our actual observations.

So the final model is written:

$$\Delta T=\frac{Q}{mC_s}=\frac{\Phi\cdot {}^1\!/\!{}_2S_{\text{♁}}\cdot(12\cdot 60\cdot 60)}{\dfrac{\bar{P}_{\text{atm.}}\cdot S_{\text{♁}}}{g}C_s}=\frac{g\cdot\Phi\cdot(12\cdot 60\cdot 60)}{2\bar{P}_{\text{atm.}}C_s} \tag{16.1.128}$$

Or fully explicitly:

$$\boxed{\Delta T_{\text{diurnal}}=\frac{g\cdot\dfrac{\frac{2\pi^5k^4}{15c^2h^3}\left(\frac{2{,}897.8\cdot 10^{-9}}{\lambda_{\text{max}}}\right)^4R_{\odot}}{d^2}\cdot(12\cdot 60\cdot 60)}{2P_0e^{\frac{-gM(h-h_0)}{RT}}C_s}} \tag{16.1.129}$$

As solar energy strikes the Earth's surface each morning, a shallow 1 to 3 centimetre layer of air directly above the ground is heated by conduction. Heat exchange between this shallow layer of warm air and the cooler air above is very inefficient. On a warm summer's day, for example, air temperatures may vary by 16.5 [°C] from just above the ground to chest height. Incoming solar radiation exceeds outgoing heat energy for many hours after noon and equilibrium is usually reached from 3–5 p.m., but this may be affected by a variety of factors such as large bodies of water, soil type and cover, wind, cloud cover/water vapor, and moisture on the ground.

High desert regions typically have the greatest diurnal-temperature variations, while low-lying humid areas near the shores (tropical, oceanic, and arctic) typically have the least. This explains why an area like the Pinnacles National Park can have high temperatures of 38 [°C] during a summer day, and then have lows of 5–10 [°C]. At the same time, Washington D.C., which is much more humid, has temperature variations of only 8 [°C] urban Hong Kong has a diurnal temperature range of little more than 4 [°C].

While the National Park Service claimed that the world single-day record is a variation of 56.7 [°C] (from 7.8 [°C] to -48.9 [°C]) in Browning, Montana in 11916 (holocene calendar), the Montana Department of Environmental Quality claimed that Loma, Montana also had a variation of (56.7 [°C]) (from -47.8 [°C] to 8.9 [°C]) in 11972 (holocene calendar). Both these extreme daily temperature changes were the result of sharp air-mass changes within a single day. The 11916 (holocene calendar) event was an extreme temperature drop, resulting from frigid Arctic air from Canada invading northern Montana, displacing a much warmer air mass. The 11972 (holocene calendar) event was a chinook event, where air from the Pacific Ocean overtopped mountain ranges to the west, and dramatically warmed in its descent into Montana, displacing frigid Arctic air and causing a drastic temperature rise.

In Europe, due to its more northern latitude and close proximity to large warm water bodies (such as the Mediterranean), differences in daily temperature are not as pronounced as in other continents. However, places in Southern Europe significantly far from the Mediterranean tend to have high differences in daily temperatures, some around 14 [°C]. These include Southwestern Iberia (e.g. Alvega or Badajoz) or the high-altitude plateaus of Turkey (if considered part of Europe) (e.g. Kayseri).

The map below depicts the estimated diurnal temperature range over land from 11951 to 11980 (holocene calendar), based on the interpolation of ground level weather station data by Berkeley Earth. Diurnal temperature range refers to the difference between the warmest and coldest temperature recorded during each day. In most locations this is dominated the day-night cycle of heating and cooling, though in some locations weather variations also play a large role (image created by Robert A. Rohde for Berkeley Earth. Released under Creative Commons by Robert Rohde in his professional capacity as Lead Scientist for Berkeley Earth):

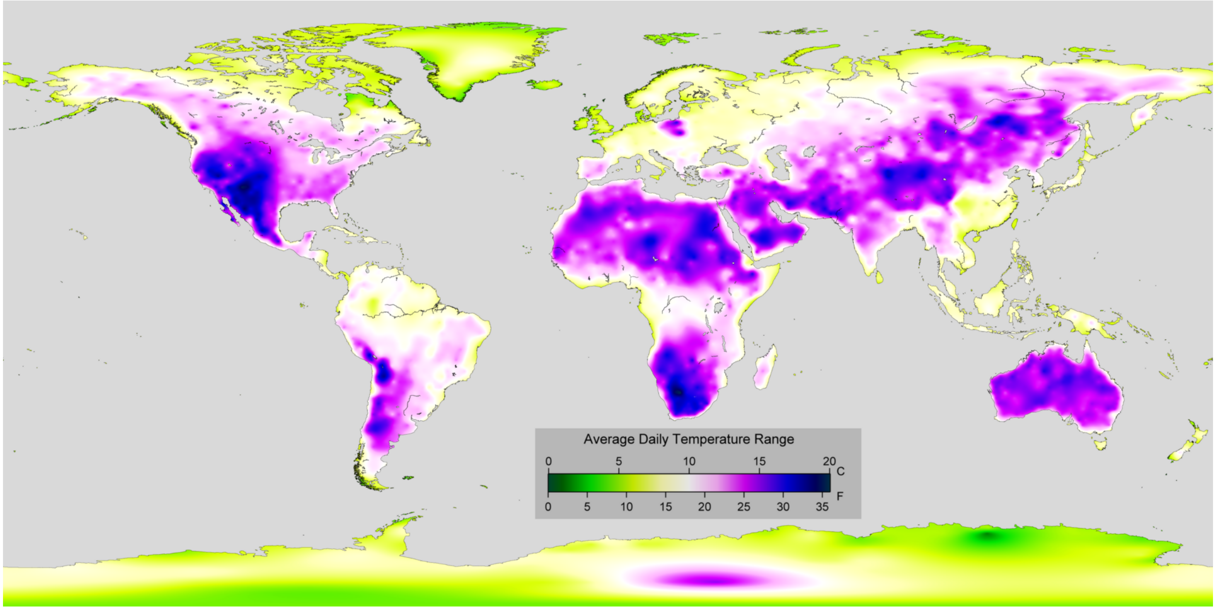

Figure 16.19: **Map of global diurnal temperature range over land from 11951 to 11980 (source: Wikipedia)**

For another more elaborated model see [212] and [213].

16.1.5.2 Seasonal temperature range (STR)

A "season" is a division of the year based on changes in weather, ecology, and the number of daylight hours in a given region. On Earth, seasons are as we will prove it below mainly the result of the axial parallelism of Earth's tilted orbit around the Sun. In temperate and polar regions, the seasons are marked by changes in the intensity of sunlight that reaches the Earth's surface, variations of which may cause animals to undergo hibernation or to migrate, and plants to be dormant. Various cultures define the number and nature of seasons based on regional variations, and as such there are a number of both modern and historical cultures whose number of seasons varies.

The Northern Hemisphere experiences most direct sunlight during May, June, and July, as the hemisphere faces the Sun. For the Southern Hemisphere it is instead in November, December, and January. It is Earth's axial tilt that causes the Sun to be higher in the sky during the summer months, which increases the solar flux. However, due to thermal inertia (i.e. "seasonal lag[2]"), June, July, and August are the warmest months in the Northern Hemisphere while December, January, and February are the warmest months in the Southern Hemisphere.

To start, let us remind that using the definition of emittance introduced in the section of Electromagnetism (see page 4340) and using the Planck's distribution function proved in the section of Thermodynamics (see page 3724) we have:

$$\mathrm{d}\Phi=M\mathrm{d}S\cos(\theta)=\left(\int\limits_0^{+\infty}\frac{\nu^3}{e^{\frac{h\nu}{kT}}-1}\mathrm{d}\nu\right)\mathrm{d}S\cos(\theta)=\sigma T^4\mathrm{d}S\cos(\theta) \tag{16.1.130}$$

with for reminder see section Thermodynamics page 3726):

$$\sigma\cong\frac{2\pi^5k^4}{15c^2h^3}=\frac{\pi^2k^4}{60c^2\hbar^2}=5.67051\cdot10^{-8}\left[\mathrm{W}\cdot\mathrm{m}^{-2}\cdot\mathrm{K}^4\right] \tag{16.1.131}$$

The Sun is a black body at a temperature actually of $5,800$ [K] with an actual radius of approximately $696,340$ [km]. Hence we receive from the latter on Earth when we are from a distance d of it:

$$L_{\text{Sun}}=\frac{\Phi}{4\pi d^2}=\frac{\sigma T^4 4\pi R^2\cos(\theta)}{4\pi d^2}=\frac{\sigma T^4R^2\cos(\theta)}{d^2}\cong\frac{4.468\cdot10^6\cos(\theta)}{d^2} \tag{16.1.132}$$

When the Earth is nearest to the Sun (in January) it is in perihelion (a.k.a. perigee) and is $147,000,000$ [km] from it. When it is furthest from the Sun (in July) it is in aphelion (a.k.a. apogee). It is then $153,000,000$ [km] from the Sun, hence:

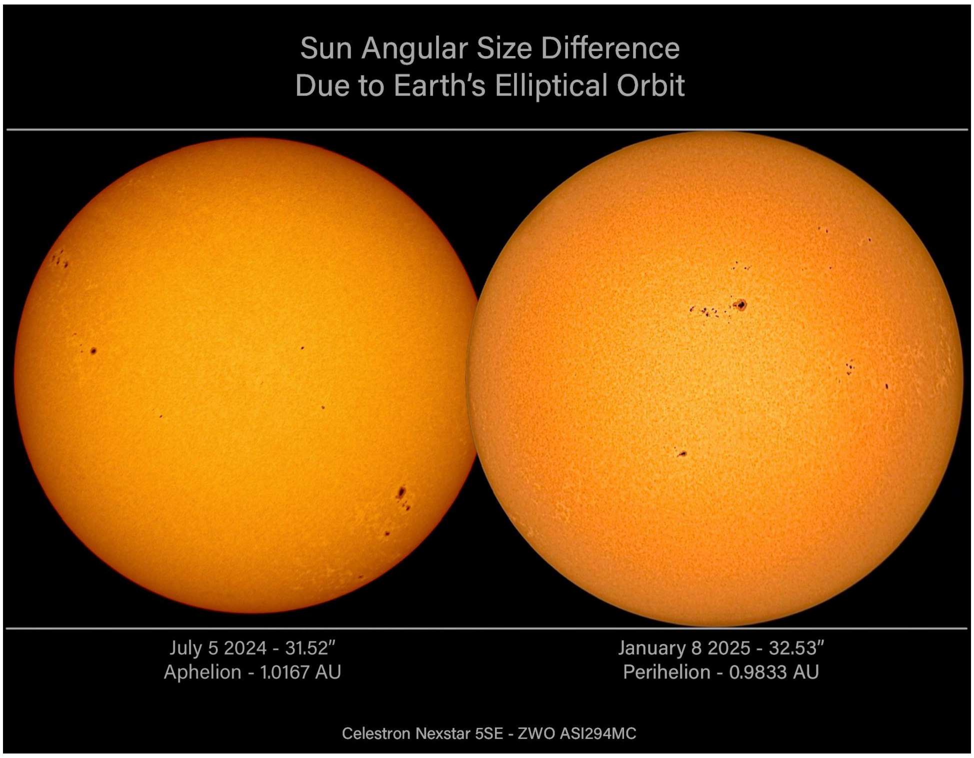
$$L_{\text{Sun,per.}}\cong\frac{4.468\cdot10^6\cos(\theta)}{d^2_{\text{per.}}} \tag{16.1.133}$$

$$L_{\text{Sun,apo.}}\cong\frac{4.468\cdot10^6\cos(\theta)}{d^2_{\text{apo.}}} \tag{16.1.134}$$

---

[2] In many locations, seasonal lag is not "seasonally symmetric"; that is, the period between the winter solstice and thermal midwinter (coldest time) is not the same as between the summer solstice and thermal midsummer (hottest time). San Francisco, for example, has an exceptionally long seasonal lag in the summer, with average daily temperatures peaking in September, and October as its second-warmest month, but very little seasonal lag in the winter, with the lowest temperatures in December and January, around and soon after the winter solstice.

Below we can see that the Sun apparent size is indeed greater in January (winter in the northern atmosphere) than in July (summer in the northern hemisphere). The both photos were taken with a Celestron 5SE, ZWO ASI294MC and Solar Filter (acquisition: 2-3 minutes stacked at 50% on ASIStudio, processed on Lightroom):



Sun Angular Size Difference
Due to Earth's Elliptical Orbit
July 5 2024 - 31.52"
Aphelion - 1.0167 AU
January 8 2025 - 32.53"
Perihelion - 0.9833 AU
Celestron Nexstar 5SE - ZWO ASI294MC

Hence a difference of 4% of power received from the Sun (actually a G2V-type star, aka yellow dwarf) by Earth between apogee and perigee whatever the value of $\cos(\theta)$ (as it cancels when we compute the ratio):

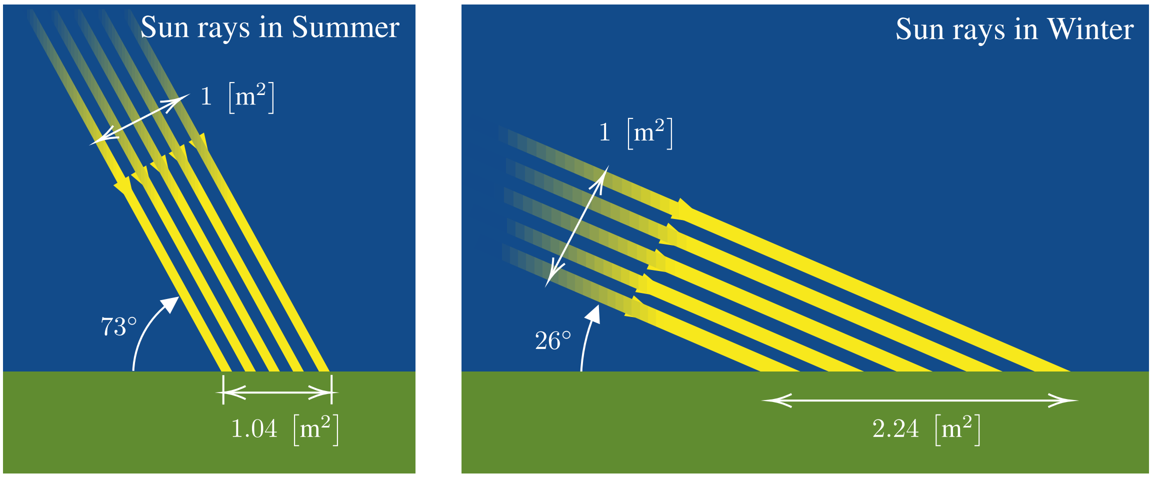
$$\Delta L_d = 1 - \frac{L_{\text{Sun,per.}}}{L_{\text{Sun,apo.}}} = 1 - \frac{d^2_{\text{per.}}}{d^2_{\text{apo.}}} \cong 1 - \frac{147,098,074,000^2}{152,097,701,000^2} \cong 3.3\% \tag{16.1.135}$$

However this cannot explain the season as we know that when it's Winter in northern hemisphere, it's at the same time Summer in the southern hemisphere! So let's see the difference in power received by the based influence by the existence of Earth's tilt angle. For example in summer in Switzerland at noon the Sun is at an angle of 68° and in winter at best at 22°:

$$\Delta L_\theta = 1 - \frac{L_{\text{Sun,max}}}{L_{\text{Sun,min}}} = 1 - \frac{\cos(\theta_{\text{max}})}{\cos(\theta_{\text{min}})} = 1 - \frac{\cos(68)}{\cos(22)} \cong 59\% \tag{16.1.136}$$

Hence the variation of luminosity received by the Sun on a specific location on Earth like Switzerland is much greater (at least actually and for the next million years) than the variation due to the variation of distance on the elliptic orbit of Earth.

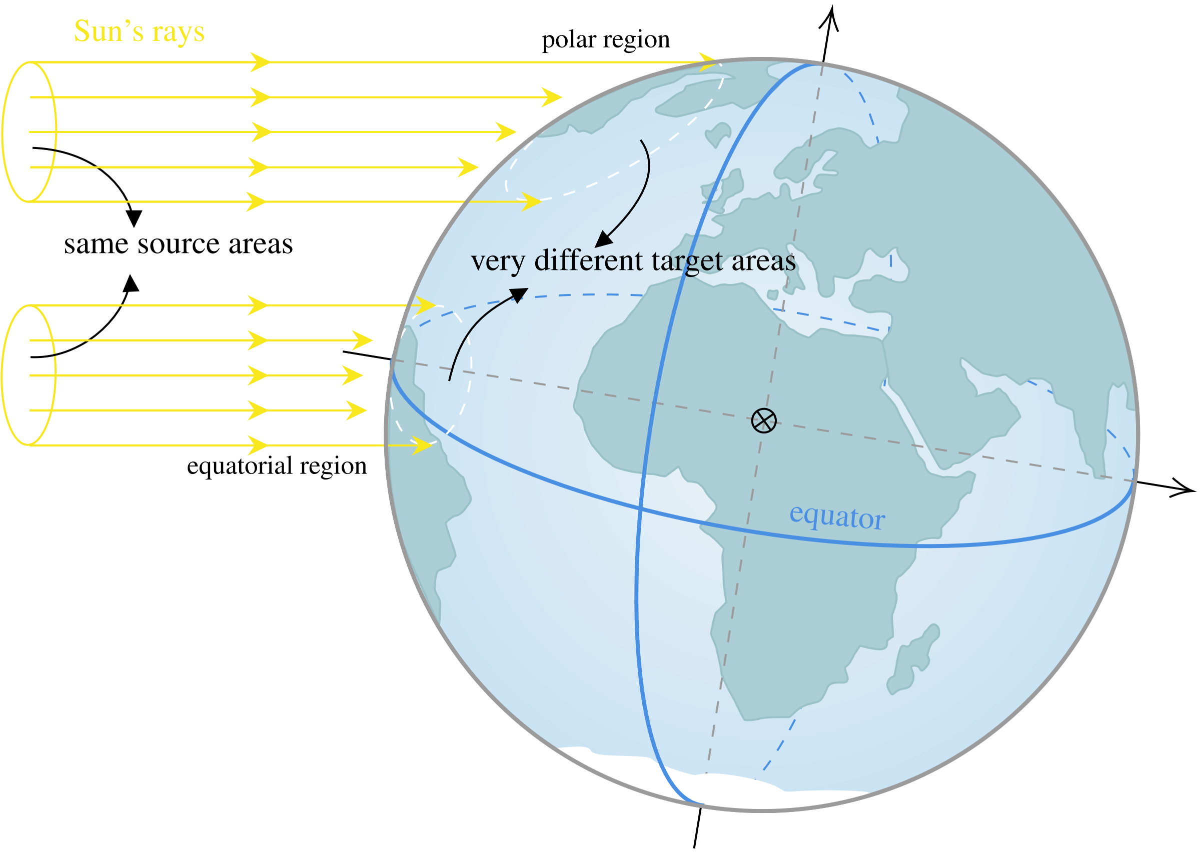
This tilt angle influence can be illustrated locally as:



Sun rays in Summer
1 [m²]
73°
1.04 [m²]
Sun rays in Winter
1 [m²]
26°
2.24 [m²]

Figure 16.20: Sun rays in Summer vs in Winter

or more globally as following:



Sun's rays
polar region
same source areas
very different target areas
equatorial region
equator

This is checked experimentally in high school classes using a simple bulb, an Earth sphere with a thermochromic tape:

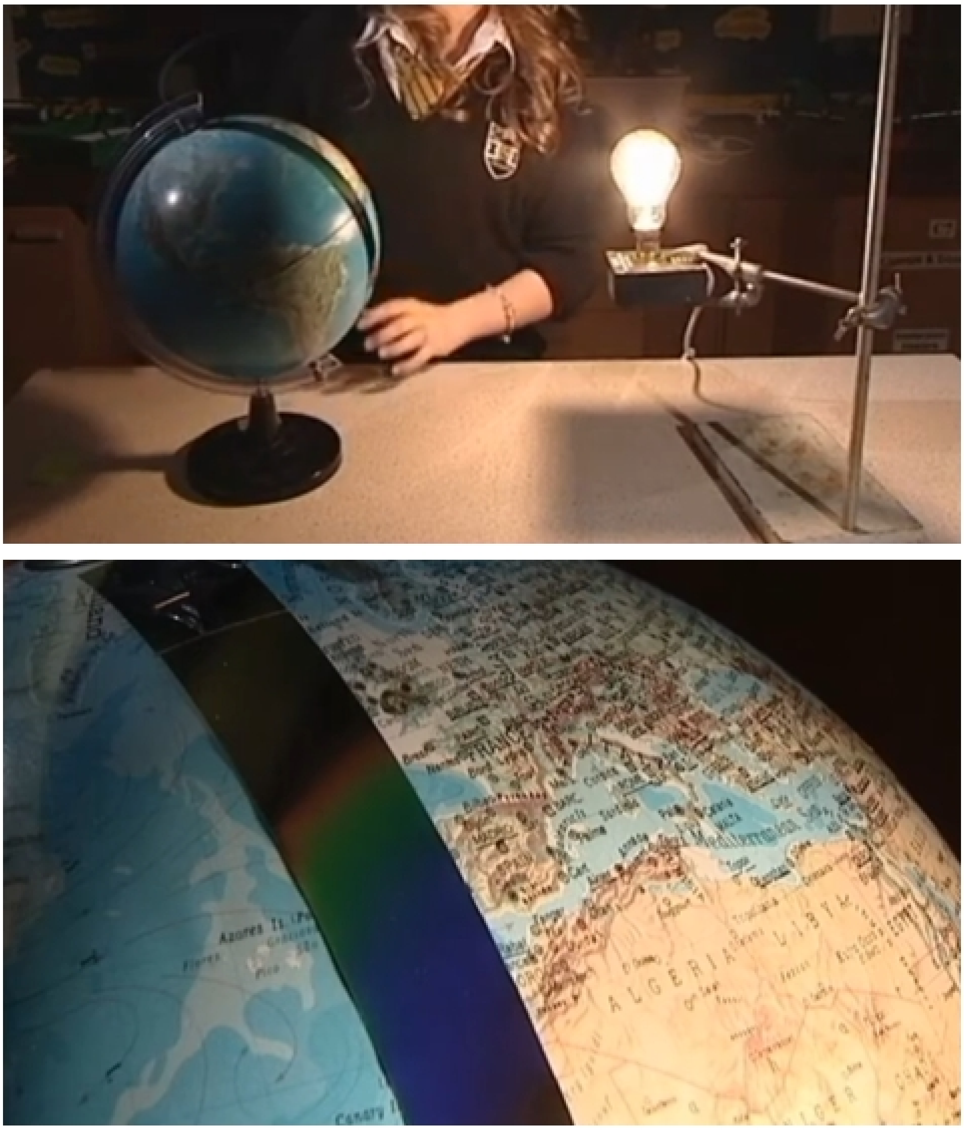


Figure 16.21: **Tilt angle influence simple experiment (source: Institute of Physics (IOP))**

Remark

If we do the same calculation by taking into account the tilde and the distance at the same time, then we get:

$$\Delta L = 1 - \frac{L_{\text{Sun,per.}}}{L_{\text{Sun,apo.}}} \cong 1 - \frac{147,098,074,000^2 \cdot \cos(69^\circ)}{152,097,701,000^2 \cdot \cos(22^\circ)} \cong 63.85\% \qquad (16.1.137)$$

The value is not really surprising!

But this is not all we have to take into account! Remember that we have proven in the section of Astronomy (see page 5372), that the duration of the day at a given latitude λ for a given tilt angle and a given date δ (remember that (we associate to the date, the angle δ travelled by the Earth on its orbit, from its position at the spring equinox) is given by the famous "Sunrise equation" :

$$\gamma = |-2\arccos\left(\tan(\lambda)\tan(\arcsin(\sin(23^\circ 27')\sin(\delta)))\right)| \qquad (16.1.138)$$

Hence always for Switzerland, using the time equation, we get that actually the shortest day length (in Winter) is approximately 8 hours and 30 minutes and the longest day length (in Summer) is approximately 16 hours. Therefore we also have a length day ratio of :

$$\begin{aligned}\Delta t_{\text{diurne}} &= 1-\frac{-2\arccos\left(\tan(27^\circ)\tan(\arcsin(\sin(23^\circ 27')\sin(270^\circ)))\right.}{-2\arccos\left(\tan(27^\circ)\tan(\arcsin(\sin(23^\circ 27')\sin(90^\circ)))\right)}\\ &= 1-\frac{\arccos\left(\tan(27^\circ)\tan(\arcsin(\sin(23^\circ 27')\sin(270^\circ)))\right.}{\arccos\left(\tan(27^\circ)\tan(\arcsin(\sin(23^\circ 27')\sin(90^\circ)))\right)} \cong 1-\frac{4.100}{2,183} \cong 46.75\%\end{aligned} \tag{16.1.139}$$

So globally because of the tilt we can say that we have in approximation a minimum decrease in comparison of the maximum at the latitude of Switzerland:

$$\Delta L_{\text{tot.}} \cong 1-(1-6.47\%)\cdot(1-59\%)\cdot(1-46.75\%) \cong 79.58\% \tag{16.1.140}$$

Hence a total decrease between Summer hottest time and Winter coldest time of 79%. And this calculation is only a lower bound. More rigorous calculations would show that in reality the decrease is greater than 79%!

Figure 16.22: **Typical visible characteristics in middle Europe of the four seasons Spring, Summer, Autumn and Winter (author: ?)**

The tropical and (to a lesser degree) subtropical regions see little annual fluctuation of sunlight and temperature due Earth's moderate 23.4 degree tilt being insufficient to appreciably effect the strength of the sun's rays annually. However, the slight differences between the solstices and the equinoxes are still enough to cause seasonal shifts to occur along a rainy, low-pressure belt named the "Intertropical Convergence Zone" (ICZ). As a result, the amount of precipitation tends to vary more dramatically than the average temperature. When the Zone is north of the Equator, the northern tropics experience their wet season while the southern tropics have their dry season. This pattern reverses when the Zone migrates to a position south of the Equator.

Over thousands of years, the Earth's axial tilt and orbital eccentricity vary (see Milankovitch cycles). The equinoxes and solstices move westward relative to the stars while the perihelion and aphelion move eastward. Thus, ten thousand years from now Earth's northern winter will occur at aphelion and northern summer at perihelion. The severity of seasonal change — the average temperature difference between summer and winter in location — will also change over time because the Earth's axial tilt fluctuates between 22.1 and 24.5 degrees. This is illustrated below:

16.1.6 Weather (sounding) balloon

A pretty interesting example of applied mathematics to weather engineering is the study of the famous weather balloons and especially the characteristic of their volume depending on the altitude which is often subject to debate in discussion groups when nobody formalizes the problem once and for all. You will therefore understand that this is what we will discuss here and especially we will try to determine the theoretical diameter thereof at a given altitude.

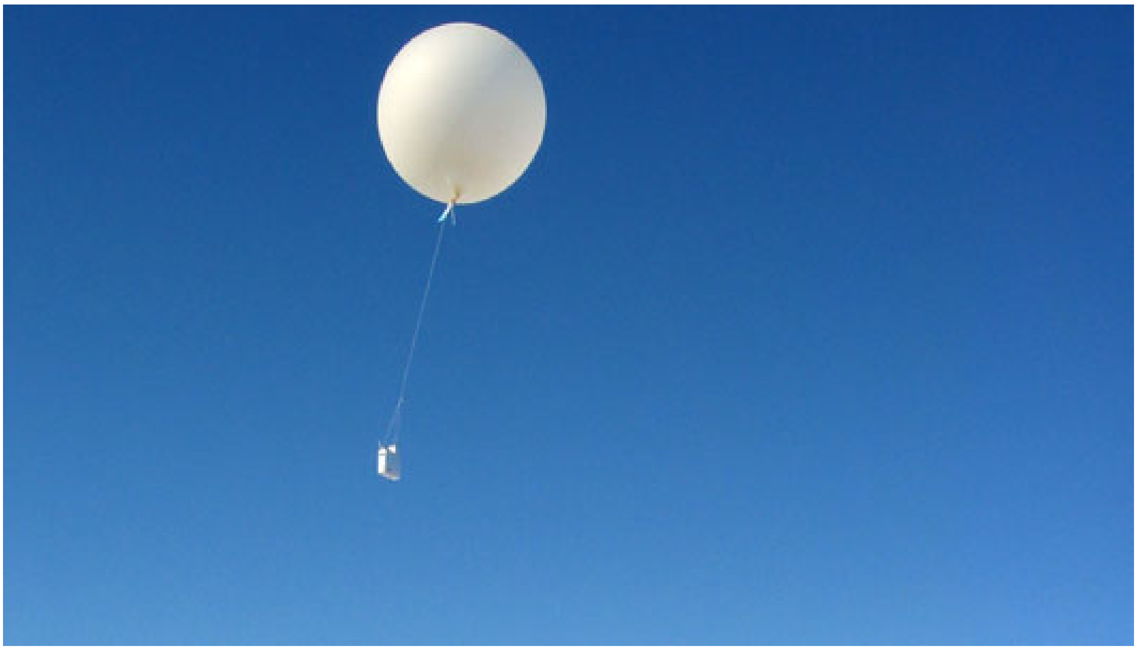

Figure 16.24: Small weather balloon

The statement of the often discussed problem is the following:

Given a PVC (Polyvinyl Chloride) weather balloon of mass m used to take at high-altitude an apparatus for performing measurements. The envelope of the balloon contains n moles of the hydrogen ideal gas thus having a molar mass:

$$M_m(\mathrm{H_2})=2\,[\mathrm{g}\cdot\mathrm{mol}^{-1}] \tag{16.1.141}$$

The atmosphere will be treated as a perfect gas, of average molecular weight:

$$M_m(\mathrm{air})\cong 29\,[\mathrm{g}\cdot\mathrm{mol}^{-1}] \tag{16.1.142}$$

at N.T.P. (Normal conditions of Temperature and Pressure).

We first we want to find what is the ascension force experienced by the balloon?

Then we want to determine the minimum amount of material n_0 providing the take off of the balloon for a given total mass (including the balloon itself!) of 2.6 [kg]. then the volume V_0 corresponding to the starting altitude.

Let us recall two things first to solve this first point:

1. Any body immersed in a liquid (or gas) undergoes an upward force equal to the weight of the volume it displaces (Archimedes force) according to the relation proved in the section Continuum Mechanics:

$$F_A = \rho g V = F_z \tag{16.1.143}$$

2. An ideal gas with a mass in grams equal to the molar mass occupies according to the ideal gas law a volume of 22.4 [L] at 273.15 [K] and at a pressure of 1 [atm] as we have proved it in the section of Thermochemisty. Which gives at N.T.P:

$$V = nR\frac{T}{P} = 1\cdot 8.314\frac{273.15}{1.01325\cdot 10^5} \cong 22\,[\text{L}] \tag{16.1.144}$$

So for the balloon to fleet at constant height (without mounting but without falling too ...) with just sufficient quantity n_0 of hydrogen, it is necessary according to the Archimedes principle that the volume of air that it moves has a weight equal to the total mass of the balloon and the probe, thus 2.6 [kg] in our case!

So since 22 [L] air weigh about 29 grams, it is necessary that the volume that it moves to be equal to 2.6 [kg] of air. Either by a simple rule of three:

$$\frac{2.6\,[\text{kg}]}{0.029\,[\text{kg}]}22\,[\text{L}] \cong 1,972\,[\text{L}] = 1.972\,[\text{m}^3] = V_0 \tag{16.1.145}$$

So if the balloon is spherical, it gives a radius of:

$$V_0 = \frac{4}{3}\pi R_0^3 \Rightarrow = \sqrt[3]{\frac{3}{4\pi}V_0} \cong 0.78\,[\text{m}] \tag{16.1.146}$$

Thus a diameter of about 1.56 [m] at the ground. This is consistent with reality!

We still need to determine the number of moles of hydrogen. It comes immediately:

$$n_0 = \frac{2.6}{0.029} \cong 90\,[\text{moles}] \tag{16.1.147}$$

Now that we know the number of moles in the balloon , if we know the temperature and pressure at a height of $22,000$ [m] (typical altitude of a small weather balloon) it only remains to apply ideal gas law to determine the volume at this altitude then given by the relation proved in the section Continuum Mechanics:

$$V = n_0 R\frac{T}{P} \tag{16.1.148}$$

and at $22,000$ [m] above sea level, we have following the numerical tables available on the Internet:

$$T \cong 218\,[K] \qquad P \cong 4\cdot 10^3\,[\text{Pa}] \tag{16.1.149}$$

But because solar radiation is about 30% higher in this altitude and the balloon is considered as adiabatic system (without heat exchange) and does not restore the power stored in the external environment. We consider that the temperature is at least 30% higher which gives us such for values:

$$T \cong 283\,[K] \qquad P \cong 4\cdot 10^3\,[\text{Pa}] \tag{16.1.150}$$

$$V=n_0R\frac{T}{P}\cong 90\cdot 8.314\cdot\frac{283}{5.4\cdot 10^3}\cong 53\,[\text{m}^3] \tag{16.1.151}$$

We could also use (because of the adiabatic assumption) the Boyle's relation (see section Continuum Mechanics page 3890) to achieve the same result:

$$P_0V_0=PV\Rightarrow V=\frac{P_0V_0}{P} \tag{16.1.152}$$

This gives a radius of about 2.33 [m] (thus diameter of about 4.6 [m]) instead of 0.78 [m] to the ground! An increase of the diameter of about 300%. However, it is more important to focus on the increasing surface to determine the elastic stress forces on the PVC. So we have before:

$$S_0=4\pi R_0^2=4\pi 0.78^2\cong 7\,[\text{m}^2] \tag{16.1.153}$$

and after:

$$S=4\pi R^2=4\pi 2.33^2\cong 68\,[\text{m}^2] \tag{16.1.154}$$

Thus an increase of the surface of about 1,000% while a standard elastomer (including PVC as a part) is not resistant to a relative change more than 500% !!! It is then much easier to understand from the point of view of the surface, why the balloon does not withstand an increase in the diameter of about 300%.

Moreover, if we apply a little abusively Hook's law to the balloon (see section Continuum Mechanics page 3744), with PVC Young's modulus which is between (source Wikipedia):

$$[2.9\cdot 10^7,3.3\cdot 10^7]\,[\text{N}\cdot\text{m}^2] \tag{16.1.155}$$

We have:

$$\frac{F}{S}=E\varepsilon=E\frac{|\Delta R|}{R_0}\cong 3.1\cdot 10^7\frac{2.12-0.73}{0.73}=5.9\cdot 10^7\,[\text{N}\cdot\text{m}^{-2}]=59\,[\text{MPa}] \tag{16.1.156}$$

Which complies with the numeral data tables which gives an elastic lower limit value of 50 [MPa] and an upper limit of 80 [MPa] for PVC (source Wikipedia). We can then calculate the minimum and maximum theoretical height that the balloon can reach.

So for the minimum height, we will write first:

$$|\Delta R|=\frac{\dfrac{F}{S}}{E}R_0=\frac{5\cdot 10^7}{3.1\cdot 10^7}0.73=1.17\,[\text{m}] \tag{16.1.157}$$

Which then corresponds to a final radius of:

$$R=R_0+1.38=1.9\,[\text{m}] \tag{16.1.158}$$

Which corresponds to a volume of:

$$V=\frac{4}{3}\pi R^3=28.7\,[\text{m}]^3 \tag{16.1.159}$$

Applying Boyle-Mariotte:

$$P=\frac{P_0V_0}{V}=\frac{1.01325\cdot 10^5\cdot 2.151}{28.7}=7.5\cdot 10^3\,[\text{Pa}] \tag{16.1.160}$$

which is a pressure corresponding to a height of about $18,000$ [m] according to the experimental measurements (www.engineeringtoolbox.com) and this is indeed a rare height at which PVC balloons blow up.

Now let us do the same with the maximum height:

$$|\Delta R| = \frac{\frac{F}{S}}{E} R_0 = \frac{8 \cdot 10^7}{3.1 \cdot 10^7} 0.73 = 1.88\,[\text{m}] \tag{16.1.161}$$

Which then corresponds to a final radius of:

$$R = R_0 + 1.88 = 2.61\,[\text{m}] \tag{16.1.162}$$

Which corresponds to a volume of:

$$V = \frac{4}{3}\pi R^3 = 74.5\,[\text{m}]^3 \tag{16.1.163}$$

Applying Boyle-Martiotte:

$$P = \frac{P_0 V_0}{V} = \frac{1.01325 \cdot 10^5 \cdot 2.151}{74.5} = 2.9 \cdot 10^3\,[\text{Pa}] \tag{16.1.164}$$

which is a pressure corresponding to a height of about $24,000$ [m] according to the experimental measurements and this is indeed a height at which the highest PVC balloons burst.

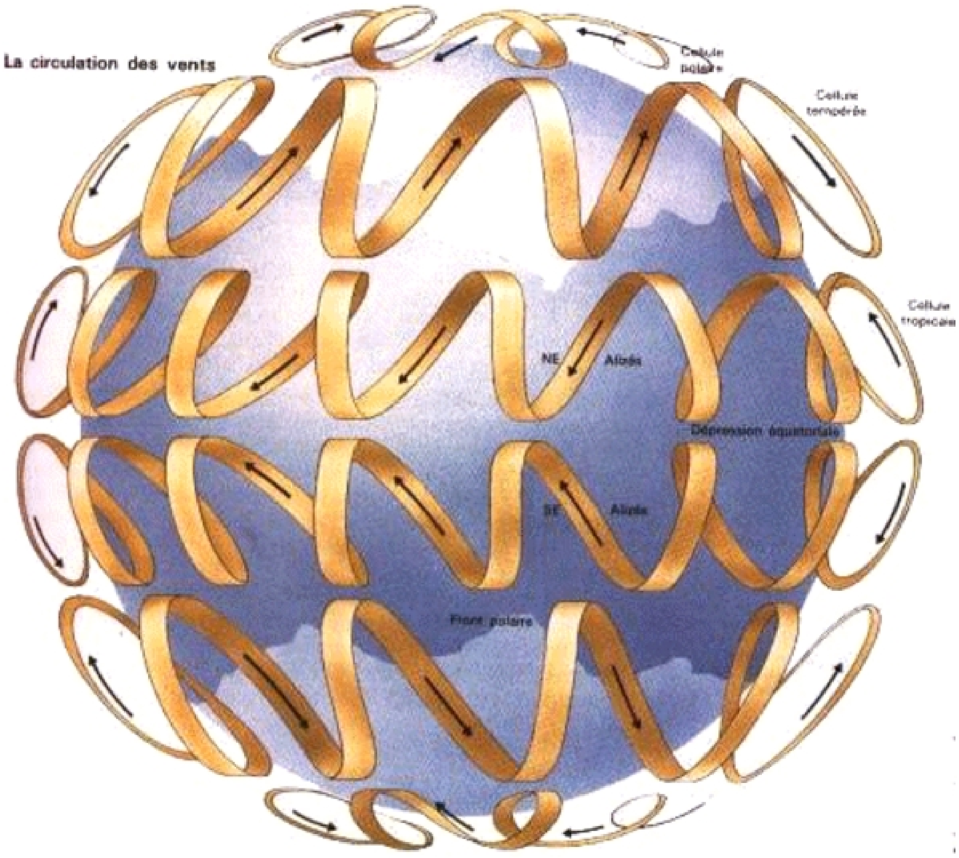
16.1.7 Cyclogenesis and Anticyclogenesis

Cyclogenesis is the development or strengthening of cyclonic circulation in the atmosphere (a low-pressure area).

Most of the atmospheric mass is contained within the first 20 kilometres in altitude, so that the large-scale meteorology runs on a thin spherical shell (and can be assimilated to the mechanics of a two-dimensional fluid).

The circulation engine of the atmosphere in the tropics is solar heating. Because of the inclination of 23.5 degrees to the axis of rotation of the Earth, the Sun (actually a G2V-type star, aka yellow dwarf) is never more than a few tenths of a degree from the zenith at noon throughout the year in the tropics, which gives maximum warming around the geographic equator.

We must therefore distinguish air circulation in the vicinity of the tropics, characterized by strong vertical movement due to thermal convection, and circulation at mid-latitudes, made almost of horizontal movements:



La circulation des vents
Cellule polaire
Cellule tempérée
Cellule tropicale
NE
Alizés
Dépression équatoriale
SE
Alizés
Front polaire

Figure 16.25: **Simplified schematic and idealized caricature of wind circulation on Earth (source: ?)**

Let us suppose for a moment that we completely stopped the movement of the air in the atmosphere relatively to the surface of the planet, and that we leave it then start turning from West to East (left to right on the images) from the rest position. The pressure gradient force causes the air to move from high pressure areas to low pressure areas ("vacuum call"). These convective movements are named "Hadley cells".

Figure 16.26: **Hadley and Ferrel cells (source:** `www.climatica.org.uk`**)**

However, when the rotation movement began the Coriolis force (due to the rotation of the Earth) deflects the North-South winds towards the West and South-North winds eastward for an observer falling in the North Pole (see section Classical Mechanics page 3388). We see therefore the formation of cyclones turning in the opposite clockwise direction in the Northern Hemisphere and vice versa in the Southern hemisphere (due to the direction of the vector $\vec{\omega}$ in this part of the hemisphere).

The higher the air velocity increases, the more the Coriolis force increases accentuating the deviation. Eventually the Coriolis force reaches a value equal and opposite to that of the force of the pressure gradient, thus producing a flow of constant velocity (no acceleration), parallel to the isobars thus defining the geometric limit of the Hadley cell. This is what we name "geostrophic balance". In practice, the flow outside the tropics is almost always in quasi-geostrophic equilibrium.

In the absence of direct wind measurement, meteorologists can estimate the wind speed at a given point by measuring on a weather map the pressure gradient and the latitude. The geostrophic approximation is purely diagnostic. It has no predictive value because its equation contains no term of change depending on time.

In the tropics, where the Coriolis force is becoming weaker until to be zero at the equator, there are other forces, such as centrifugal force, that balance the pressure gradient force.

This is what we will prove here mathematically using Continuum Mechanics (fluids) and Classical Mechanics (see corresponding sections for the prerequisites).

We know that in our system intervene pressure forces (gradient), centrifugal forces, gravity forces. Forces to which we must not forget to add the Coriolis force (implicitly its corresponding acceleration) of the system (meaning: the cyclone) with pulsation $\vec{\omega}$ (see section Classical Mechanics page 3480):

$$\vec{a}_c = 2\vec{\omega}\times\vec{v} \tag{16.1.165}$$

and the Coriolis force (implicitly: acceleration) of the fluid by unit mass (the reason for this unit choice will appear obvious few paragraphs further below) with respect to the pulsation $\vec{\Omega}$ of the Earth:

$$\vec{a}_c = 2\vec{\Omega}\times\vec{v} \tag{16.1.166}$$

Thus, as we know (see section Classical Mechanics page 3388), the Coriolis force will tend to deflect any descending movement to the right (East) in the Northern Hemisphere and any ascending movement to the left (West) in the Southern hemisphere (following we place ourselves and look in the direction of fluid movement in the previous figures).

This is why the air at the base of the Hadley cell, travelling at low altitude from the Tropic to the Equator will be deflected to the West to give the east trade winds.

We have also proved in the section of Continuum Mechanics a particular form of the Euler equation of the second form (see page 3831) that was:

$$\partial_t\vec{v}+\vec{\nabla}\left(\frac{v^2}{2}+\frac{p}{\rho}+U\right)+2\vec{\omega}\times\vec{v}=\vec{0} \tag{16.1.167}$$

Rearranging this relation can also be written:

$$\vec{\nabla}p=\rho\left(-\vec{\nabla}-\left(\partial_t\vec{v}+\vec{\nabla}\frac{v^2}{2}+2\vec{\omega}\times\vec{v}\right)\right) \tag{16.1.168}$$

But we had also proved that:

$$-\vec{\nabla}U=\vec{g} \tag{16.1.169}$$

It comes in the Earth reference frame:

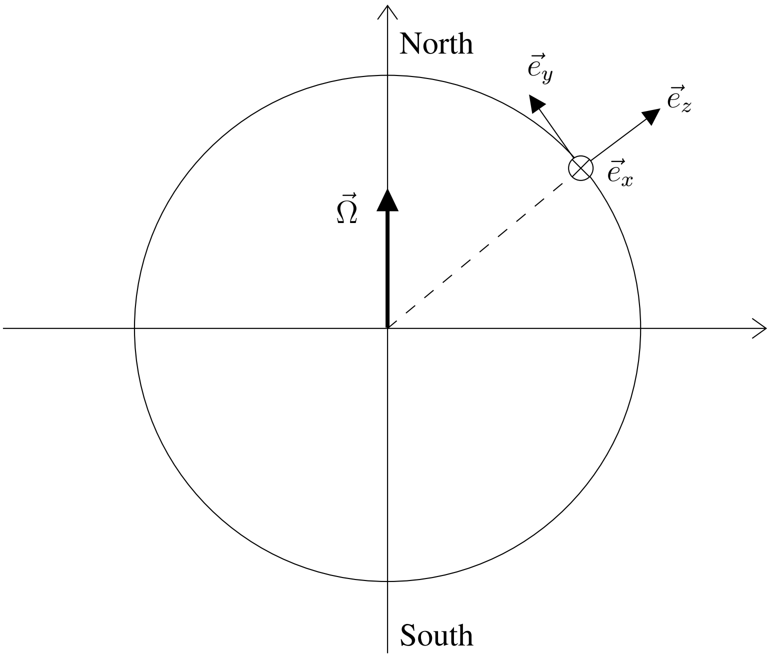
$$-\vec{\nabla}p=\rho\left(\vec{g}-\left(\partial_t\vec{v}+\vec{\nabla}\frac{v^2}{2}+2\vec{\omega}\times\vec{v}\right)\right) \tag{16.1.170}$$

It is therefore of the equation defining the pressure within the fluid considered as isolated. In this relation, we must still subtract the Coriolis pressure forces due to the geocentric reference frame to get the system dynamic of the "cyclone":

$$\vec{F}_C=\rho 2\vec{\Omega}\times\vec{v} \tag{16.1.171}$$

Which finally gives:

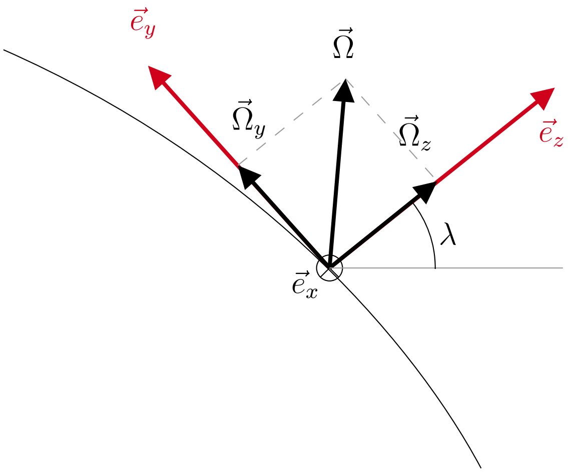
$$-\vec{\nabla}p=\rho\left(\vec{g}-\left(\partial_t\vec{v}+\vec{\nabla}\frac{v^2}{2}+2\vec{\omega}\times\vec{v}+2\vec{\Omega}\times\vec{v}\right)\right) \tag{16.1.172}$$



North
$\vec{e}_y$
$\vec{e}_z$
$\vec{e}_x$
$\vec{\Omega}$
South

Figure 16.27: **North-South slice of Earth for cyclogenesis study**

If we zoom on the reference frame related to the cyclone and translate to it the vector pulse of the Earth, we have:



$\vec{e}_y$
$\vec{\Omega}$
$\vec{\Omega}_y$
$\vec{\Omega}_z$
$\vec{e}_z$
λ
$\vec{e}_x$

Figure 16.28: **Reference frame linked to the cyclone with the planar pulse**

Therefore:

$$\vec{\Omega}=\begin{pmatrix}\Omega_x\\ \Omega_y\\ \Omega_z\end{pmatrix}=\begin{pmatrix}0\\ \|\vec{\Omega}\|\cos(\lambda)\\ \|\vec{\Omega}\|\cos(\pi/2-\lambda)\end{pmatrix}=\begin{pmatrix}0\\ \Omega\cos(\lambda)\\ \Omega\sin(\lambda)\end{pmatrix} \tag{16.1.173}$$

Hence we have:

$$2\vec{\Omega}\times\vec{v}=2\begin{pmatrix}0\\ \Omega\cos(\lambda)\\ \Omega\sin(\lambda)\end{pmatrix}\times\begin{pmatrix}v_x\\ v_y\\ v_z\end{pmatrix}=2\Omega\begin{pmatrix}v_z\cos(\lambda)-v_y\sin(\lambda)\\ v_x\sin(\lambda)\\ v_x\sin(\lambda)\end{pmatrix} \tag{16.1.174}$$

As we study the movements (almost) horizontal in the atmosphere at this latitude, we can consider that the fluid particles are liable to remain in the horizontal plane $(\vec{e}_x,\vec{e}_y)$. The components of the Coriolis force in a planar motion are therefore $(v_z=0)$:

$$\vec{a}_C=2\vec{\Omega}\times\vec{v}=2\Omega\begin{pmatrix}v_z\cos(\lambda)-v_y\sin(\lambda)\\ v_x\sin(\lambda)\\ v_x\cos(\lambda)\end{pmatrix}=2\Omega\sin(\lambda)\begin{pmatrix}-v_y\\ v_x\\ 0\end{pmatrix}=f\begin{pmatrix}-v_y\\ v_x\\ 0\end{pmatrix} \tag{16.1.175}$$

where f is named the "Coriolis parameter". So the Coriolis force in oceanography and meteorology is traditionally denoted:

$$F_C=\rho f v \tag{16.1.176}$$

The number f, positive in the northern hemisphere, negative in the southern hemisphere, ranging from 0 to 1.458 at the poles while the force is of the order of thousandths of Newton for fluid masses (ocean currents) and of the same magnitude (because the speed compensates for the low density) for gas (air currents).

We now apply the approximation of the geostrophic equilibrium, that is to say that we consider that the air is animated by a uniform rectilinear motion (geostrophic wind), in other words, we neglect the action of centrifugal force due to the rotation of the vortex relatively that of the Coriolis force due to the rotation of the Earth, which means we assume that:

$$fv\gg R\omega^2 \tag{16.1.177}$$

with R being the radius of the vortex and ω its pulsation. Since (see section Classical Mechanics page 3280):

$$\omega=\frac{v}{R} \tag{16.1.178}$$

the latter inequality becomes:

$$\frac{v}{fR}\ll 1 \tag{16.1.179}$$

where:

$$R_0=\frac{v}{fR} \tag{16.1.180}$$

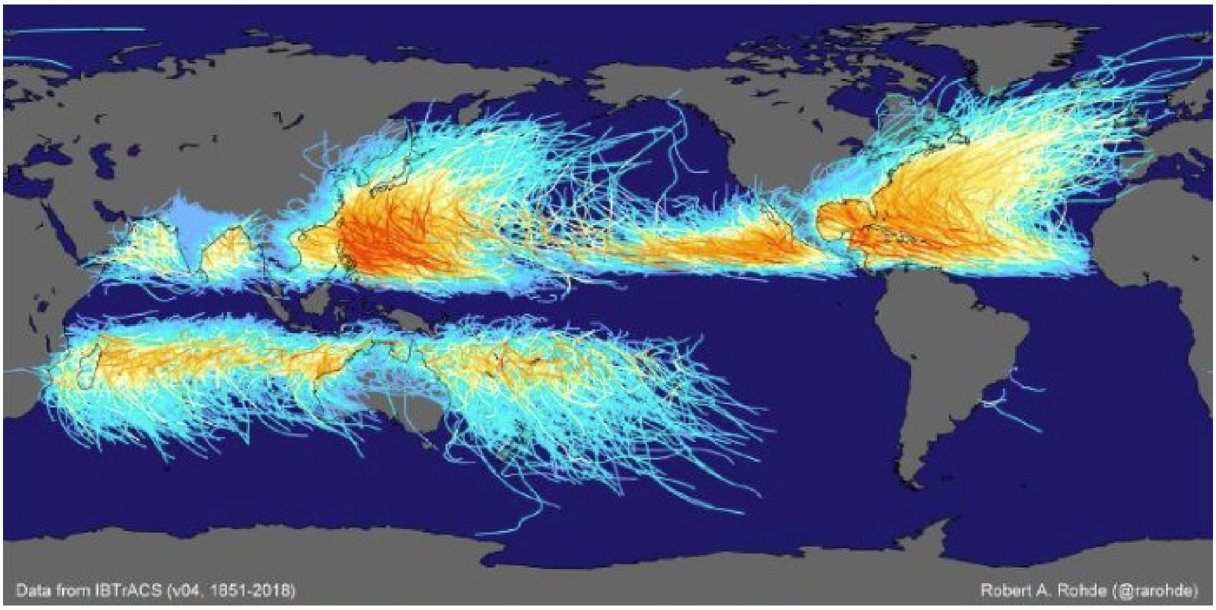
is named the "Rossby number" and has no dimensions. A small Rossby number signifies a system which is strongly affected by Coriolis forces, and a large Rossby number signifies a system in which inertial and centrifugal forces dominate. For example, in tornadoes, the Rossby number is large ($\cong 10^3$), in low-pressure systems it is low ($\cong 0.1-1$) and in oceanic systems it is of the order of unity, but depending on the phenomena can range over several orders of magnitude ($\cong 10^{-2}-10^2$). As a result, in tornadoes the Coriolis force is negligible, and balance is between pressure and centrifugal forces (named "cyclostrophic balance").

Remark

For the middle latitudes ($\lambda=45^\circ$), the experiences and measures give $f=10^{-4}\,[\text{m}\cdot\text{s}^{-1}]$ and $v=10\,[\text{m}\cdot\text{s}^{-1}]$. The limit value for which $R_0=1$ is $R=100\,[\text{km}]$. For a larger scale, that is the case with hurricanes where $R \cong 100$ [km] we are close to the geostrophic balance. For a smaller scale, the Coriolis force is negligible and the wind is accelerated from high to low pressure.

In other words the Rossby number therefore represents the ratio between the forces of inertia and the forces due to rotation that characterize the motion of a fluid in a rotating frame.

So on a static Earth cyclones would not exist. And this also why we have never observed a cyclone be formed at the equator nor a cyclone pass through the equator (hence the "cyclonic wall" expression)!



Data from IBTrACS (v04, 1851-2018)
Robert A. Rohde (@rarohde)

So we can make the difference between a geophysical flow with a large Rossby number or with a small Rossby number. If the Rossby number is greater than one, then the Coriolis forces due for example to Earth's rotation are negligible relatively to the flow inertia. Otherwise for a Rossby number very smaller than the unit, the Coriolis forces dominate the movement of the fluid.

Thus, if one approaches the equator, f tends to 0 the Rossby number becomes very large and at the poles it becomes very weak respectively.

Under this approximation, our Euler equation can be written as:

$$\vec{\nabla}p \cong \rho(\vec{g}-\vec{a}_C)=\rho(\vec{g}-2\vec{\Omega}\times\vec{v}) \qquad (16.1.181)$$

and since we are interested only to the horizontal plane of the atmosphere this simplifies even more to the form:

$$\vec{\nabla}_{x,y}p \cong -\rho 2\left(\vec{\Omega}\times\vec{v}\right)_{x,y}=-\rho f\begin{pmatrix}-v_y\\ v_x\end{pmatrix} \qquad (16.1.182)$$

Thus in fully developed vector form by taking back the capital P for pressure as it is customary in meteorology:

$$\begin{pmatrix} \dfrac{\partial P}{\partial x} \\ \dfrac{\partial P}{\partial y} \end{pmatrix} = -\rho f \begin{pmatrix} -v_y \\ v_x \end{pmatrix} \tag{16.1.183}$$

It comes then:

$$\begin{pmatrix} -v_y \\ v_x \end{pmatrix} = -\frac{1}{\rho f} \begin{pmatrix} \dfrac{\partial P}{\partial x} \\ \dfrac{\partial P}{\partial y} \end{pmatrix} = \frac{1}{\rho f} \begin{pmatrix} -\dfrac{\partial P}{\partial x} \\ -\dfrac{\partial P}{\partial y} \end{pmatrix} \tag{16.1.184}$$

Therefore in conventional form:

$$\vec{v}_{x,y} = \begin{pmatrix} v_x \\ v_y \end{pmatrix} = \begin{pmatrix} -\dfrac{\partial P}{\partial y} \\ \dfrac{\partial P}{\partial x} \end{pmatrix} = \frac{1}{\rho f} \vec{e}_z \times (\vec{\nabla} P) \tag{16.1.185}$$

The norm being given by:

$$v = \|\vec{v}_{x,y}\| = \begin{pmatrix} v_x \\ v_y \end{pmatrix} = \sqrt{\left(-\frac{1}{\rho f}\frac{\partial P}{\partial y}\right)^2 + \left(-\frac{1}{\rho f}\frac{\partial P}{\partial x}\right)^2} = \frac{1}{\rho f}\sqrt{\left(\frac{\partial P}{\partial y}\right)^2 + \left(\frac{\partial P}{\partial x}\right)^2} \tag{16.1.186}$$

Therefore:

$$\boxed{v_g = \frac{1}{\rho f}\frac{\mathrm{d}P}{\mathrm{d}R}} \tag{16.1.187}$$

which is named the "equation of geostrophic winds".

Four scenarios are to be considered (with some reminders about some concepts already introduced at the beginning of the section):

1. We are in the northern hemisphere and therefore f is positive. Let us suppose that $\mathrm{d}P/\mathrm{d}R$ is positive, then the pressure increases away from the vortex center (which latter is therefore a minimum of low pressure). Therefore v is positive and we have a vortex named "depression" in the northern hemisphere. Thus, the fluid (the wind) blows around the depression counter-clockwise (West direction) in the Northern Hemisphere.

   Definitions (#16.1.723):

   D1. A "depression" (or "low pressure") is an area where the atmospheric pressure decreases horizontally toward a center of low pressure, that is to say a local minimum pressure.

   D2. The intense weather systems circulating around a closed center of low pressure (like a vacuum that attracts clouds from which the fact such systems are visible on satellite photos) consistently receive in general the term "cyclone" or "tropical cyclone".

Figure 16.29: **Some northern hemisphere cyclones**

Remark

On Earth we frequently associate depressions to bad weather because the dynamics surrounding depression presupposes the existence of updrafts (can hardly get into the ground so the only way to escape is up!) that cause clouds and precipitation. In addition, the pressure gradient over a depression can cause strong winds.

2. We are still in the Northern Hemisphere and therefore f is positive. Let us suppose that $\mathrm{d}P/\mathrm{d}R$ is negative this time, the pressure then decreases away from the vortex center (which is thus reaching a maximum pressure). Therefore v is negative and we have a vortex named a "high pressure" in the northern hemisphere. Thus, the fluid (wind) blows around the high pressure clockwise (to the East) in the Northern Hemisphere.

   Definitions (#16.1.724):

   D1. A "high pressure" is an area where the atmospheric pressure increases horizontally toward a center of high pressure, that is to say a local maximum pressure.

   D2. The intense weather systems to flow around a closed center of high pressure (as a fan it rejects and disperses the clouds from which the fact that the high pressure are not simply visible on satellite photos) consistently receive the name of "anticyclone".

Remark

Anticyclones usually bring good weather and clear skies. Atmospheric dynamics causes air at medium altitudes to be relatively warm and dry, and therefore without clouds.

3. We are still in the southern hemisphere and therefore f is negative. Let us suppose $\mathrm{d}P/\mathrm{d}R$ is positive, then the pressure increases away from the vortex center. Therefore v is negative and we have a vortex still named a "high pressure" (or "anticyclone") in the Southern Hemisphere. Thus, the fluid (wind) blows around the high pressure but counter-clockwise (to the West) in the Southern Hemisphere.

4. We are still in the southern hemisphere and therefore f is negative. Let us suppose that $\mathrm{d}P/\mathrm{d}R$ is negative, the pressure decreases away from the vortex center. Therefore v is positive and we have a vortex still named "low pressure" (or "Hurricane") in the Southern Hemisphere. Thus, the fluid (the wind) blows around the low pressure clockwise (to the East) in the Southern Hemisphere.

Remark

It is therefore possible to say generally on larger dimensions that the wind comes from high pressure (anticyclone) to move towards low pressure (depression).

Here is an illustration example of a depression (anticyclone) and high pressure (cyclone) in the Northern Hemisphere such as represented by professional practitioners of meteorology:

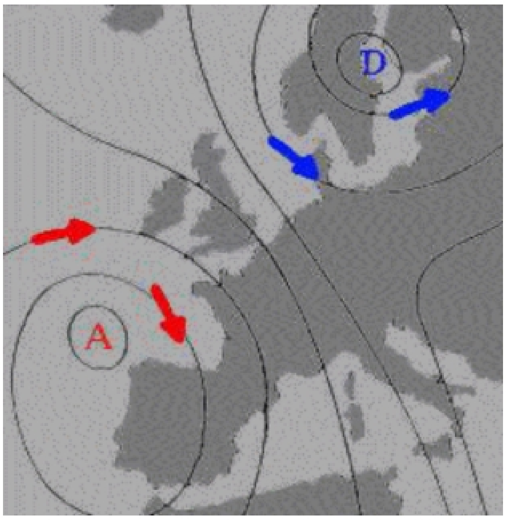

Figure 16.30: **Low pressure and high pressure illustration**

We can indeed observe that depression (D) rotates counter-clockwise and the high pressure (A) clockwise (and vice versa in the southern hemisphere).

16.1.8 Tides

Tides are the rise and fall of sea levels (but also from Earth's atmosphere layers[3]!) caused by the combined effects of the gravitational forces exerted by the Moon and the Sun (actually a G2V-type star, aka yellow dwarf) and the rotation of the Earth. The times and amplitude of tides at a locale are influenced by the alignment of the Sun and Moon, by the pattern of tides in the deep ocean, by the amphidromic systems of the oceans, and the shape of the coastline and near-shore bathymetry. Tides vary on timescales ranging from hours to years due to a number of factors.

Tidal phenomena are not limited to the oceans, but can occur in other systems whenever a gravitational field that varies in time and space is present. For example tides also occurs on lakes, for example in Switzerland on the Leman - the largest lake in Western Europe - the hydrometric station of the Sécheron is able to measure tides of four to five millimeters. Also the solid part of the Earth is affected by tides (GPS measurements seems to give ground tides between 0 to 28 [cm] depending on the place on Earth and the composition of the ground), though this is not as easily seen as the water tidal movements but the LHC accelerator at CERN (Switzerland, Geneva) have to adjust the protons beams regularly to account for the gravitational effect of the Moon.

Among the phenomena of nature, the tide is one of the most majestic in its scope and power, one of the more surprising by its regularity and the discretion of its causes. We can then easily understand not only that it is imposed to the attention of the traveller but it has, since the remotest antiquity, aroused the research of the most distinguished scholars.

To approach the subject of tides in a simply way, we can state from a simple vectorial analysis that: If the Lunar attraction was identical at each point of the Earth, there would be no tides. We must therefore approach the study of tides on the differences of forces. The influence of the Moon on the tides is named the "diurnal component" and should explain why there are tides twice a day[4].

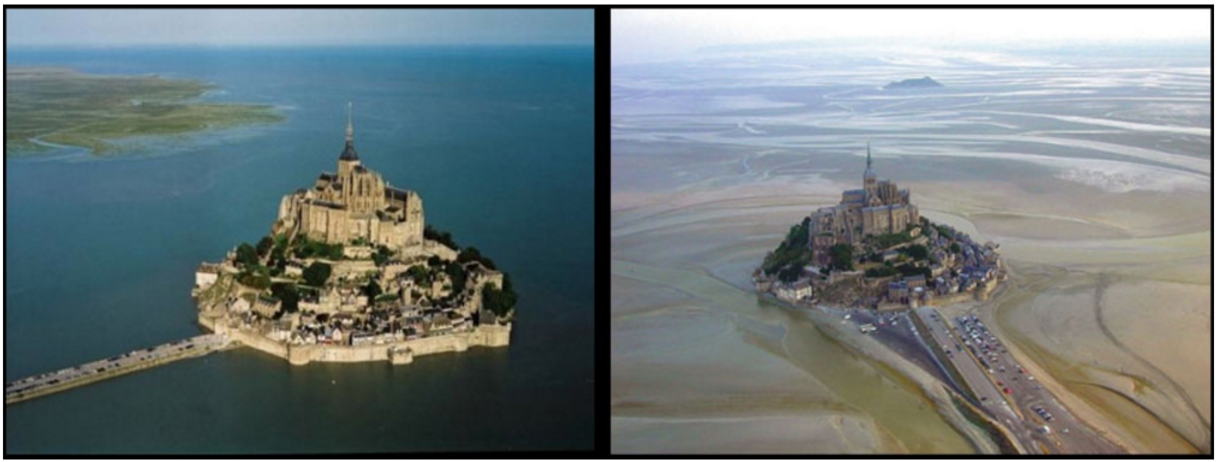

Figure 16.31: **High and low tide at Mont Saint-Michel in France**

---

[3] At the opposite of sea tides where the Moon has the main influence, for the atmosphere it is the Sun (because that latter is strongly heating the atmosphere layers too!)

[4] Even if most tides are visible by the human eyes on beaches of Ocean and Seas, for lakes tides also exist but are difficult to observe. We need careful experimental measurements as the amplitudes are very small and take into account that most of the time for lakes the weather (atmospheric pressure) has more impact than the Moon itself...

Another nice phenomenon to study mathematically (and to see in real life or on YouTube) are the "tidal bore" which is the leading edge of the incoming tide that forms a wave (or waves) of water that travels up a river or narrow bay against the direction of the river or bay's current[5]:

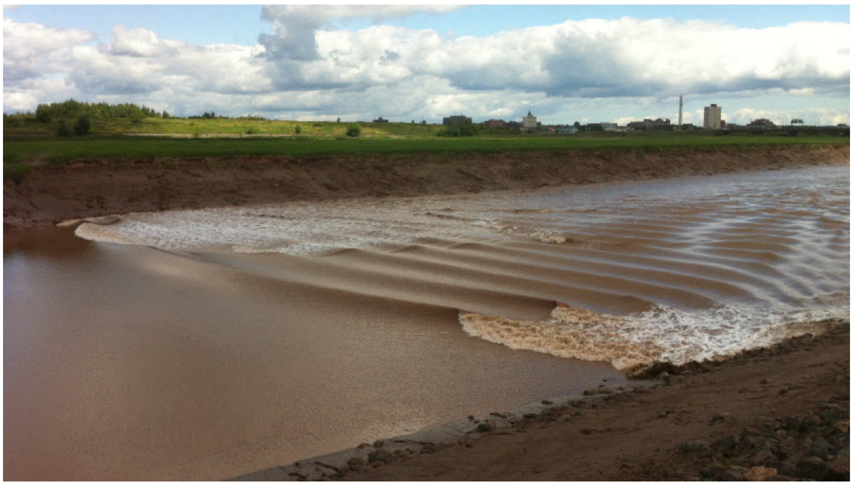

Figure 16.32: **Tidal bore**

The most common type of tides are (some have cyclic and others are totally random and their duration vary a lot):

- Astronomical tides (influence Moon/Sun)
- Rotational tides (due to rotation of Earth)
- Atmospheric tides/Barometric tides[6] (due to meteorological conditions)
- Wind tides[7] (due to the effect of winds on large sea areas)
- Tectonic tides (due to earthquakes)

The ocean and seas tides on Earth are caused by both the Moon's gravity and the Sun's gravity. In general, ocean and seas tides are not generated by the overall strength of gravity as we will see it, but instead by the differences in gravity from one spot to the next (the gravitational gradient). Even though the Sun is much more massive and therefore has stronger overall gravity than the Moon, the Moon is closer to the Earth so that its gravitational gradient is stronger than that of the Sun. Because ocean and seas tides are the effect of ocean water responding to a gravitational gradient, the Moon plays a larger role in creating tides than does the Sun. But the Sun's gravitational gradient across the Earth is significant and it does contribute to tides as well.

As the tides are caused by the gradient of the gravitational field, the tidal force experienced drops with the third power of the distance. This means that the relative strength of the tides should go as :

---

[5] The world largest tidal bore at the time we write these lines seems to be the one located in China's Zhejiang province where it can reach a maximum of nine meter in height at a speed of $40\;[\text{km}\cdot\text{h}^{-1}]$

[6] In areas of high pressure (anticyclones), the sea level decreases. Inversely in areas of low pressure (cyclones). Mean sea level (level 0) corresponds to a pressure of 1013.25 hectopascals (reference pressure). It is necessary to add 1 [cm] or remove 1 [cm] of water height per hectopascal of difference with the reference pressure.

[7] A strong and constant offshore wind causes a drop in sea level of up to 1 meter. Conversely in case of opposite wind direction.

$$\text{ratio} = \frac{M_{\text{moon}} \cdot D_{\text{sun}}^3}{M_{\text{sun}} \cdot D_{\text{moon}}^3} = \frac{7 \cdot 10^{22} \cdot (1.5 \cdot 10^{11})^3}{2 \cdot 10^{30} \cdot (3.7 \cdot 10^8)^3} = 2.3 \tag{16.1.188}$$

So although the Sun is more massive, its greater distance makes its tidal force about 2.3× weaker than the Moon.

16.1.8.1 Astronomical tides (influence Moon/Sun)

Let us first deal with the most famous type of tide that are the astronomical one (due mainly to Sun and Moon)!

Astronomical tide models range from basic theoretical approaches to highly detailed computational simulations. Here's a progression from the simplest to the most advanced:

- **Equilibrium Tide Model** (high-school and undergraduate level model): Based purely on gravitational forces from the Moon and Sun, assuming a perfectly uniform ocean exists in two versions (on considering only the center of mass and can be introduced to almost any high-school student and another considering the vector field that need undergraduate level knowledge of physics). Ignores real-world effects like Earth's rotation, coastlines effects, ocean depth, tidal inertia, etc. The model was developed by Pierre-Simon Laplace in the late 118th century (see the derivations below) according to holocene calendar.
- **Harmonic Analysis Tide Model** (graduate level model): Based on vector field analysis and Navier-Stokes equations taking into account Earth's rotation, fluid sheet thickness, friction resonance and natural periods of ocean basins and leads to spherical harmonics solutions based on historical tide gauge data to identify the tidal parameters of the model and predict future tides ("Laplace's tides equations"). This model requires long-term observations and does not account for sudden oceanographic changes (the theoretical derivation will be written maybe in the future in this textbook). The model was also developed by Pierre-Simon Laplace in the late 118th century (see the derivations below) according to holocene calendar.
- **Hydrodynamic Tide Models** (postgraduate level model): Simulates tidal movements using fluid dynamics equations, incorporating bathymetry, currents, and meteorological influences. This model is computationally demanding; depends on precise input data and need supercomputers (this model will never be detailed in this textbook). The model was developed by a lot of different people from the beginning the early 119th century according to holocene calendar and is still improving today with actually 400 parameters...

16.1.8.1.1 First approach (naive center of mass model)

Let us consider for the naive study of tilde a mass of water m at the equator and at the poles of a rigid Earth (i.e. ground not under the influence of the Moon gravity). We will calculate the attractive force on the mass relatively to the center of the Earth and taking into account the influence of the Moon that has a mass M_L (Lunar influence).

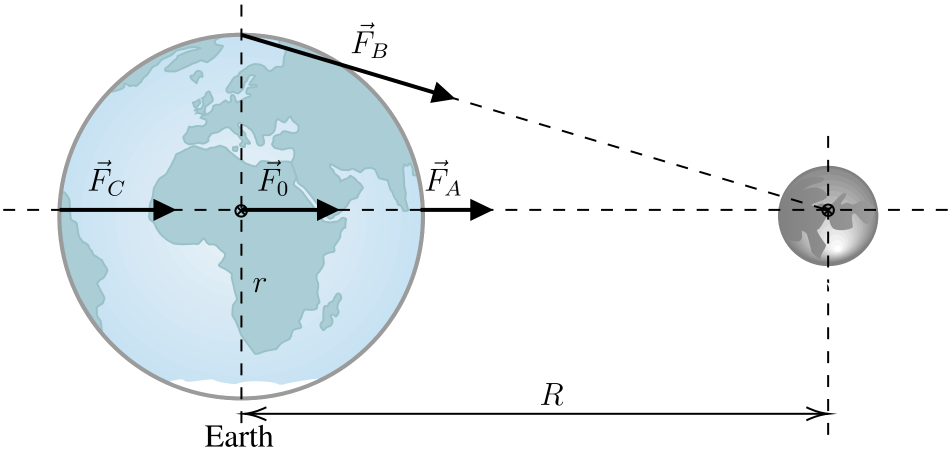

Figure 16.33: **Earth-Moon configuration for a first study of tides**

Let us first compute the force F_a at the equator to the nearest point to the Moon relatively to the figure above.

Then we have:

$$\begin{aligned}\Delta F_L &= F_A - F_0 = G\frac{mM_L}{(R-r)^2} - G\frac{mM_L}{R^2} = GmM_L\frac{R^2-(R-r)^2}{R^2(R-r)^2}\\ &= GmM_L\frac{R^2-R^2+2Rr-r^2}{R^4-2R^3r+R^2r^2} \cong GmM_L\frac{2Rr}{R^4} = 2GmM_L\frac{r}{R^3} = 2f\end{aligned} \tag{16.1.189}$$

considering that $R \gg r$ and denoting the "static tidal force":

$$\boxed{f = GmM_L\frac{r}{R^3}} \tag{16.1.190}$$

A numerical application for a mass $m = 1$ [kg] at the equator then gives $f = 1\cdot 10^{-6}\,[\mathrm{m}\cdot\mathrm{s}^{-1}]$. It's negligible relatively to Earth's gravity g, so this can't explain the tides we observe on the beaches (that have amplitudes of a few meters!).

In vector form the previous relation is obviously written:

$$\Delta\vec{F}_L = 2GmM_L\frac{r}{R^2}\frac{\vec{R}}{\|\vec{R}\|} \tag{16.1.191}$$

As the Earth-Moon distance is approximately 60 Earth radii, the intensity of acceleration varies approximately linearly (...) along the land portion of a line passing through the center of the Moon. This is particularly the case for the segment that connects the two antipodal points A

and C in the figure above. We can write, O denoting the center of the Earth, that:

$$\begin{aligned}\vec{F}_A &\cong \vec{F}_0+\Delta\vec{F}_L\\ \vec{F}_C &\cong \vec{F}_0-\Delta\vec{F}_L\end{aligned} \tag{16.1.192}$$

We must now have to separate the two contributions of the Moon:

1. The force $\vec{F}_0$ applied on the center of mass G is then uniform to the planet by construction. It is this force that is responsible for the revolution of our planet around the common center of mass of the two celestial objects.
2. The residual term $\pm\Delta\vec{F}_L$ is superimposed and takes opposite values at the antipodes. It is responsible for the tides (in the first approximation in this simplistic model).

Thus, the force due to the Moon is of opposite sign to the horizontal. We then have two (lunar) tides per day at antipodal locations:

- That of the Moon who attracts (from this side of the Earth)
- That of the Moon that pushes (at the opposite side of the Earth)

Or schematically (without any respect for real proportions nor the fact that the Moon orbit is elliptical and the Earth is placed on one of the foci of the ellipse):

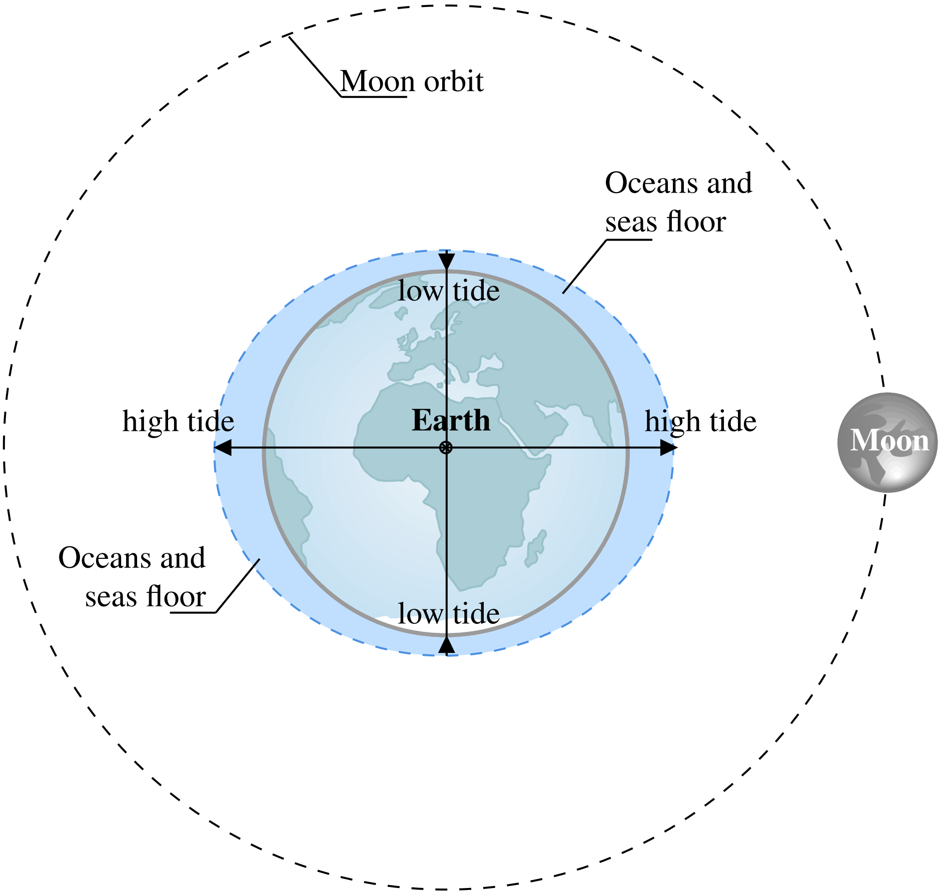

Figure 16.34: **Antipodal tide with antipodal bulge**

If we consider the surface of the Earth as perfectly spherical and covered with water, it would then take the form of an ellipsoid whose axis would be directed to the celestial object generating the tide. We should then observe high tide and low tide that would take place twice a day and always at the same time. We name this the "static tide" and the corresponding model "static model of the tides".

> 💣 The above figure is wrong even if we found it in many textbooks and even some TV show! The outgrowth is incorrectly placed - referred as the "Newtonian model of tides" - and should be rotated from $\pi/2$ as observed experimentally on our planet (there is almost no tides when the Moon is visible above us) and referred as the "Laplacian model of tides".

It should be noted that the subtle play between the rotation of the Earth and the Moon produces enormous friction in water volume that have the effect of slowing the speed of rotation of the Earth about 1 second every thousand years (this will result in a far future in a "tidal lock[8]").

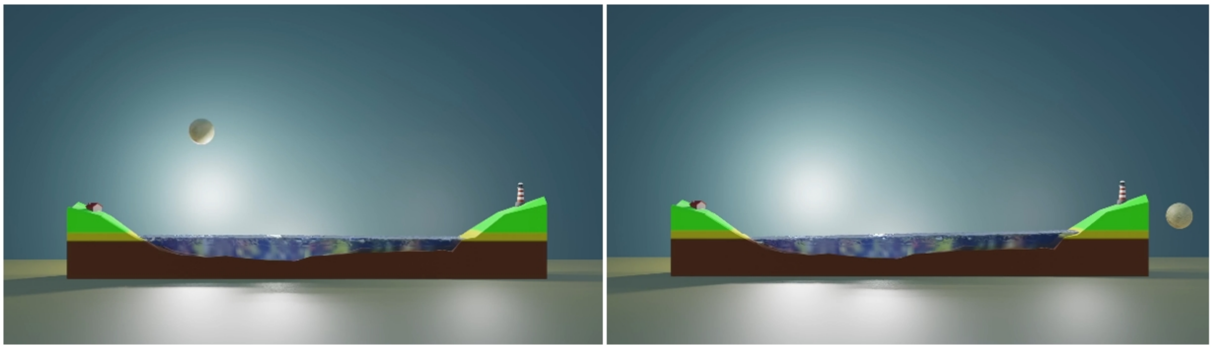

Figure 16.35: Tides are visible in their horizontal component, not in their vertical one (a common misconception by many people) (source: Idées froides/YouTube)

The tides can be huge and varies a lot from area to area because they are simply horizontal waves, moving quite slowly in comparison to conventional waves (even if they move as quick as a running average human), which behaviours depends strongly on the profile of the coasts and the depth of the water (see page 8344). That's why most of the times, ocean tides are bigger than seas tides.

The reflection of waves on the continents explains also why there are also sometimes only on tide per day or even more depending on the place on Earth... obviously of unequal amplitudes! As the reader can imagine, this is real life much more complicated because it is highly multi-factorial!

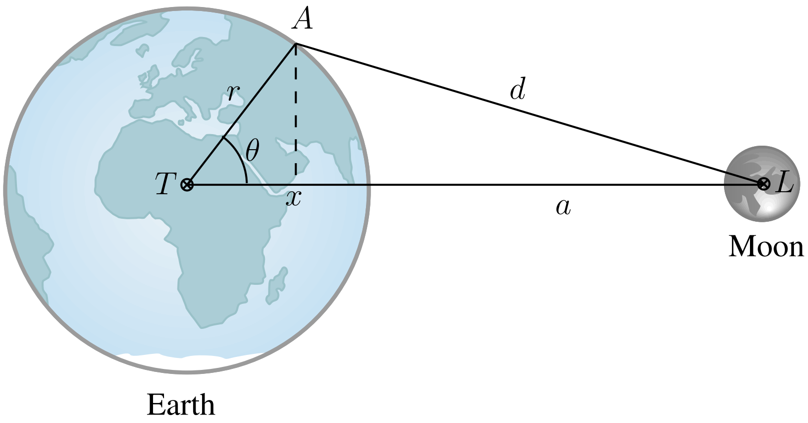
Tides happen without surprise due to the gravitational interactions between the Earth and the Moon. We can say that the tides are pulled by the Moon's gravitational field and so it keeps on changing as it moves out of the Moon's range. The Moon is orbiting the Earth so it has kinetic energy as a consequence of its motion. The Earth is also rotating on its axis, so it has kinetic energy as a consequence of its motion. It is the kinetic energy of the Earth and the Moon which is ultimately the source of tidal energy. That kinetic energy is continually being reduced as a consequence of the tidal friction, but the loss is relatively small.

---

[8] Tidal locking is the phenomenon by which a body has the same rotational period as its orbital period around a partner. So, the Moon is tidally locked to the Earth because it rotates in exactly the same time as it takes to orbit the Earth.

16.1.8.1.2 Second approach (vector field model)

For the second approach, which is worth seeing for general culture and also because it presents another interesting aspect of the explanation of the attraction between two celestial objects, let us consider the following scheme where the Earth doesn't need to be considered as rigid:



We have proved in the section Trigonometry at page 2524 the cosine theorem (Al-Kashi formula) which gives us for recall:

$$d^2 = a^2 + r^2 - 2ar\cos(\theta) \tag{16.1.193}$$

Hence the gravitational potential (see section Astronomy page 5266):

$$\varphi = \frac{GM}{d} = \frac{GM}{\sqrt{a^2 + r^2 - 2ar\cos(\theta)}} = \frac{GM}{a}\frac{1}{\sqrt{1 + \dfrac{r^2}{a^2} - \dfrac{2r\cos(\theta)}{a}}} \quad [\mathrm{J} \cdot \mathrm{kg}^{-1}] \tag{16.1.194}$$

where M is the mass of the Moon. But:

$$\frac{r}{a} \ll 1 \tag{16.1.195}$$

and the gravitational potential is of the form:

$$f(x) = \frac{1}{\sqrt{1+x}} \tag{16.1.196}$$

Which we can develop in series of Maclaurin (see section Sequences and Series page 1703) until order 2:

$$\begin{aligned} f(x) = \frac{1}{\sqrt{1+x}} \underset{x_0=0}{\cong} &= \frac{1}{0!}f(x_0)x^0 + \frac{1}{1!}f'(x_0)x^1 + \frac{1}{2!}f''(x_0)x^2 \\ &= \frac{1}{0!}\frac{1}{(1+x_0)^{1/2}} - \frac{1}{1!}\frac{1}{2}\frac{1}{(1+x_0)^{3/2}}x + \frac{1}{2!}\frac{3}{4}\frac{1}{(1+x_0)^{5/2}}x^2 \\ &= \frac{1}{0!} - \frac{1}{1!}\frac{1}{2}x + \frac{1}{2!}\frac{3}{4}x^2 = 1 - \frac{1}{2}x + \frac{3}{8}x^2 \end{aligned} \tag{16.1.197}$$

The gravitational potential then becomes:

$$\begin{aligned}\varphi &= \frac{GM}{a}\frac{1}{\sqrt{1+\dfrac{r^2}{a^2}-\dfrac{2r\cos(\theta)}{a}}}=\frac{GM}{a}\left[1-\frac{1}{2}\left(\frac{r^2}{a^2}-\frac{2r\cos(\theta)}{a}\right)+\frac{3}{8}\left(\frac{r^2}{a^2}-\frac{2r\cos(\theta)}{a}\right)^2\right]\\ &=\frac{GM}{a}\left[1-\frac{1}{2}\frac{r^2}{a^2}+\frac{r\cos(\theta)}{a}+\frac{3}{8}\left(\frac{r^4}{a^4}-2\frac{r^2}{a^2}\frac{2r\cos(\theta)}{a}+\frac{4r^2\cos^2(\theta)}{a^2}\right)\right]\end{aligned}\tag{16.1.198}$$

If we keep only the terms of power 1 and 2 on r/a, it remains:

$$\begin{aligned}\varphi &\cong \frac{GM}{a}\left[1+\frac{r}{a}\cos(\theta)-\frac{1}{2}\frac{r^2}{a^2}+\frac{3}{8}\frac{4r^2\cos^2(\theta)}{a^2}\right]=\frac{GM}{a}\left[1+\frac{r}{a}\cos(\theta)-\frac{1}{2}\frac{r^2}{a^2}+\frac{1}{2}\frac{3r^2\cos^2(\theta)}{a^2}\right]\\ &=\frac{GM}{a}\left[1+\frac{r}{a}\cos(\theta)+\frac{r^2}{a^2}(3\cos^2(\theta)-1)\right]\end{aligned}\tag{16.1.199}$$

The first term of the potential is:

$$\varphi_1=\frac{GM}{a}\tag{16.1.200}$$

It is the potential for $r=0$, that is to say the potential created by the Moon at the center of the Earth. This term contains no variable, it is constant and therefore its gradient is zero, it gives no force since:

$$\vec{F}=-m\vec{\nabla}\varphi_1=0\tag{16.1.201}$$

The second term:

$$\varphi_2=\frac{GM}{a^2}r\cos(\theta)\tag{16.1.202}$$

contains the two variables r and θ. Its gradient will not be zero. It will generate a gravitational force that we will calculate, but using a trick.

Since:

$$x=r\cos(\theta)\tag{16.1.203}$$

It comes:

$$\varphi_2=\frac{GM_L}{a^2}x\tag{16.1.204}$$

Consequently, the gradient in Cartesian coordinates is reduced for the mass $\mathrm{d}m$ situated at point A by:

$$\mathrm{d}\vec{F}=-\mathrm{d}m\vec{\nabla}\varphi_2=-\mathrm{d}m\begin{pmatrix}\partial_x\\ \partial_y\end{pmatrix}\varphi_2=-\mathrm{d}m\begin{pmatrix}\partial_x\\ \partial_y\end{pmatrix}\frac{GM_L}{a^2}x=-\mathrm{d}m\begin{pmatrix}\dfrac{GM_L}{a^2}\\ 0\end{pmatrix}\tag{16.1.205}$$

Thus all the elements of the Earth undergo from the Moon parallel forces (on the x-axis only) directed towards the Moon. The total mass of the Earth is the sum of all these masses and the total force that the Earth undergoes on the part of the Moon is the sum of the elementary forces. Therefore:

$$\vec{F}=\sum -\mathrm{d}m\vec{\nabla}\varphi_2=\sum -\mathrm{d}m\begin{pmatrix}\dfrac{GM_L}{a^2}\\0\end{pmatrix}=\begin{pmatrix}\dfrac{GM_TM_L}{a^2}\\0\end{pmatrix} \tag{16.1.206}$$

And therefore the total force is only along the x-axis and is given by:

$$F_x=\frac{GM_TM_L}{a^2} \tag{16.1.207}$$

This force is the same as if all the mass of the Earth were concentrated at the center T and if the whole mass of the Moon were concentrated at the center L. The Moon undergoes on the part of the Earth the same force of contrary sense, it is the principle of mutual actions. It is the latter which forces the Moon to revolve around the Earth.

The third term is the one responsible for the tides (some reader may recognize here the spherical harmonic Y_2^0, i.e.. the second Legendre polynomial $P_2(x)=1/2(3x^2-1)$):

$$\boxed{\varphi_3=\frac{GM}{a}\frac{1}{2}\frac{r^2}{a^2}\left(3\cos^2(\theta)-1\right)} \tag{16.1.208}$$

The force deriving from the gradient in polar coordinates is given by (see section Vector Calculus page 1875):

$$\vec{F}=-m\begin{pmatrix}\dfrac{\partial}{\partial r}\\\dfrac{1}{r}\dfrac{\partial}{\partial\theta}\end{pmatrix}\varphi_3=-m\begin{pmatrix}\dfrac{\partial}{\partial r}\\\dfrac{1}{r}\dfrac{\partial}{\partial\theta}\end{pmatrix}\frac{GM}{a}\frac{1}{2}\frac{r^2}{a^2}\left(3\cos^2(\theta)-1\right) \tag{16.1.209}$$

Therefore, the radial component of the force is:

$$F_r=-m\frac{\partial}{\partial r}\frac{GM}{a}\frac{1}{2}\frac{r^2}{a^2}(3\cos^2(\theta)-1)=-\frac{GmMr}{a^3}\left(3\cos^2(\theta)-1\right) \tag{16.1.210}$$

The orthoradial component:

$$\begin{aligned}F_\theta&=-m\frac{1}{r}\frac{\partial}{\partial\theta}\frac{GM}{a}\frac{1}{2}\frac{r^2}{a^2}\left(3\cos^2(\theta)-1\right)=-\frac{GmMR}{2a^3}\frac{\partial}{\partial\theta}(3\cos^2(\theta)-1)\\&=-\frac{3GmMr}{2a^3}\frac{\partial}{\partial\theta}(\cos^2(\theta))=-\frac{3GmMr}{2a^3}(-2\cos(\theta)\sin(\theta))=\frac{3GmMr}{a^3}\cos(\theta)\sin(\theta)\end{aligned} \tag{16.1.211}$$

Therefore:

$$\vec{F}=\begin{pmatrix}F_r\\F_\theta\end{pmatrix}=\begin{pmatrix}F_r\\F_\theta\end{pmatrix}=\begin{pmatrix}-\dfrac{GmMr}{a^3}(3\cos^2(\theta)-1)\\\dfrac{3GmMr}{a^3}\cos(\theta)\sin(\theta)\end{pmatrix} \tag{16.1.212}$$

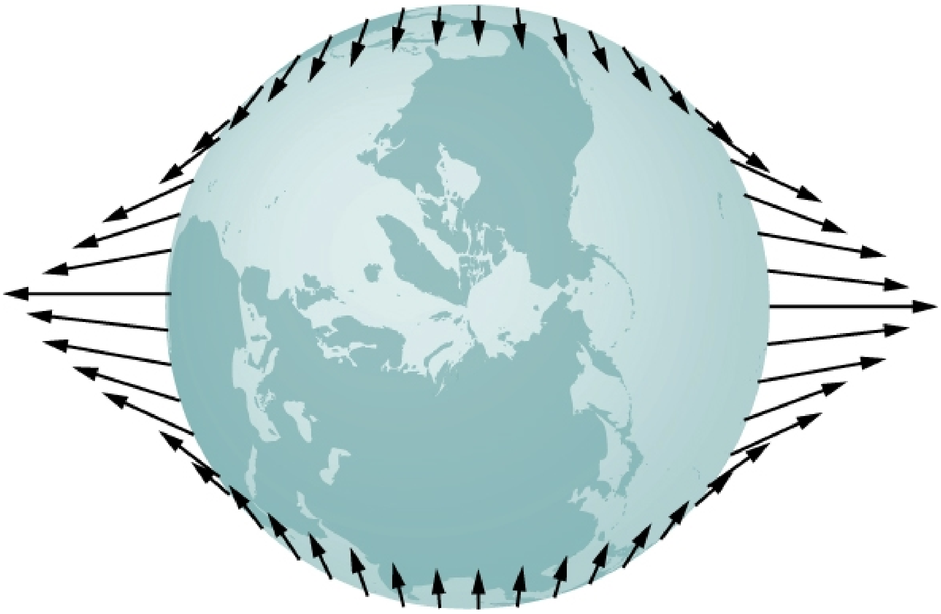
For a mass m of water, the tidal force is:

$$\vec{F}=-m\vec{\nabla}\varphi_3 \tag{16.1.213}$$

For $\theta=\{0,\pi/2,\pi\}$, the orthoradial component F_θ vanishes. We then have for these three angles:

$$\vec{F}=\begin{pmatrix}F_r\\F_\theta\end{pmatrix}=\begin{pmatrix}-\dfrac{GmMr}{a^3}(3\cos^2(\theta)-1)\\0\end{pmatrix}\tag{16.1.214}$$

The tidal force is the difference between the gravitational force at the center and that elsewhere. In the figure below, the tidal forces are shown at the ocean surface. These forces would diminish to zero as you approach Earth's center:



For $\theta=0$ the force is only radial:

$$F_r=-\frac{GmMr}{a^3}(3\cos^2(\theta)-1)=-\frac{GmMr}{a^3}(3\cdot(1)^2-1)=-\frac{2GmMr}{a^3}\tag{16.1.215}$$

The sign of this force is negative and it is directed towards the Moon. For $\theta=\pi$ the force is also only radial and we fall back on the same expression:

$$F_r=-\frac{GmMr}{a^3}(3\cos^2(\theta)-1)=-\frac{GmMr}{a^3}(3\cdot(-1)^2-1)=-\frac{2GmMr}{a^3}\tag{16.1.216}$$

Therefore, the amplitude is the same for the angle $\theta=0=\pi$. Notice that the result is similar with the one we have get with the first approach, at the difference of a factor 2. It is however still not enough to explain the tides as we observe them!

On the other hand, if the reader remember that to return to Cartesian components we have (see section Vector Calculus page 1863):

$$\begin{aligned}x&=r\cos(\theta)\\y&=r\sin(\theta)\end{aligned}\tag{16.1.217}$$

We see then that for $\theta=0$, the force is oriented in the positive direction of the x-axis since x will be positive (but zero following y). There is therefore a tide in the direction of the Moon (almost intuitive).

We also see that for $\theta=\pi$, the force is oriented in the negative direction of the x-axis since x will be negative (but zero following y). There is therefore a tide in the opposite direction to the Moon (counter-intuitive for most people).

For $\theta=\{\pi/2, 3\pi/2\}$, the component x is zero and the radial component will be:

$$F_r=-\frac{GmMr}{a^3}(3\cos^2(\theta)-1)=\frac{GmMr}{a^3} \tag{16.1.218}$$

And it is directed towards the center of the Earth since:

$$\begin{aligned}x&=r\cos(\theta)\\y&=r\sin(\theta)\end{aligned} \tag{16.1.219}$$

We see then that for $\theta=\pi/2$ the force is oriented in the positive direction of the axis y since y will be positive (but zero following x). We also see that for $\theta=3\pi/2$, the force is oriented in the negative direction of the y axis since y will be negative (but zero following x).

In reality, the tides are much more complex than the above model (eccentricity of the lunar orbit, superimposition of the diurnal tide, lunar orbit, Moon-Sun alignment, inclination of the plane of the Moon's orbit, equinoxes, etc.). Here is a superb series of images of the elevation of the surface of the oceans in meters, on one tide cycle , calculated from a more elaborate model:

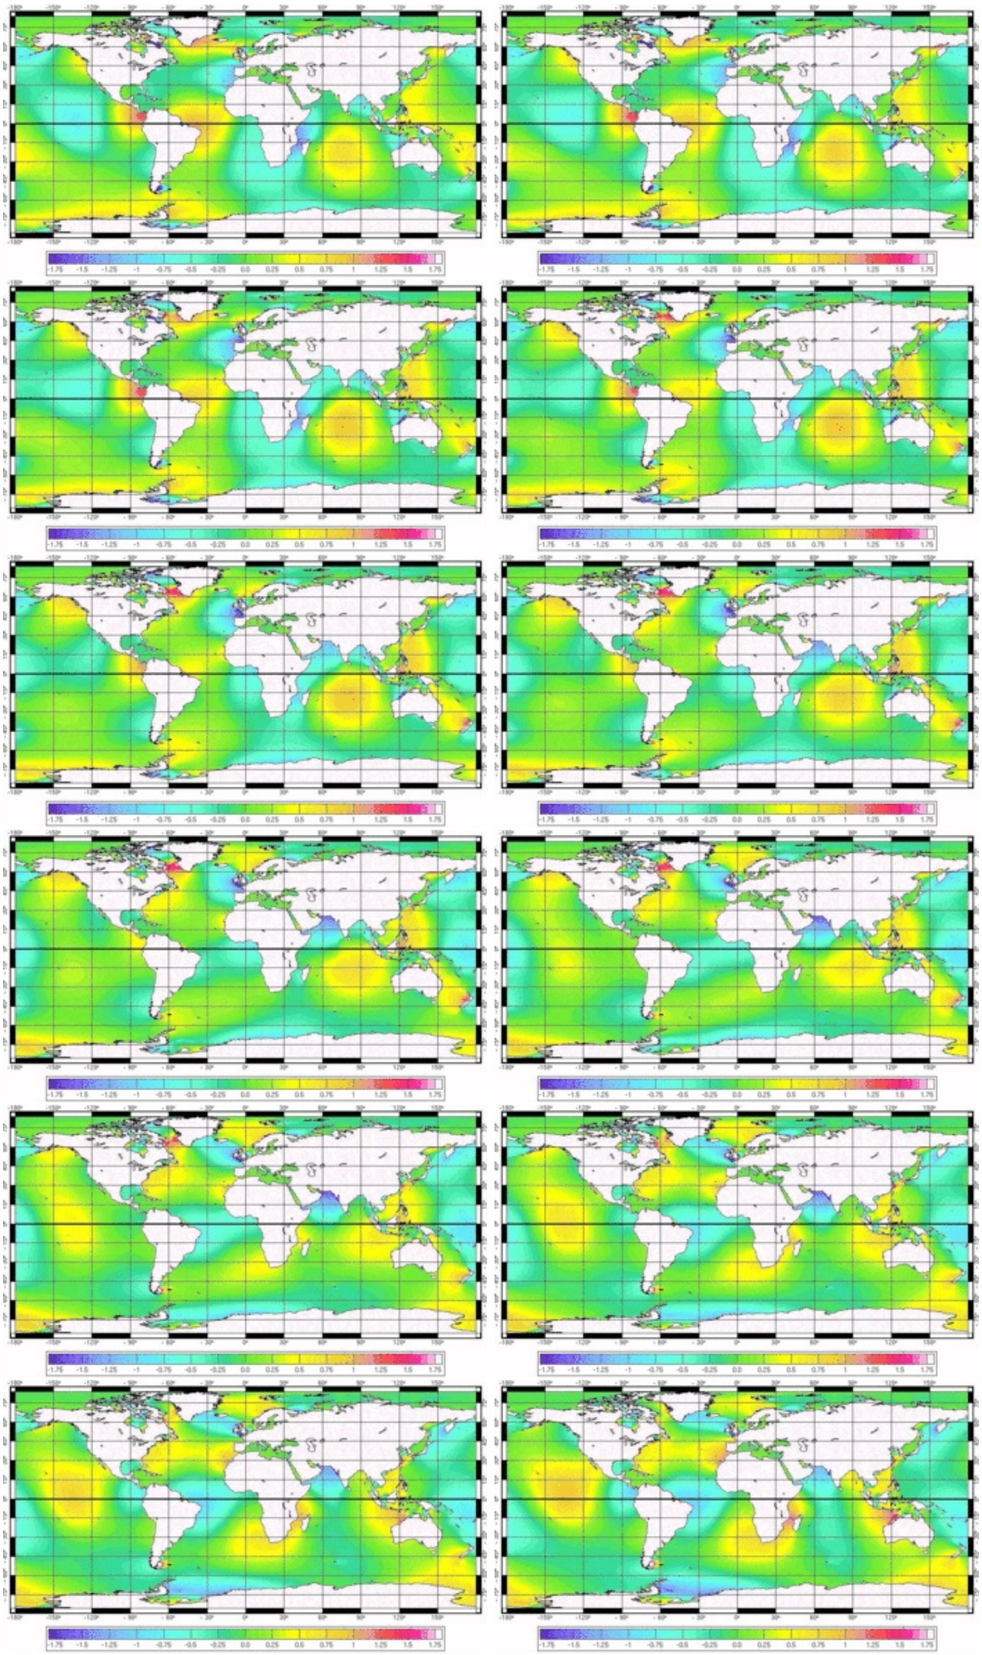

Figure 16.37: **Real complexity of tides on Earth (source: Wikipedia)**

If the Earth were a perfect sphere without large continents, all areas on the planet would experience two equally proportioned high and low tides every lunar day. The large continents on the planet, however, block the westward passage of the tidal bulges as the Earth rotates. Unable to move freely around the globe, these tides establish complex patterns within each ocean basin that often differ greatly from tidal patterns of adjacent ocean basins or other regions of the same ocean.

Three basic tidal patterns occur along the Earth's major shorelines. In general, most areas have two high tides and two low tides each day. When the two highs and the two lows are about the same height, the pattern is named a "semi-daily or semidiurnal tide". If the high and low tides differ in height, the pattern is named a "mixed semidiurnal tide".

Some areas, such as the Gulf of Mexico, have only one high and one low tide each day. This is named a "diurnal tide". The U.S. West Coast tends to have mixed semidiurnal tides, whereas a semidiurnal pattern is more typical of the East Coast.

Remark

The phenomenon is therefore due to the deformation of the surface of the oceans as a result of the combined attractions of the celestial bodies. This movement can even destroy the celestial object which undergoes it: if the tidal force prevails over the gravitational force of its constituents, the celestial objects disintegrates. This limit where the tidal forces outweigh the gravitational force is named the "Roche limit" (see section Astronomy page 5337).

Besides the diurnal tide due to the attraction of the Moon, it is necessary to count on a tide due to the centrifugal force of the movement of the Earth and the Moon around their center of mass (but it depends on the latitudes, the relief and a lot of other parameters objectively because in some places of the planet there is only one tide per day). Indeed, the Earth and the Moon revolve around the center of mass which defines the orbit of Earth-Moon couple (the scales are not respected):

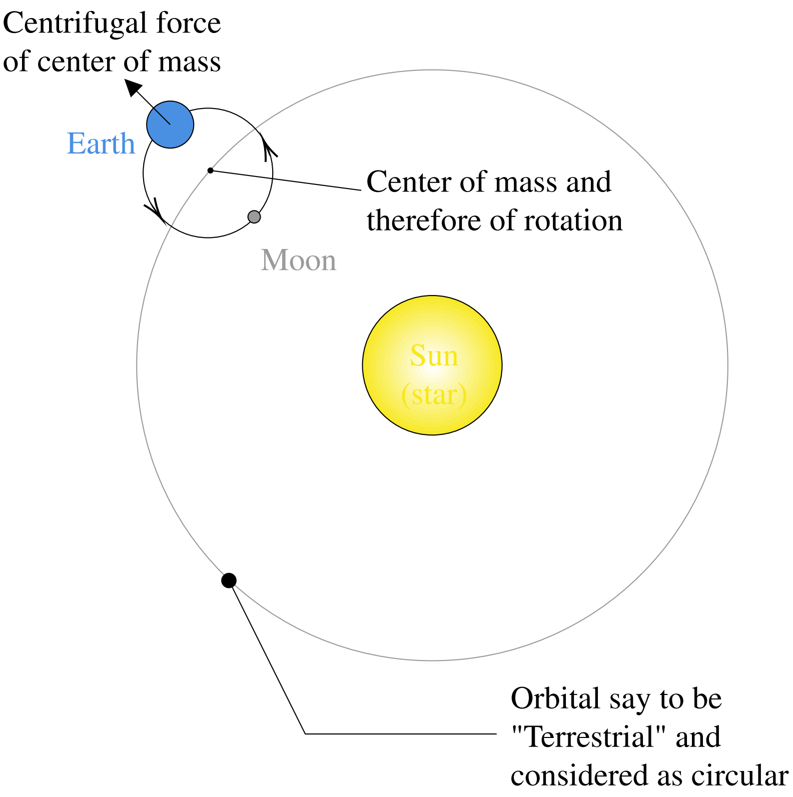

Figure 16.38: **Principle of tides superimposed on diurnal tides**

And we will ignore the tides of equinoxes and others... at least for now...

16.1.8.1.2.1 Tides hight

The simplest way to find the height difference between high and low tides Δh is to observe that the surface of the ocean is an equipotential surface - a surface of constant potential energy. For this, consider a drop of sea water on the surface of the ocean. The drop is in equilibrium (relative to the Earth's reference frame) under the influence of three forces (i.e. potentials): the Earth's gravitational pull, the tidal force and the pressure force of the surrounding sea water. Since a static fluid cannot exert any shearing force, the pressure force must be normal to the surface of the ocean (it is in fact just the buoyancy force of Archimedes' principle). Since the drop of water is in equilibrium, it follows that the tidal potential derived earlier above (for reminder r is the Earth radius and a is the Earth-Moon distance center-to-center):

$$\varphi_{\text{tid.}} = \frac{GM_{\text{moon}}r^2}{2a^3}\left(3\cos^2(\theta)-1\right)\;[\mathrm{J}\cdot\mathrm{kg}^{-1}] \tag{16.1.220}$$

is equal to the geopotential (see section Continuum Mechanics page 3840):

$$\varphi_{\text{geo.}} = g\Delta h\,[\mathrm{J}\cdot\mathrm{kg}^{-1}] \tag{16.1.221}$$

Therefore we can equate these both relations such that:

$$g\Delta h = \frac{GM_{\text{moon}}r^2}{2a^3}\left(3\cos^2(\theta)-1\right) \tag{16.1.222}$$

Rearranging we get:

$$\Delta h=\frac{GM_{\text{moon}}r^2}{g2a^3}\left(3\cos^2(\theta)-1\right) \tag{16.1.223}$$

and as:

$$g=\frac{GM_{\text{earth}}}{r^2} \tag{16.1.224}$$

we get:

$$\Delta h=\frac{M_{\text{moon}}r^4}{2M_{\text{earth}}a^3}\left(3\cos^2(\theta)-1\right) \tag{16.1.225}$$

Or more explicitly written:

$$\boxed{\Delta h=\frac{M_{\text{moon}}R_{\text{earth}}^4}{2M_{\text{earth}}d_{\text{earth-moon}}^3}\left(3\cos^2(\theta)-1\right)} \tag{16.1.226}$$

The extreme values of Δh occur for $\theta=0°$ and $\theta=90°$ gives:

$$\begin{aligned}\Delta h(\text{moon})&=0.38\,[\text{m}]\text{ and }-0.19\,[\text{m}]\\ \Delta h(\text{sun})&=0.17\,[\text{m}]\text{ and }-0.08\,[\text{m}]\end{aligned} \tag{16.1.227}$$

Hence we see that the maximum cumulative difference in this model with the highest and lowest tide is of $(0.38+0.17)+(0.19+0.08)=0.82\,[\text{m}]$. So we are for example very far from the 13 [m] tides of the Mont-Saint-Michel.

Remark

A common question on the Internet relatively to tides is: "*If gravitation can rise entire seas, lands and oceans why doesn't it rise human bodies from the ground (or other animals) ?*" The answer is quite simple and can be understood in two steps. The first one is that the gravitational force is the product of the mass that attracts with the mass that is attracted $(M_1\cdot M_2)$. As the mass of an ocean has a ratio typically of $2\cdot 10^{19}$ with that of a human so is the attractive force too! So the analogy is (as always) a false equivalence... The second step is to understand that humans cannot sense very weak accelarations excepted if they are in a lab and use very sensitive instruments. To grasp the magnitude involved, the reader must keep in mind that the gravitational force of the Moon on a typical human is extremely weak, estimated at approximately $0.004\,[\text{N}]$.

16.1.9 Lorenz equations

The "free convection" or "natural convection" is the flow regime obtained when we heat a fluid without imposing any external flow. This is the case for atmospheric convection movements (hot gases in cold gases), convection movements of the molten rock responsible for plate tectonics, movements of hot water under pressure in geysers or cakes... and many other phenomena...

These flows are inexplicable if we do not couple the equations of dynamics and thermodynamics!

We will in this context establish the famous system of Lorenz equations at the price, however, of numerous approximations and assumptions in order to simplify as much as possible the calculations and the mathematical tools used (because at the time of the development of the model the computers were not what they are today).

We will therefore prove in the context of convection (one of the important dynamics of our atmosphere) that the equations which determine certain parameters of the motion are very sensitive to the initial conditions, the purpose of which is to show the difficulty of predicting to a more or less long term with deterministic theoretical models (reason why in meteorology we use nowadays the method of the finite elements).

A priori, the density ρ is a function of temperature and pressure by the state law of ideal gases (see section Continuum Mechanics page 3903). It is therefore natural to think that if we heat a wall, the temperature of the surrounding fluid increases by diffusion. The pressure stratification is changed, the pressure gradient creates the movement.

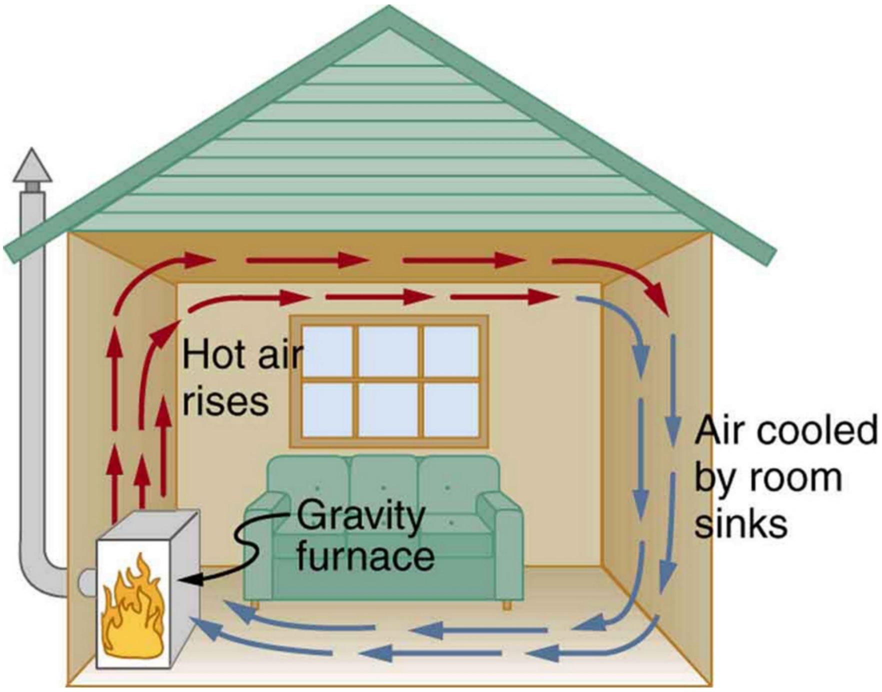

Figure 16.39: **One of the everyday life most known convection...**

In all sections of this textbook, we have so far neglected any variation of ρ. But decoupling is no longer valid here since it is heating that causes movement. We will therefore allow a variation of the density with the heating assuming however that this perturbation is small. It is therefore necessary to reintroduce a variation of ρ around an equilibrium position: rest. On the other hand, the viscosity will be assumed constant...

Thus, given a far fluid at rest and at the temperature T_∞, it is in the presence of a wall heated to the temperature T_P. To obtain the dependence of ρ, let us recall some classical thermo-elastic coefficients (see section Thermodynamics page 3612):

- Coefficient of isobaric compressibility (or dilatation according to the writing in terms of density):

$$\alpha=\frac{1}{V}\frac{\partial V}{\partial T}=\frac{1}{M\rho}\frac{\partial M\rho}{\partial T}=\frac{1}{\rho}\frac{\partial\rho}{\partial T} \tag{16.1.228}$$

- Isothermal compressibility coefficient:

$$\chi=-\frac{1}{V}\frac{\partial V}{\partial P}=-\frac{1}{M\rho}\frac{\partial M\rho}{\partial P}=-\frac{1}{\rho}\frac{\partial\rho}{\partial P} \tag{16.1.229}$$

By assuming now that density is mainly related to temperature (for simplicity) we can write (this hypothesis works well for fluids but not too much ... for gas !!):

$$\rho=f(T) \tag{16.1.230}$$

Using the general form of Taylor's development (see section Sequences and Series page 1696):

$$f(x)=\sum_{k=0}^{n}\frac{1}{k!}\frac{\mathrm{d}^k f(x_0)}{\mathrm{d}x^k}(x-x_0)^k \tag{16.1.231}$$

We then have an approach with the engineer way... :

$$\begin{aligned}\rho(T)&=\sum_{k=0}^{n}\frac{1}{k!}\frac{\mathrm{d}^k f(x_0)}{\mathrm{d}T^k}(T-T_\infty)^k\cong\rho_\infty+(T-T_\infty\frac{\mathrm{d}\rho(T_\infty)}{\mathrm{d}T}=\rho_\infty+\alpha\rho_\infty(T-T_\infty)\\&=\rho_\infty(1+\alpha(T-T_\infty))=\rho_\infty(1+\bar{T}\alpha(T_P-T_\infty)=\rho_\infty(1+\bar{T}\varepsilon)\end{aligned} \tag{16.1.232}$$

Therefore:

$$\boxed{\rho=\rho_\infty\left(1+\bar{T}\varepsilon\right)} \tag{16.1.233}$$

where $\bar{T}$ is therefore a coefficient without dimensions (as ε ...) more easily measurable experimentally.

The continuity equation (see section Thermodynamics page 3679) or of mass balance that is for recall:

$$\frac{\partial\rho(T)}{\partial t}-\vec{\nabla}\circ(\rho(T)\vec{v})=0 \tag{16.1.234}$$

Then becomes:

$$\frac{\partial\rho_\infty(1+\bar{T}\varepsilon)}{\partial t}-\vec{\nabla}\circ(\rho_\infty(1+\bar{T}\varepsilon)\vec{v})=\rho_\infty\varepsilon\frac{\partial\bar{T}}{\partial t}-\rho_\infty(1+\bar{T}\varepsilon)\vec{\nabla}\circ\vec{v}=0 \tag{16.1.235}$$

to the first order in ε. Moreover, we have proved in the section of Continuum Mechanics (see page 3828) that if the fluid is incompressible:

$$\vec{\nabla}\circ\vec{v}=0 \tag{16.1.236}$$

Let us remember that in a first approximation the fluid is incompressible. It then only remains:

$$\rho_\infty\varepsilon\frac{\partial\bar{T}}{\partial t}=0 \tag{16.1.237}$$

As we wish to study a flow in the presence of gravity, it would be judicious to put:

$$P=p+\rho_\infty gz \tag{16.1.238}$$

and therefore to focus only on variations around the hydrostatic equilibrium position (δp is dimensionless!). We have proved still in the same section of Continuum Mechanics (see page 3828) that in the case of the incompressible fluid with viscosity, the first form of Euler's equation (equation of motion):

$$\rho\mathrm{d}_t\vec{v}=-\vec{\nabla}P+\mu_d\vec{\nabla}^2v+\rho f \tag{16.1.239}$$

Let us first consider the both terms:

$$-\vec{\nabla}P+\rho\vec{f} \tag{16.1.240}$$

which are written along the Z axis:

$$-\frac{\partial}{\partial z}P+\rho f_z=-\frac{\partial}{\partial z}P+\rho g=0 \tag{16.1.241}$$

When there is movement, the projection along Z thus make appears:

$$-\frac{\partial}{\partial z}P+\rho g \tag{16.1.242}$$

which we then rewrite:

$$-\frac{\partial}{\partial z}(p+\rho_\infty gz)+\rho g=-\rho_\infty g\frac{\partial}{\partial z}z-\frac{\partial}{\partial z}p+\rho g=-\rho_\infty g-\frac{\partial}{\partial z}p+\rho g \tag{16.1.243}$$

Therefore:

$$-\frac{\partial}{\partial z}p+(\rho-\rho_\infty)g \tag{16.1.244}$$

since:

$$(\rho-\rho_\infty)=\rho_\infty\varepsilon\bar{T} \tag{16.1.245}$$

It comes:

$$-\frac{\partial}{\partial z}p+\rho_\infty\varepsilon\bar{T}g \tag{16.1.246}$$

It remains therefore a buoyancy force directed upward.

The variation of the density as a function of temperature in the product $\rho \mathrm{d}_t\vec{v}$ of the relation:

$$\rho \mathrm{d}_t\vec{v} = -\vec{\nabla}P + \rho\vec{f} \tag{16.1.247}$$

will be neglected ($\rho \mathrm{d}_t\vec{v} \cong \rho_\infty \mathrm{d}_t\vec{v}$) because we will restrict ourselves in case where the speed is small. We have then by reintroducing the viscosity...:

$$\rho_\infty \mathrm{d}_t\vec{v} = -\vec{\nabla}p + \rho_\infty\varepsilon\bar{T}g\vec{e}_z + \mu_d\vec{\nabla}^2 v \tag{16.1.248}$$

and we have then material derivative (see section Continuum Mechanics page 3829):

$$\mathrm{d}_t\vec{v} = (\vec{v}\circ\vec{\nabla})\vec{v} + \partial_t\vec{v} \tag{16.1.249}$$

that we can simplify as:

$$\mathrm{d}_t = \vec{v}\circ\vec{\nabla} + \partial_t \tag{16.1.250}$$

We then have as expression of the force density:

$$\boxed{\rho_\infty\left(\vec{v}(\vec{v}\circ\vec{\nabla}) + \partial_t\vec{v}\right) = -\vec{\nabla}p + \rho_\infty\varepsilon\bar{T}g\vec{e}_z + \mu_d\vec{\nabla}^2 v} \tag{16.1.251}$$

To continue, we will seek to determine the energy law of the equation of behaviour proved in the section Continuum Mechanics (see page 3825) that was for recall:

$$\sigma_{ij} = -p\delta_{ij} - \frac{2}{3}\mu_d(\vec{\nabla}\circ\vec{v})\delta_{ij} + 2\mu_d\theta_{ij} \tag{16.1.252}$$

so that it also accounts for the relation between the stresses and thermodynamic characteristics of the fluid, such as heat flow and temperature. We will do this by characterizing the diffusion of energy in the medium due to the effects (supposedly decoupled) of the viscosity of the fluid and the thermal conduction of the fluid.

We rewrite this relation with new constants and another notation for the divergence:

$$\sigma_{ij} = -p\delta_{ij} + \lambda\mathrm{div}(\vec{v})\delta_{ij} + 2\mu_d\theta_{ij} \tag{16.1.253}$$

where μ_d and λ are in this context named the "Lamé coefficients" (also named the "Lamé parameters" or "Lamé constants"). The terms λ and μ are individually referred to as "Lamé's first parameter" and "Lamé's second parameter".

We have also proved in the section of Continuum Mechanics (see page 3826) the relation:

$$\rho \mathrm{d}_t\vec{v} = \vec{\nabla}(\vec{\sigma}) + \rho\vec{f} \tag{16.1.254}$$

Therefore:

$$\rho((\vec{v}\circ\vec{\nabla})\vec{v} + \partial_t\vec{v}) = \vec{\nabla}(\vec{\sigma}) + \rho\vec{f} \tag{16.1.255}$$

Which gives:

$$\rho\partial_t\vec{v} + \rho(\vec{v}\circ\vec{\nabla})\vec{v} = \vec{\nabla}(\vec{\nabla}) + \rho\vec{g} \tag{16.1.256}$$

Let us denote the total energy as:

$$E_{\text{tot}}=E_c+U=\int_D \frac{1}{2}\rho\vec{v}^2\mathrm{d}V+\int_D e\mathrm{d}V=\rho\int_D\left(\frac{1}{2}\vec{v}^2+e\right)\mathrm{d}V \tag{16.1.257}$$

where e is the internal mass energy of the fluid (so related to a unit of fluid mass). Now the instantaneous variation of the internal energy of the fluid is equal to the contribution of a mechanical power and of the supply of heat (according to what has been seen in the section of Thermodynamics):

$$\frac{\mathrm{d}}{\mathrm{d}t}\rho\int_D\left(\frac{1}{2}\vec{v}^2+e\right)\mathrm{d}V=\frac{\mathrm{d}W}{\mathrm{d}t}+\frac{\mathrm{d}Q}{\mathrm{d}t}=P+\dot{Q} \tag{16.1.258}$$

where P gives the power of the external forces to the system given necessarily by the force of the ambient potential field and the mechanical forces given by the stress tensor only (we are always in the situation of a perfect fluid). That is:

$$P=\int_D \rho\vec{g}\circ\vec{v}\mathrm{d}V+\int_D(\sigma\vec{v})\mathrm{d}\vec{S} \tag{16.1.259}$$

and using the Ostrogradsky theorem (see section Vector Calculus page 1882):

$$\begin{aligned}P&=\int_D\rho(\vec{g}\circ\vec{v})\mathrm{d}V+\int_D((\vec{\nabla})\circ\sigma\vec{v})\mathrm{d}V=\int_D\rho(\vec{g}\circ\vec{v})\mathrm{d}V+\int_D\mathrm{div}(\sigma\vec{v})\mathrm{d}V\\&=\int_D\left[\rho\vec{g}\circ\vec{v}+\mathrm{div}(\sigma\vec{v})\right]\mathrm{d}V=\int_D\left[\rho g_i v_i+\frac{\partial(\sigma_{ij}v_j)}{\partial x_i}\right]\mathrm{d}V\end{aligned} \tag{16.1.260}$$

which has indeed the units of a power. We also have:

$$\begin{aligned}\mathrm{div}(\sigma\vec{v})&=\vec{\nabla}\circ\left(\begin{bmatrix}\sigma_{11}&\sigma_{12}&\sigma_{13}\\\sigma_{21}&\sigma_{22}&\sigma_{23}\\\sigma_{31}&\sigma_{32}&\sigma_{33}\end{bmatrix}\begin{bmatrix}v_1\\v_2\\v_3\end{bmatrix}\right)\\&=\vec{\nabla}\circ\left(\begin{bmatrix}\sigma_{11}v_1+\sigma_{12}v_2+\sigma_{13}v_3\\\sigma_{21}v_1+\sigma_{22}v_2+\sigma_{23}v_3\\\sigma_{31}v_1+\sigma_{32}v_2+\sigma_{33}v_3\end{bmatrix}\right)\\&=\frac{\partial(\sigma_{11}v_1+\sigma_{12}v_2+\sigma_{13}v_3)}{\partial x_1}+\frac{\partial(\sigma_{21}v_1+\sigma_{22}v_2+\sigma_{23}v_3)}{\partial x_2}+\frac{\partial(\sigma_{31}v_1+\sigma_{32}v_2+\sigma_{33}v_3)}{\partial x_3}\\&=\frac{\partial\sigma_{ij}v_j}{\partial x_i}\end{aligned} \tag{16.1.261}$$

For the heat power $\dot{Q}$ it is very easy also thanks to the developments we had made in the section of Thermodynamics where we obtained the equation of heat (see page 3684):

$$\frac{\partial q}{\partial t}+\vec{\nabla}\circ\vec{\Phi}_q=\dot{q}+\vec{\nabla}\circ\vec{\Phi}_q=0 \tag{16.1.262}$$

Therefore:

$$\dot{Q}=\int_D\dot{q}\mathrm{d}V=-\int_D\vec{\nabla}\circ\vec{\Phi}_q\mathrm{d}V \tag{16.1.263}$$

We have finally:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\rho\int_D\left(\frac{1}{2}\vec{v}^2+e\right)\mathrm{d}V&=\int_D\left(\rho g\vec{v}+\mathrm{div}(\sigma\vec{v})\right)\mathrm{d}V-\int_D\vec{\nabla}\circ\Phi_q\mathrm{d}V\\&=\int_D\left(\rho g\vec{v}+\mathrm{div}(\sigma\vec{v})-\vec{\nabla}\circ\vec{\Phi}_q\right)\mathrm{d}V\end{aligned}\tag{16.1.264}$$

So all this gives us the equation of the energy of a fluid:

$$\rho\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{1}{2}\vec{v}^2+e\right)=\rho g\vec{v}+\mathrm{div}(\sigma\vec{v})-\vec{\nabla}\circ\vec{\Phi}_q\tag{16.1.265}$$

Therefore:

$$\rho\frac{\mathrm{d}e}{\mathrm{d}t}+\frac{1}{2}\rho\frac{\mathrm{d}\vec{v}^2}{\mathrm{d}t}=\rho g\vec{v}+\mathrm{div}(\sigma\vec{v})-\vec{\nabla}\circ\vec{\Phi}_q\tag{16.1.266}$$

and as (see section Thermodynamics page 3684) the heat flow follows the Fourier law:

$$\vec{\Phi}_q=-\kappa\vec{\nabla}T\tag{16.1.267}$$

We have then:

$$\rho\frac{\mathrm{d}e}{\mathrm{d}t}+\frac{1}{2}\rho\frac{\mathrm{d}\vec{v}^2}{\mathrm{d}t}=\rho g\vec{v}+\mathrm{div}(\sigma\vec{v})-\vec{\nabla}\circ(-\kappa\vec{\nabla}T)\tag{16.1.268}$$

Either by using the Laplacian definition of a scalar field (see section Vector Calculus page 1899):

$$\rho\frac{\mathrm{d}e}{\mathrm{d}t}+\frac{1}{2}\rho\frac{\mathrm{d}\vec{v}^2}{\mathrm{d}t}=\rho g\vec{v}+\mathrm{div}(\sigma\vec{v})+\kappa\vec{\nabla}^2T\tag{16.1.269}$$

Or explicitly:

$$\rho\frac{\mathrm{d}e}{\mathrm{d}t}+\frac{1}{2}\rho\frac{\mathrm{d}v_iv_i}{\mathrm{d}t}=\rho g_iv_i+\frac{\sigma_{ij}v_j}{\partial x_i}+\kappa\frac{\partial T}{\partial^2x_i}\tag{16.1.270}$$

Now, by making the scalar product of:

$$\rho\mathrm{d}_t\vec{v}=\vec{\nabla}(\vec{\sigma})+\rho\vec{g}\tag{16.1.271}$$

With the velocity $\vec{v}$ we get the balance of the kinetic energy:

$$\rho\vec{v}\circ\mathrm{d}_t\vec{v}=\vec{v}\circ\vec{\nabla}(\vec{\sigma})+\rho\vec{v}\circ\vec{g}\tag{16.1.272}$$

That is to say explicitly:

$$\rho v_i\mathrm{d}_tv_i=\rho\mathrm{d}_t\left(\frac{v_iv_i}{2}\right)=\frac{1}{2}\rho\frac{\mathrm{d}(v_iv_i)}{\mathrm{d}t}=v_i\frac{\partial\sigma_{ij}}{\partial x_i}+\rho v_ig_i\tag{16.1.273}$$

By subtracting (just proved earlier):

$$\rho\frac{\mathrm{d}e}{\mathrm{d}t}+\frac{1}{2}\rho\frac{d\vec{v}^2}{\mathrm{d}t}=\rho g\vec{v}+\mathrm{div}(\sigma\vec{v})+\kappa\vec{\nabla}^2T\tag{16.1.274}$$

and (just proved also earlier above):

$$\rho\vec{v}\circ \mathrm{d}_t\vec{v}=\vec{v}\circ\vec{\nabla}(\vec{\sigma})+\rho\vec{v}\circ\vec{g} \tag{16.1.275}$$

we get a local relation of the specific internal energy e:

$$\rho\frac{\mathrm{de}}{\mathrm{dt}}=-\vec{v}\circ\vec{\nabla}(\vec{\sigma})+\mathrm{div}(\sigma\vec{v})+\kappa\vec{\nabla}^2T \tag{16.1.276}$$

That is to say explicitly:

$$\rho\frac{\mathrm{de}}{\mathrm{dt}}=-v_i\frac{\sigma_{ij}}{\partial x_j}+\frac{\partial(\sigma_{ij}v_j)}{\partial x_i}+\kappa\frac{\partial T}{\partial^2 x_j} \tag{16.1.277}$$

But we also have (derivation of a product):

$$\frac{\partial(\sigma_{ij}v_j)}{\partial x_i}=\sigma_{ij}\frac{\partial v_i}{\partial x_j}+v_i\frac{\partial\sigma_{ij}}{\partial x_j} \tag{16.1.278}$$

Therefore:

$$\frac{\partial(\sigma_{ij}v_j)}{\partial x_i}-v_i\frac{\partial\sigma_{ij}}{\partial x_j}=\sigma_{ij}\frac{\partial v_i}{\partial x_j} \tag{16.1.279}$$

Indeed:

$$\begin{aligned}\frac{\partial(\sigma_{ij}v_j)}{\partial x_i}&=\frac{\partial(\sigma_{11}v_1+\sigma_{12}v_2+\sigma_{13}v_3)}{\partial x_1}+\frac{(\sigma_{21}v_1+\sigma_{22}v_2+\sigma_{23}v_3)}{\partial x_2}+\frac{\partial(\sigma_{31}v_1+\sigma_{32}v_2+\sigma_{33}v_3)}{\partial x_3}\\&=v_1\frac{\partial\sigma_{11}}{\partial x_1}+\sigma_{11}\frac{\partial v_1}{\partial x_1}+v_2\frac{\sigma_{12}}{\partial x_1}+\sigma_{12}\frac{\partial v_2}{\partial x_1}+v_3\frac{\partial\sigma_{13}}{\partial x_1}+\sigma_{13}\frac{\partial v_3}{\partial x_1}\\&+v_1\frac{\partial\sigma_{21}}{\partial x_2}+\sigma_{21}\frac{\partial v_1}{\partial x_2}+v_2\frac{\sigma_{22}}{\partial x_2}+\sigma_{22}\frac{\partial v_2}{\partial x_2}+v_3\frac{\partial\sigma_{23}}{\partial x_2}+\sigma_{23}\frac{\partial v_3}{\partial x_2}\\&+v_1\frac{\partial\sigma_{31}}{\partial x_3}+\sigma_{31}\frac{\partial v_1}{\partial x_3}+v_2\frac{\sigma_{32}}{\partial x_3}+\sigma_{32}\frac{\partial v_2}{\partial x_3}+v_3\frac{\partial\sigma_{33}}{\partial x_3}+\sigma_{33}\frac{\partial v_3}{\partial x_3}\end{aligned} \tag{16.1.280}$$

We have therefore:

$$\rho\frac{\mathrm{de}}{\mathrm{dt}}=\sigma_{ij}\frac{\partial v_i}{\partial x_j}+\kappa\frac{\partial T}{\partial^2 x_j} \tag{16.1.281}$$

And as the stress tensor σ is symmetric:

$$\sigma_{ij}\frac{\partial v_i}{\partial x_j}=\frac{1}{2}\sigma_{ij}\left(\frac{\partial v_i}{\partial x_j}+\frac{\partial v_j}{\partial x_i}\right)=\sigma_{ij}\frac{1}{2}\left(\frac{\partial v_i}{\partial x_j}+\frac{\partial v_j}{\partial x_i}\right)=\sigma_{ij}\mathrm{d}_{ij} \tag{16.1.282}$$

we have therefore:

$$\rho\frac{\mathrm{de}}{\mathrm{dt}}=\sigma_{ij}d_{ij}+\kappa\frac{\partial T}{\partial^2 x_j} \tag{16.1.283}$$

which is sometimes written (yes I also don't believe what I see sometimes...):

$$\rho\frac{\mathrm{de}}{\mathrm{dt}}=\overline{\overline{\sigma}}:\overline{\overline{D}}+\kappa\nabla^2T \tag{16.1.284}$$

where $\overline{\overline{D}}$ is named the "tensor of deformation rate" and $\overline{\overline{\sigma}}:\overline{\overline{D}}$ represents the double contracted product of the stress tensor and deformation rate tensor.

We have proved, for recall, in the section of Continuum Mechanics (see page 3825) that:

$$\sigma=-p\delta_{ij}-\frac{2}{3}\mu_d(\vec{\nabla}\circ\vec{v})\delta_{ij}+2\mu_d\theta_{ij}=-p\theta_{ij}+2\mu_d\left(\theta_{ij}-\frac{1}{3}(\vec{\nabla}\circ\vec{v})\delta_{ij}\right) \tag{16.1.285}$$

where:

$$\tau=2\mu_d\left(\theta_{ij}-\frac{1}{3}(\vec{\nabla}\circ\vec{v})\delta_{ij}\right) \tag{16.1.286}$$

Therefore, it is simple to make the difference between normal forces and tangential forces. Whatever, to come back on the energy equation:

$$\rho\frac{\mathrm{d}e}{\mathrm{d}t}=\sigma_{ij}d_{ij}+\kappa\frac{\partial T}{\partial^2 x_j} \tag{16.1.287}$$

and replacing explicitly the stress tensor σ, we get:

$$\rho\frac{\mathrm{d}e}{\mathrm{d}t}=-p\delta_{ij}d_{ij}+2\mu_d\left(\theta_{ij}-\frac{1}{3}(\vec{\nabla}\circ\vec{v})\delta_{ij}\right)+\kappa\frac{\partial T}{\partial^2 x_j} \tag{16.1.288}$$

But in our case:

$$d_{ij}=\theta_{ij} \tag{16.1.289}$$

therefore we can write:

$$\rho\frac{\mathrm{d}e}{\mathrm{d}t}=-p\delta_{ij}d_{ij}+2\mu_d\left(d_{ij}-\frac{1}{3}(\vec{\nabla}\circ\vec{v})\delta_{ij}\right)+\kappa\frac{\partial T}{\partial^2 x_j} \tag{16.1.290}$$

But we also have (using the trace as seen in the section of Linear Algebra at page 1953):

$$\delta_{ij}d_{ij}=d_{ii}=tr(D)=\frac{1}{2}\left(\frac{\partial v_i}{\partial x_i}+\frac{\partial v_i}{\partial x_i}\right)=\frac{\partial v_i}{\partial x_i}=\vec{\nabla}\circ\vec{v} \tag{16.1.291}$$

We have therefore:

$$\rho\frac{\mathrm{d}e}{\mathrm{d}t}=-p(\vec{\nabla}\circ\vec{v})+2\mu_d d_{ij}d_{ij}+\frac{1}{3}\mu(\vec{\nabla}\circ\vec{v})^2+\kappa\nabla^2 T \tag{16.1.292}$$

Thus into technical condensed form (just for information...):

$$\rho\dot{e}=-p(\vec{\nabla}\circ\vec{v})+2\mu_d\overline{\overline{D}}^2+\lambda(\vec{\nabla}\circ\vec{v})^2+\kappa\nabla^2 T \tag{16.1.293}$$

It is clear that from the point of view of the entropy (see section Thermodynamics page 3658) we have:

$$S=\int_D \rho s\mathrm{d}V \tag{16.1.294}$$

We also have:

$$\mathrm{d}U=T\mathrm{d}S-p\mathrm{d}V\Leftrightarrow\mathrm{d}S=\frac{\mathrm{d}U}{T}+\frac{p\mathrm{d}V}{T} \tag{16.1.295}$$

Thus reduced to the massic values:

$$\mathrm{d}s=\frac{\mathrm{d}e}{T}+\frac{p\mathrm{d}V}{T}\Leftrightarrow \rho T\mathrm{d}s=\rho\mathrm{d}e+\rho p_m\mathrm{d}V \tag{16.1.296}$$

The time variation giving:

$$\rho T\frac{\mathrm{d}s}{\mathrm{d}t}=\rho\frac{\mathrm{d}e}{\mathrm{d}t}+p_m\frac{\mathrm{d}m}{\mathrm{d}t} \tag{16.1.297}$$

But we have the continuity equation (see section Thermodynamics page 3679):

$$\frac{\mathrm{d}m}{\mathrm{d}t}-\vec{\nabla}\circ(m\vec{v})=0\Leftrightarrow\frac{\mathrm{d}m}{\mathrm{d}t}=\vec{\nabla}\circ(m\vec{v}) \tag{16.1.298}$$

Which gives finally:

$$\rho T\frac{\mathrm{d}s}{\mathrm{d}t}=\rho\frac{\mathrm{d}e}{\mathrm{d}t}+p\vec{\nabla}\circ\vec{v} \tag{16.1.299}$$

or written slightly differently:

$$\rho\frac{\mathrm{d}e}{\mathrm{d}t}=\rho T\frac{\mathrm{d}s}{\mathrm{d}t}-p\vec{\nabla}\circ\vec{v} \tag{16.1.300}$$

Injected in:

$$\rho\frac{\mathrm{d}e}{\mathrm{d}t}=-p(\vec{\nabla}\circ\vec{v})+2\mu_d d_{ij}d_{ij}+\lambda(\vec{\nabla}\circ\vec{v})^2+\kappa\nabla^2 T \tag{16.1.301}$$

This gives:

$$\rho T\frac{\mathrm{d}s}{\mathrm{d}t}=2\mu_d d_{ij}d_{ij}+\lambda(\vec{\nabla}\circ\vec{v})^2+\kappa\nabla^2 T \tag{16.1.302}$$

If we consider the velocity gradient to be very small (quasi-static) then we can write the approximation:

$$\rho T\frac{\mathrm{d}s}{\mathrm{d}t}=2\mu_d d_{ij}^2+\kappa\nabla^2 T \tag{16.1.303}$$

Let us now give the expression of the entropy (exact total differential) as a function of the temperature and pressure parameters only:

$$\mathrm{d}S=\left(\frac{\partial S}{\partial T}\right)_P\mathrm{d}T+\left(\frac{\partial S}{\partial P}\right)_T\mathrm{d}P \tag{16.1.304}$$

Either in massic form:

$$\mathrm{d}s=\left(\frac{\partial s}{\partial T}\right)_P\mathrm{d}T+\left(\frac{\partial s}{\partial P}\right)_T\mathrm{d}P \tag{16.1.305}$$

But we have also proved in the section Thermodynamics (see page 3180) the following relation:

$$T\left(\frac{\partial S}{\partial T}\right)_P=C_P=\left(\frac{\partial H}{\partial T}\right)_P \tag{16.1.306}$$

Either in massic form:

$$T\left(\frac{\partial s}{\partial T}\right)_P = c_P = \left(\frac{\partial h}{\partial T}\right)_P \tag{16.1.307}$$

Which gives us:

$$\mathrm{d}s = \frac{c_p}{T}\mathrm{d}T + \left(\frac{\partial s}{\partial P}\right)_T \mathrm{d}P \tag{16.1.308}$$

But, we have also proved in the section Thermodynamics (see page 3672), one of the following Maxwell's relations:

$$\left(\frac{\partial V}{\partial T}\right)_P = -\left(\frac{\partial S}{\partial P}\right)_T \tag{16.1.309}$$

Either in massic form:

$$\left(\frac{\partial \rho^{-1}}{\partial T}\right)_P = -\left(\frac{\partial s}{\partial P}\right)_T \tag{16.1.310}$$

hence:

$$\mathrm{d}s = \frac{c_p}{T}\mathrm{d}T - \left(\frac{\partial \rho^{-1}}{\partial T}\right)_P \mathrm{d}P \tag{16.1.311}$$

Therefore:

$$\rho T \mathrm{d}S = \rho c_p \mathrm{d}T - \rho T\left(\frac{\partial \rho^{-1}}{\partial T}\right)_P \mathrm{d}P = \rho c_P \mathrm{d}T - \frac{T}{\rho}\left(\frac{\partial \rho}{\partial T}\right)_P \mathrm{d}P \tag{16.1.312}$$

Then our relation:

$$\rho T\frac{\mathrm{d}s}{\mathrm{d}t} \cong 2\mu_d (d_{ij})^2 + \kappa \nabla^2 T \tag{16.1.313}$$

can be written:

$$\rho c_p \frac{\mathrm{d}T}{\mathrm{d}t} - \frac{T}{\rho}\left(\frac{\partial \rho}{\partial T}\right)_P \frac{\mathrm{d}P}{\mathrm{d}T} \cong 2\mu_d (d_{ij})^2 + \kappa \nabla^2 T \tag{16.1.314}$$

If we assume that the variation of the density with the temperature is small, we then have at the atmospheric scale:

$$\rho_\infty c_P \frac{\mathrm{d}}{\mathrm{d}t} T \cong 2\mu_d (d_{ij})^2 + \kappa \nabla^2 T \tag{16.1.315}$$

and remembering that (material derivative):

$$\mathrm{d}_t = \vec{v} \circ \vec{\nabla} + \partial_t \tag{16.1.316}$$

It finally comes:

$$\boxed{\rho_\infty c_P (\vec{v} \circ \vec{\nabla} + \partial_t) T \cong 2\mu_d (d_{ij})^2 + \kappa \nabla^2 T} \tag{16.1.317}$$

We now have two important equations:

$$\begin{gathered}\rho_\infty((\vec{v} \circ \vec{\nabla})\vec{v} + \partial_t \vec{v}) = -\vec{\nabla} p + \rho_\infty \varepsilon \bar{T} g \vec{e}_z + \mu_d \vec{\nabla}^2 v \\ \rho_\infty c_P (\vec{v} \circ \vec{\nabla} + \partial_t) T \cong 2\mu_d (d_{ij})^2 + \kappa \nabla^2 T\end{gathered} \tag{16.1.318}$$

Therefore:

$$\boxed{\begin{gathered}(\vec{v} \circ \vec{\nabla})\vec{v} + \partial_t \vec{v} = -\frac{1}{\rho_\infty}\vec{\nabla} p + \varepsilon \bar{T} \vec{g} + \frac{\mu_d}{\rho_\infty}\vec{\nabla}^2 v \\ \rho_\infty c_P (\vec{v} \circ \vec{\nabla} + \partial_t) T \cong 2\mu_d (d_{ij})^2 + \kappa \nabla^2 T\end{gathered}} \tag{16.1.319}$$

16.1.9.1 Rayleigh-Bénard convection cells (Benard-Marangoni instability)

Let us now briefly examine the Rayleigh-Bénard problem, which consists of two plates limiting one fluid being more heated than the other.

Remark

The "Bénard-Marangoni instability" is a free surface configuration of Rayleigh-Bénard instability. In fact, a thin layer of fluid is placed on a horizontal plane but its upper face is not in contact with an other plane but it is a free surface in contact with the air. The temperature of the lower plane must be superior to the temperature of the air to develop instabilities.

We can then observe parallel longitudinal rolls in a film of viscous fluid (silicone oil) held between two plates at a hot temperature at the bottom and cold at the top. Here is a picture of these rolls seen from sides (but normally we don't notice it, because they only get visible when you add mark-particles):

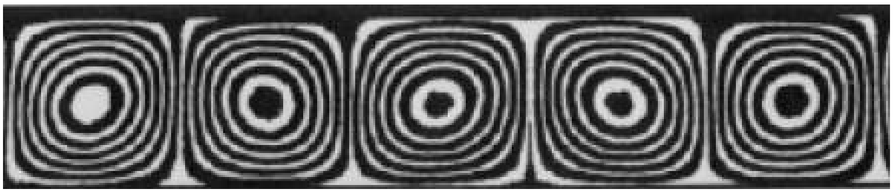

Figure 16.40: Rayleigh-Bénard convection cells (instability)

view from the top:

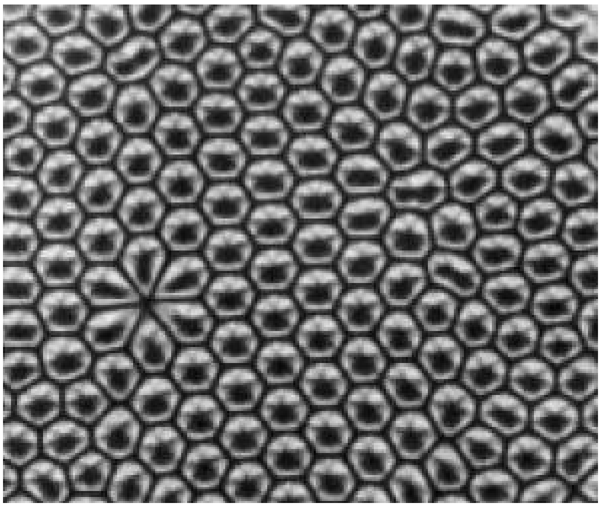

Figure 16.41: Rayleigh-Bénard convection cells viewed from top (instability)

It is a problem of natural convection: the heated fluid at the bottom expands and ascends entrained by the Archimedes principle, arrived at the top it cools and falls down. It is this movement that must be explained that is similar to that of the Earth's atmosphere, Sun (actually a G2V-type star, aka yellow dwarf) convection cells and also Earth's mantel dynamics as illustrated below:

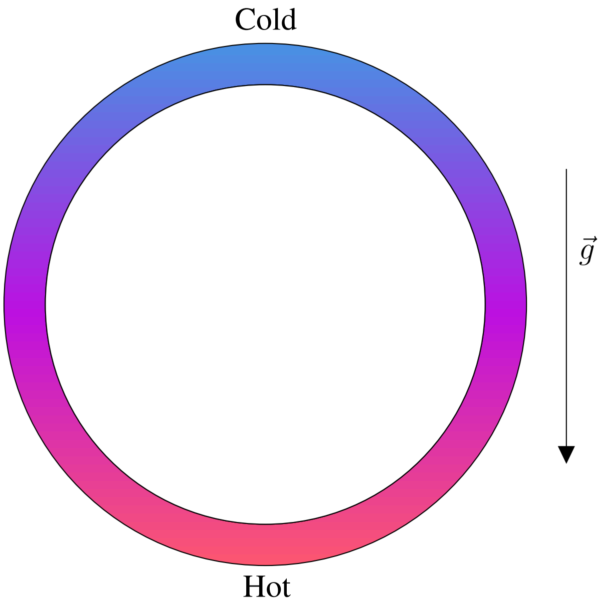
We also notice experimentally that the convection movements are made approximately according to a torus (see the photo seen from the side just above). We can take advantage of this symmetry to simplify the analysis.

Let us consider then a vertical loop of fluid circulating at constant speed (thus without too much turbulence ...):



Cold
$\vec{g}$
Hot

Figure 16.45: **Vertical fluid loop with gradient in homogeneous gravific field**

The configuration will be set as follows:

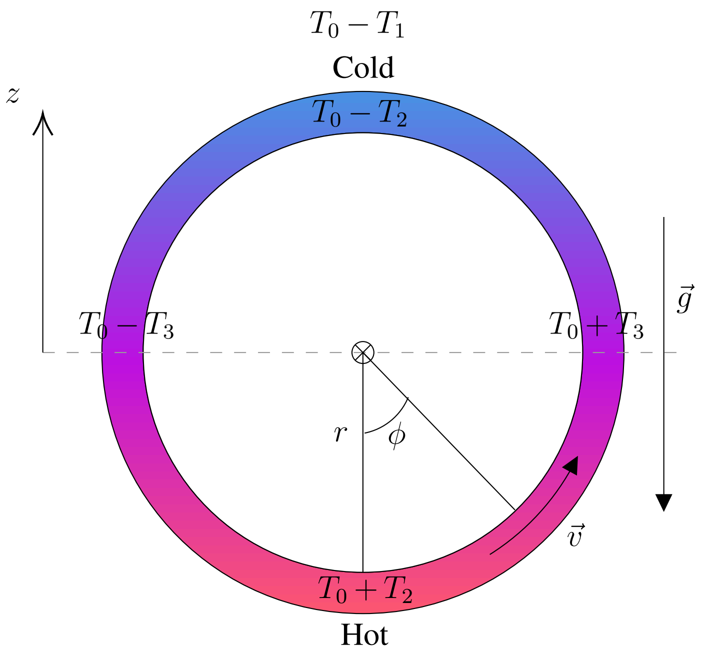


Figure 16.46: Required configuration for the theoretical model of convection cell

Where T_0 is the average temperature of the fluid (caution!: do not forget that it is not an extensive quantity!) and where we indicated respectively the temperatures inside the torus and outside it (i.e. the environment) which may all vary with time.

We see that the difference of temperature is of $2T_2$ between the top and the bottom and of $2T_3$ between the right and the left.

We put that the temperature varies linearly with the height (which of course is false in an atmospheric model ...):

$$T_E = T_0 - T_1\frac{z}{r} = T_0 + T_1\cos(\phi) \tag{16.1.320}$$

We notice that it is possible to parametrise the temperature along the inside of the torus with the following relation (parametric equation of the circle):

$$\Delta T = T - T_0 = T_2\cos(\phi) + T_3\sin(\phi) \tag{16.1.321}$$

We have then according to the figure above:

$$\begin{aligned} T(0) &= T_2\cos(0) + T_3\sin(0) = T_2 + T_0 \\ T(\pi) &= T_2\cos(\pi) + T_3\sin(\pi) = -T_2 + T_0 \\ &\ldots \end{aligned} \tag{16.1.322}$$

Having put this, let us return to:

$$(\vec{v}\circ\vec{\nabla})\vec{v} + \partial_t\vec{v} = -\frac{1}{\rho_\infty}\vec{\nabla}p + \varepsilon\bar{T}\vec{g}\vec{\nabla}^2 v \tag{16.1.323}$$

We will pass this system in polar coordinates best matching the geometry of our problem. Let us recall first that in term:

$$(\vec{v}\,'\circ\vec{\nabla})\vec{v}\,' \tag{16.1.324}$$

the differential operator $\vec{\nabla}$ is the divergence. Now, we have proved in the section of Vector Calculus (see page 1884) that this one was then written in polar coordinates:

$$\vec{\nabla}=\left(\frac{1}{r}\frac{\partial(r}{\partial r},\frac{1}{r}\frac{\partial}{\partial\phi}\right)\tag{16.1.325}$$

Now, if we rely on the hypothesis that in the volume of the torus the velocity varies neither as a function of the angle nor inside the torus (and therefore does not vary according to the radius r), then in polar coordinates :

$$(\vec{v}\,'\circ\vec{\nabla})\vec{v}\,'=0\tag{16.1.326}$$

We have then:

$$\partial_t\vec{v}=-\frac{1}{\rho_\infty}\vec{\nabla}p+\varepsilon\bar{T}\vec{g}+\frac{\mu_d}{\rho_\infty}\vec{\nabla}^2v\tag{16.1.327}$$

We will reduce the analysis to a single dimension which will be that the phenomenon depends only on the angle. We then have in polar coordinates and explicating all the terms:

$$\partial_tv=-\frac{1}{\rho_\infty}\frac{\partial}{\partial\phi}p+\varepsilon(T-T_0)\sin(\phi)-\frac{\mu_d}{\rho_\infty}\frac{1}{r^2}\frac{\partial^2}{\partial\phi^2}v\tag{16.1.328}$$

where we have at the same time made the projection along the z axis such that:

$$\vec{g}=g\vec{e}_z=g\sin(\phi)\tag{16.1.329}$$

The differential coefficient of the last term will bother us. We replace it by a coefficient Γ which we assume to be constant and which opposes the motion such as we have:

$$\partial_tv=-\frac{1}{\rho_\infty}\frac{\partial p}{\partial\phi}+g\varepsilon(T-T_0)\sin(\phi)-\Gamma v\tag{16.1.330}$$

or more explicitly:

$$\partial_tv=-\frac{1}{\rho_\infty}\frac{\partial p}{\partial\phi}+g\varepsilon(T_2\cos(\phi)+T_3\sin(\phi))\sin(\phi)-\Gamma v\tag{16.1.331}$$

We now integrate this on the whole loop as a function of ϕ. We have then:

$$\int\limits_0^{2\pi}\partial_tv'\mathrm{d}\phi=-\frac{1}{\rho_\infty}\underbrace{\int\limits_0^{2\pi}\frac{\partial p}{\partial\phi}\mathrm{d}\phi}_{=0}+g\varepsilon\int\limits_0^{2\pi}(T_2\cos(\phi)+T_3\sin(\phi))\sin(\phi)\mathrm{d}\phi-\Gamma\int\limits_0^{2\pi}v\mathrm{d}\phi\tag{16.1.332}$$

We then have the pressure term which disappears, because there is no pressure gradient along the loop. So:

$$2\pi\partial_tv=\varepsilon g\int\limits_0^{2\pi}(T_2\cos(\phi)+T_2\sin(\phi))\sin(\phi)\mathrm{d}\phi-2\pi\Gamma v\tag{16.1.333}$$

We then have for the first term (see section Differential and Integral Calculus page 1534):

$$\int\limits_0^{2\pi}\cos(\phi)\sin(\phi)\mathrm{d}\phi=\frac{1}{2}\sin^2(\phi)\Big|_0^{2\pi}=0\tag{16.1.334}$$

and for the second term:

$$\int_0^{2\pi} \sin^2(\phi)\mathrm{d}\phi = \pi \tag{16.1.335}$$

Then it remains:

$$2\pi\partial_t v = \varepsilon g \pi T_3 - 2\pi\Gamma v \tag{16.1.336}$$

Therefore:

$$\partial_t v = \varepsilon g \pi \frac{T_3}{2} - \Gamma v \tag{16.1.337}$$

We see in this equation that the motion is driven by the horizontal temperature difference T_3.

Now, let us come back to:

$$\partial_T + \vec{v} \circ \vec{\nabla} T \cong \frac{2\mu_d}{\rho_\infty c_P}(d_{ij})^2 + \frac{\kappa}{\rho_\infty c_P}\nabla^2 T \tag{16.1.338}$$

If we neglect the tangential forces inside fluid, then we have:

$$\partial_t T + \vec{v} \circ \vec{\nabla} T \cong D\nabla^2 T \tag{16.1.339}$$

where D is the thermal diffusion coefficient (see section Thermodynamics page 3595).

In polar coordinates this is reduced to:

$$\partial_t T + v\frac{1}{r}\frac{\partial}{\partial\phi}T = D\frac{1}{r}\frac{\partial^2}{\partial\phi^2}T \tag{16.1.340}$$

and we will also make another approximation:

$$\partial_t T + \frac{v}{r}\frac{\partial T}{\partial\phi} \cong KT \tag{16.1.341}$$

And we have the two relations:

$$\begin{gathered} T_E = T_0 + T_1\cos(\phi) \\ T - T_0 = T_2\cos(\phi) + T_3\sin(\phi) \end{gathered} \tag{16.1.342}$$

By subtracting:

$$T_E - T = (T_1 - T_2)\cos(\phi) - T_3\sin(\phi) \tag{16.1.343}$$

Therefore:

$$\partial_t T + \frac{v}{r}\frac{\partial T}{\partial\phi} \cong K\left[(T_1 - T_2)\cos(\phi) - T_2\sin(\phi)\right] \tag{16.1.344}$$

and also:

$$\partial_t(T_0 + T_2\cos(\phi) + T_3\sin(\phi)) + \frac{v}{r}\frac{\partial}{\partial\phi}(T_0 + T_2\cos(\phi) + T_3\sin(\phi)) \cong K(T_1 - T_2)\cos(\phi) - KT_3\sin(\phi) \tag{16.1.345}$$

Therefore:

$$\frac{\mathrm{d}T_2}{\mathrm{d}t}\cos(\phi)+\frac{\mathrm{d}T_3}{\mathrm{d}t}\sin(\phi)+\frac{v}{r}T_2\frac{\partial\cos(\phi)}{\partial\phi}+\frac{v}{r}T_3\frac{\partial\sin(\phi)}{\partial\phi}\cong K(T_1-T_2)\cos(\phi)-KT_3\sin(\phi) \tag{16.1.346}$$

After derivation:

$$\frac{\mathrm{d}T_2}{\mathrm{d}t}\cos(\phi)+\frac{\mathrm{d}T_3}{\mathrm{d}t}\sin(\phi).\frac{v}{r}T_2\sin(\phi)+\frac{v}{r}T_3\cos(\phi)\cong K(T_1-T_2)\cos(\phi)-KT_3\sin(\phi) \tag{16.1.347}$$

We group together the terms:

$$\left[\frac{\mathrm{d}T_2}{\mathrm{d}t}+\frac{vT_3}{r}\right]\cos(\phi)+\left[\frac{\mathrm{d}T_3}{\mathrm{d}t}-\frac{v}{r}T_2\right]\sin(\phi)\cong K(T_1-T_2)\cos(\phi)-KT_3\sin(\phi) \tag{16.1.348}$$

We then have the following three differential equations that govern the dynamics of the system:

$$\begin{aligned}&\frac{\mathrm{d}T_2}{\mathrm{d}t}+\frac{vT_3}{r}\cong K(T_1-T_2)\\&\frac{\mathrm{d}T_3}{\mathrm{d}t}-\frac{v}{r}T_2\cong -KT_3\\&\frac{\mathrm{d}v}{\mathrm{d}t}=\varepsilon g\frac{T_3}{2}-\Gamma v\end{aligned} \tag{16.1.349}$$

We finish the multiple simplifications by putting...:

$$T_4(t)=T_1-T_2(t) \tag{16.1.350}$$

Which gives us:

$$\begin{aligned}&\frac{\mathrm{d}T_2}{\mathrm{d}t}=\frac{\mathrm{d}(T_1-T_4(t))}{\mathrm{d}t}=-\frac{\mathrm{d}T_4}{\mathrm{d}t}\cong KT_4-\frac{vT_3}{r}\\&\frac{\mathrm{d}T_3}{\mathrm{d}t}=-KT_3+\frac{vT_2}{r}=-KT_3+\frac{vT_1}{r}-\frac{vT_4}{r}\\&\frac{\mathrm{d}v}{\mathrm{d}t}=\varepsilon g\frac{T_3}{2}-\Gamma v\end{aligned} \tag{16.1.351}$$

Putting it this in a more clean way, we get:

$$\boxed{\begin{aligned}&\frac{\mathrm{d}v}{\mathrm{d}t}=-\Gamma v+\varepsilon g\frac{T_3}{2}\\&\frac{\mathrm{d}T_3}{\mathrm{d}t}=-KT_3+\frac{vT_1}{r}-\frac{vT_4}{r}\\&\frac{\mathrm{d}T_4}{\mathrm{d}t}\cong -KT_4+\frac{vT_3}{r}\end{aligned}} \tag{16.1.352}$$

Now, let introduce the following dimensionless variables:

$$X=\frac{v}{rK}\qquad Y=\frac{g\varepsilon T_3}{2r\Gamma K}\qquad Z=\frac{g\varepsilon T_4}{2r\Gamma K}\qquad t'=tK \tag{16.1.353}$$

where we can assimilate:

- X at the non-dimensional speed
- Y to the non-dimensional temperature difference between rising and falling currents
- Z to the dimensionless deviation of the convection equilibrium

We then have indeed:

$$\begin{aligned}\frac{\mathrm{d}\left(\dfrac{v}{rK}\right)}{\mathrm{d}tK}&=-\frac{\Gamma}{K}\frac{v}{rK}+\frac{\Gamma}{K}\frac{g\varepsilon T_3}{2r\Gamma K}\\ \frac{\mathrm{d}\left(\dfrac{g\varepsilon T_3}{2r\Gamma K}\right)}{\mathrm{d}tK}&=-\frac{g\varepsilon T_3}{2r\Gamma K}+\frac{g\varepsilon T_1}{2r\Gamma K}\frac{v}{rK}-\frac{g\varepsilon T_4}{2r\Gamma K}\frac{v}{rK}\\ \frac{\mathrm{d}\left(\dfrac{g\varepsilon T_4}{2r\Gamma K}\right)}{\mathrm{d}tK}&\cong-\frac{g\varepsilon T_4}{2r\Gamma K}+\frac{g\varepsilon T_3}{2r\Gamma K}\frac{v}{rK}\end{aligned}\tag{16.1.354}$$

Therefore:

$$\begin{aligned}\frac{\mathrm{d}X}{\mathrm{d}t'}&=-\mathrm{Pr}X+\mathrm{Pr}Y\\ \frac{\mathrm{d}Y}{\mathrm{d}t'}&=-Y+\mathrm{Re}X-XZ\\ \frac{\mathrm{d}Z}{\mathrm{d}t'}&=-Z+YX\end{aligned}\tag{16.1.355}$$

In an even more condensed and traditional form:

$$\boxed{\begin{aligned}X'&=\mathrm{Pr}(Y-X)\\ Y'&=rX-Y-XZ\\ Z'&=-Z+YX\end{aligned}}\tag{16.1.356}$$

where we have:

$$\mathrm{Pr}=\frac{\Gamma}{K}\cong\frac{\dfrac{\mu_d}{\rho_\infty}\dfrac{1}{r}\dfrac{\partial^2}{\partial\phi}}{k\dfrac{1}{r}\dfrac{\partial^2}{\partial\phi^2}}=\frac{\mu_d}{\rho_\infty k}=\frac{\mu_d}{\rho_\infty\dfrac{\kappa}{\rho_\infty c_P}}=\frac{\mu_d c_P}{\kappa}\tag{16.1.357}$$

where we have:

$$\mathrm{Pr}=\frac{\Gamma}{K}\cong\frac{\dfrac{\mu_d}{\rho_\infty}\dfrac{1}{r}\dfrac{\partial^2}{\partial\phi}}{k\dfrac{1}{r}\dfrac{\partial^2}{\partial\phi^2}}=\frac{\mu_d}{\rho_\infty k}=\frac{\mu_d}{\rho_\infty\dfrac{\kappa}{\rho_\infty c_P}}=\frac{\mu_d c_P}{\kappa}\tag{16.1.358}$$

that correspond to the "Prandtl number" that a dimensionless number, named after the German physicist Ludwig Prandtl, defined as the ratio of "momentum diffusivity" to "thermal diffusivity" and where for recall:

- Γ is the momentum diffusivity (kinematic viscosity) in $[\text{m}^2 \cdot \text{s}^{-1}]$
- K is the thermal diffusivity in $[\text{m}^2 \cdot \text{s}^{-1}]$
- μ_d is the dynamic viscosity in $[\text{Ps}^2 \cdot \text{s}]$
- κ is the thermal conductivity in $[\text{W} \cdot \text{m}^{-1} \cdot \text{K}^{-1}]$
- c_P is the specific heat in $[\text{J} \cdot \text{kg}^{-1} \cdot \text{K}^{-1}]$

with some typical values:

Material	**Prandtl Number Value**
Molten potassium at 975 [K]	0.003
Mercury	0.015
Noble gases	0.16-0.17
Oxygen	0.63
Molten lithium at 975 [K]	0.065
Air	0.7-0.8
Gaseous ammoniac	1.38
Water	7
Seawater at 293 [K]	7.2
Seawater at 273 [K]	13.4
n-butanol	50
Engine oil	100-$40,000$
Glycerol	$1,000$
Polymer melts	$10,000$
Earth's mantle	$1 \cdot 10^{25}$

Table 16.6: Typical values for Pr (source: Wikipedia)

And:

$$\text{Re} = \frac{g\varepsilon T_1}{2r\Gamma K} = \frac{g\varepsilon T_1}{2r\Gamma K} = \frac{g\varepsilon T_1}{2r\dfrac{\mu_d}{\rho_\infty}D\left(\dfrac{1}{r}\dfrac{\partial^2}{\partial\phi^2}\right)^2} = \frac{g\varepsilon\dfrac{T_1}{2}r}{\mu_c D\left(\dfrac{\partial^2}{\partial\phi^2}\right)^2} = \frac{g\varepsilon\dfrac{T_1}{2}L^3}{\mu_c D} \tag{16.1.359}$$

which is assimilated to the "Rayleigh number" that is also a dimensionless number associated with "buoyancy-driven flow", also known as "free convection" or "natural convection". When the Rayleigh number is below a critical value for that fluid, heat transfer is primarily in the form of conduction; when it exceeds the critical value, heat transfer is primarily in the form of convection.

16.1.9.2 Lorenz attractor and chaos

The previous system of three equations is essentially the same as that of the famous "Lorenz system". With one difference (!), the (real) Lorenz system contains a factor b in the last equation (which does not change the result anyway since we still get a strange attractor in the end as we will see):

$$\boxed{\begin{aligned}\frac{\mathrm{d}X}{\mathrm{d}t'}&=-\mathrm{Pr}X+\mathrm{Pr}Y\\ \frac{\mathrm{d}Y}{\mathrm{d}t'}&=-Y+\mathrm{Re}X-XZ\\ \frac{\mathrm{d}Z}{\mathrm{d}t'}&=-bZ+YX\end{aligned}} \tag{16.1.360}$$

Pr, Re and b are strictly positive, and we often put $\mathrm{Pr}=10$, $\mathrm{Re}=28$, $b=8/3$ where the Prandtl number corresponds to the value of that of water.

The Lorenz equations describe the convection phenomena of an ideal two-dimensional fluid in a reservoir heated from below.

We see by this by this proof that contrary to the statements not proved on many Internet pages and forums that:

1. The system is by no far not simple mathematically and is very approximate
2. That there are simpler systems to study that are also chaotic (see section Population Dynamics page 7317)

The interest of the Lorenz equations lies, however, in the sensitivity to the initial conditions and the convergence of the dimensionless variables.

Let's see an example with Maple™ 4.00b:

```
>with(DEtools):
>lorenz:=diff(x(t),t) = 10*(y(t)-x(t)),diff(y(t),t) =
28*x(t)-y(t)-x(t)*z(t),
diff(z(t),t) = x(t)*y(t)-8/3*z(t);
>DEplot3d(lorenz, [x(t),y(t),z(t)], t=0..100, stepsize=0.01, [[x(0)=10,
y(0)=10, z(0)=10]], orientation=[-35,75], linecolor = t, thickness = 1);
```

This gives for the first 100 units of dimensionless time (it's a perfect example of chaos producing order!):

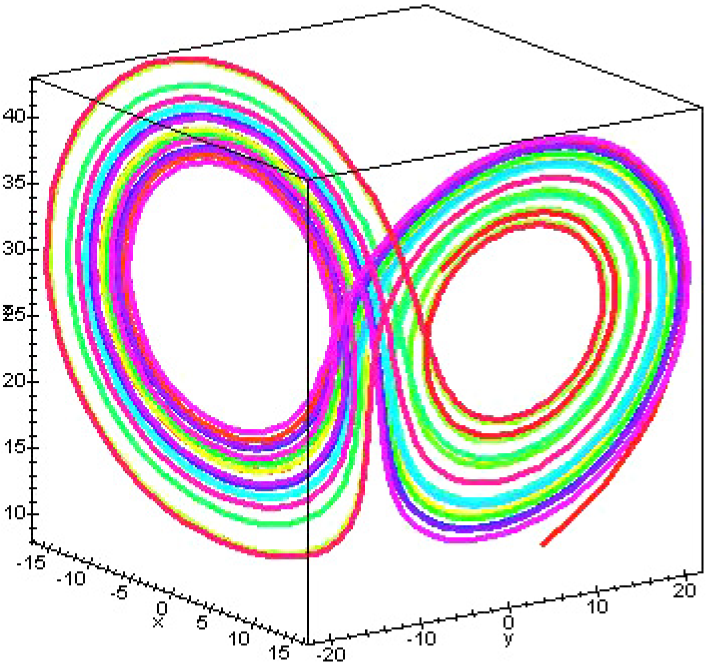

Figure 16.47: **Phase space of the Lorenz equations system in Maple™ 4.00b**

or for the first 10 units of dimensionless time:

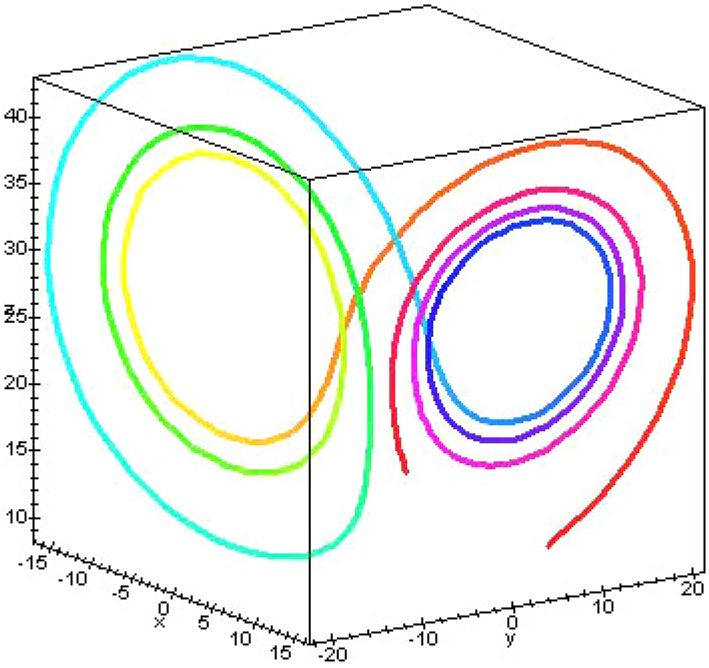

Figure 16.48: **Phase space of the Lorenz equations system in Maple™ 4.00b**

Well so far we realize that the dimensionless parameters revolve around two points named the "strange attractors".

Definition (#16.1.725): In the study of dynamic systems, an "attractor" (or "set-limit") is a set, a curve or a space towards which a system evolves irreversibly in the absence of perturbations.

Now always for the same values of adimensional time, we take $x(0)=10.1$, that is to say a relatively small change of the initial conditions. We have then:

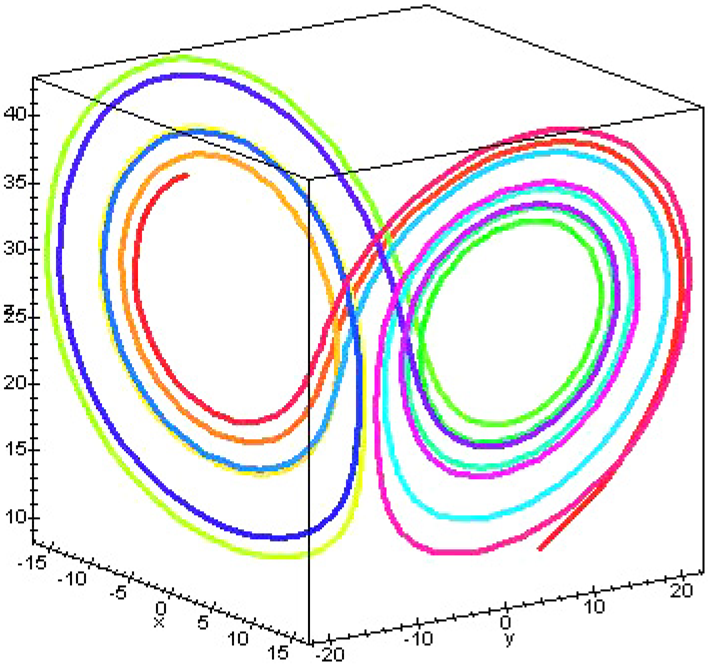

Figure 16.49: Small variation in initial conditions of the Lorenz system with Maple™ 4.00b

We thus notice that the phenomenon is no longer really similar.

Let us consider for example the variable x taking as initial conditions:

$$x(0)=10 \qquad y(0)=10 \qquad z(0)=10$$

then:

$$x(0)=10 \qquad y(0)=10.1 \qquad z(0)=10$$

thus a small variation of 0.01 on the value of $y(0)$.

Either in Maple™ 4.00b:

```
>DEplot(lorenz, [x(t), y(t), z(t)], t=0..15, stepsize = 0.01, [[x(0)=10,
y(0)=10, z(0)=10],[x(0)=10, y(0)=10.01, z(0)=10]], scene = [t,x],
linecolor = [blue,green], thickness = 1);
```

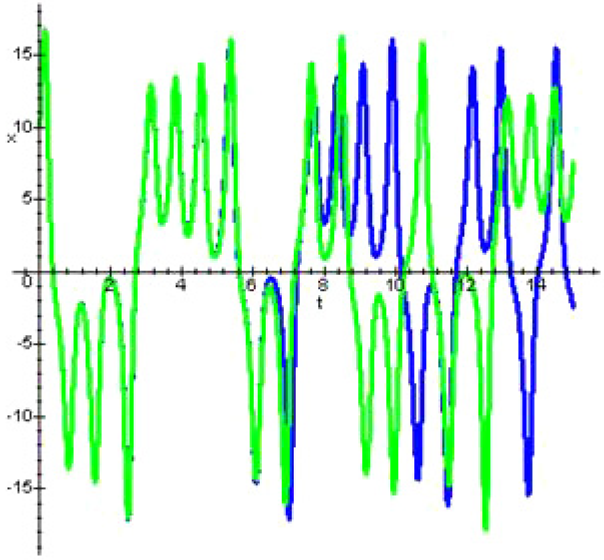

Figure 16.50: **Analysis of the dimensionless variable x for a small variation of initial conditions with Maple™ 4.00b**

We see that the system shifts rather quickly from the initial model whereas at the beginning it remains identical but the overall shape remains.

Another thing ... depending on the parameters the system can converge. Indeed, by changing the factor 28 by the value 22 we have for example (convergence on the left):

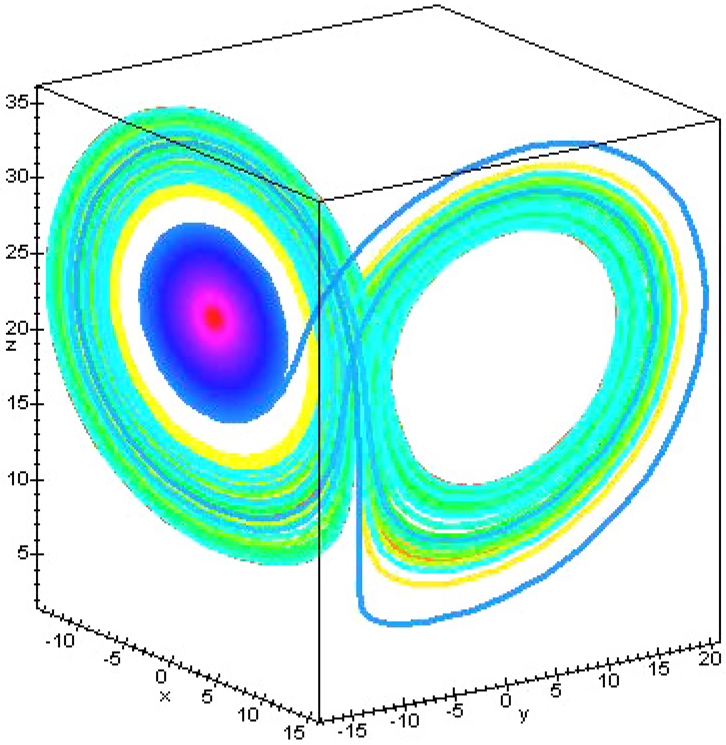

Figure 16.51: **Convergence of the Lorenz system with Maple™ 4.00b**

or with the value 19 the result is even more trivial:

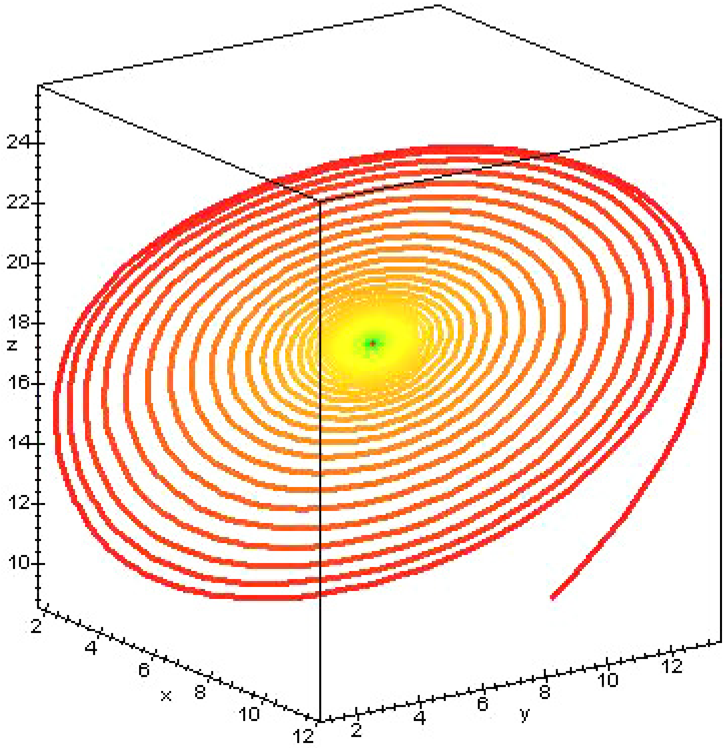

Figure 16.52: **Convergence of the Lorenz system with Maple™ 4.00b**

Or with a value close to 1:

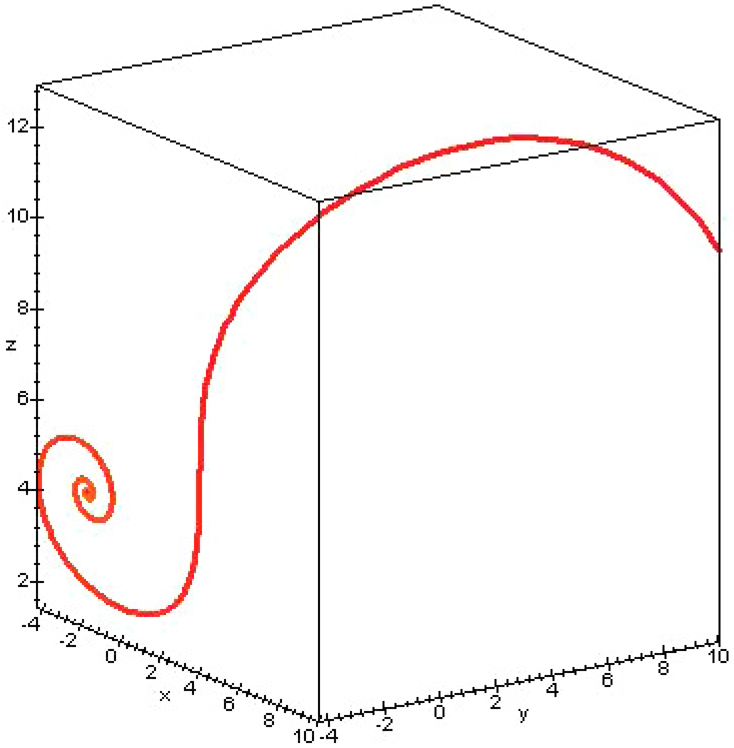

Figure 16.53: **Fast convergence of the Lorenz system with Maple™ 4.00b**

We notice a last interesting case is that if the Prandtl number is 1 then the system is stable:

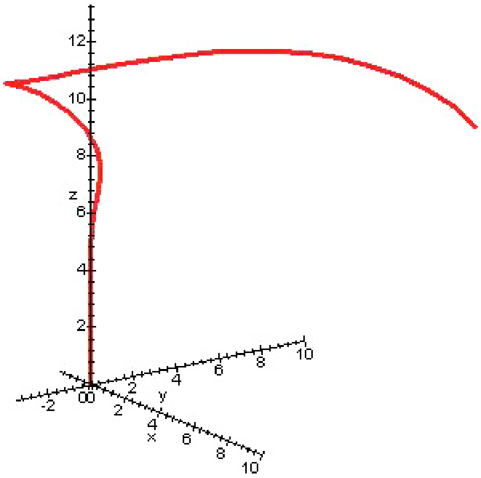

Figure 16.54: **System Stability with Maple™ 4.00b**

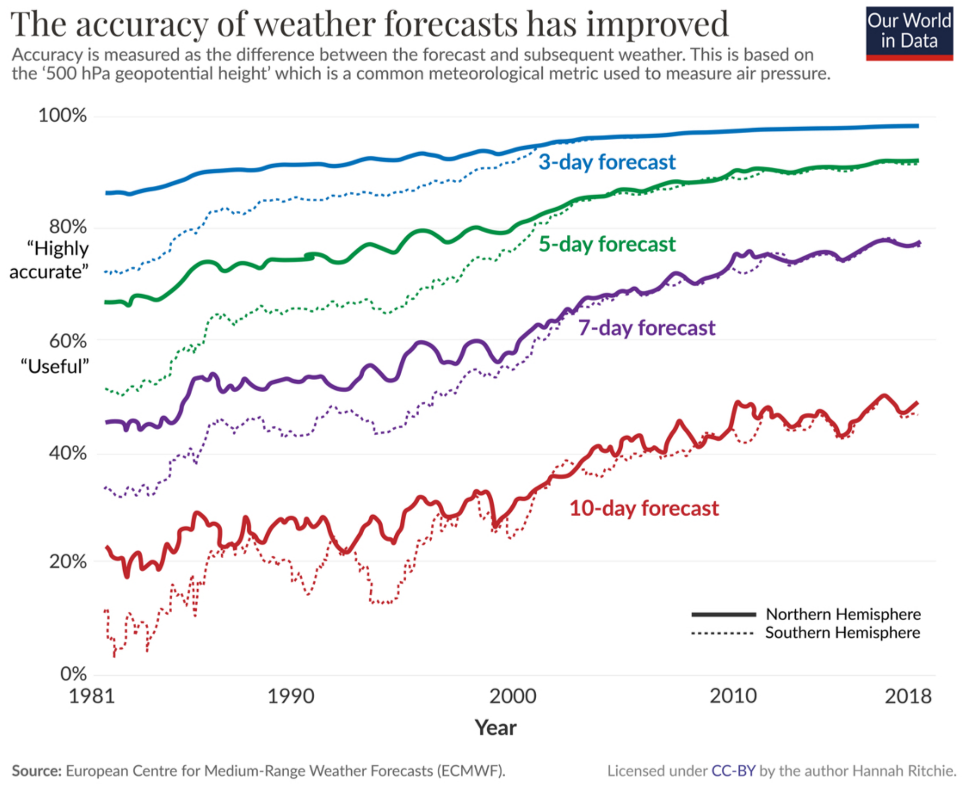
This sensitivity to the initial conditions, as well as the shape of the strange attractor of Lorenz, led the meteorologists to make a metaphor with the following sentence: can the flutter of a butterfly in Brazil cause a tornado in Texas?

Hence the name afterwards of "butterfly effect" for the study of the attractor of Lorenz also named in the field the "Lorenz's butterfly".

Despite the fact the weather engineering has for purpose to forecast complex multifactorial chaotic systems, thanks to the increase of computer power and satellites data survey, the accuracy of weather forecasting has significantly evolved in only four years as visible below:



Source: European Centre for Medium-Range Weather Forecasts (ECMWF).

Licensed under CC-BY by the author Hannah Ritchie.

Figure 16.55: **Evolution of weather forecasting accuracy**

The figure below from the 2013 (gregorian calendar) Intergovernmental Panel on Climate Change (IPCC) report compares the global surface warming projections made in the 1990, 1995, 2001, and 2007 (gregorian calendar) IPCC reports to the temperature measurements. Solid lines and squares represent measured average global surface temperature changes by NASA (blue), NOAA (yellow), and the UK Hadley Center (green). The colored shading shows the projected range of surface warming in the IPCC First Assessment Report (FAR; yellow), Second (SAR; green), Third (TAR; blue), and Fourth (AR4; red). We can see therefore at a global world level that the computers simulations are quite accurate also on a few decades even if the weather is a complex multifactorial chaotic system (!):

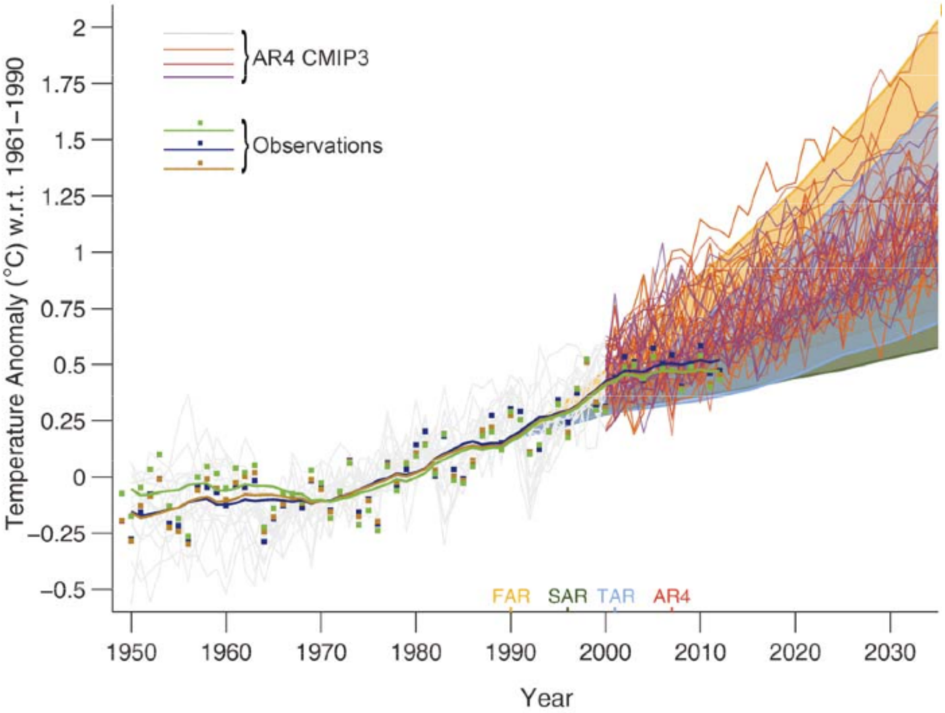


Figure 16.56: **Intergovernmental Panel on Climate Change (IPCC) forecasts vs measurements**

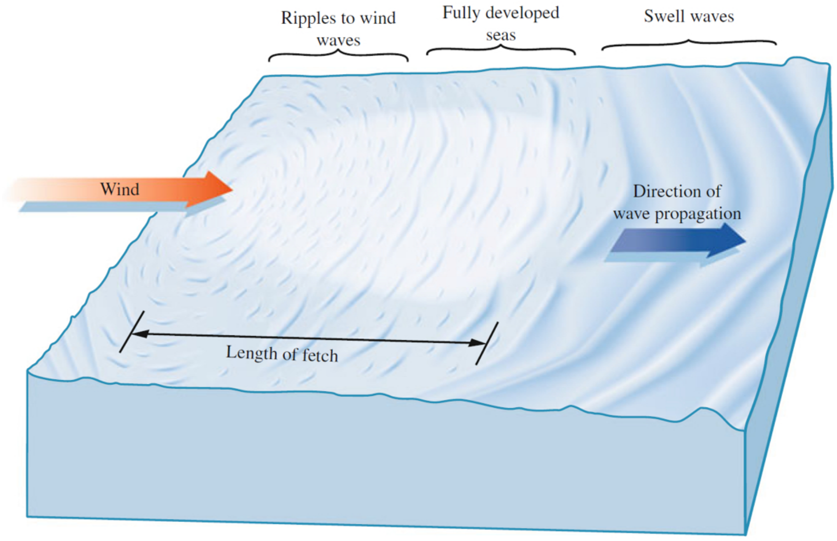
Obviously the forecasts can be become significanlty wrong when in the meantime the majority of humanity change its climate fingerprint.

16.1.10 Waves

When one finds himself on a boat, the movement of the water makes many people sick. It is also the case when one is in the galley to calculate this type of movement... Indeed, the waves in the water are neither transverse waves nor longitudinal waves. They are a bit of both. The water particles describe circles or ellipses, in a vertical plane parallel to the displacement of the wave. The big problem is that one of the boundary conditions is on the surface of the water and we do not know where that surface is. It is precisely one of the unknowns.



The problem is arduous enough for this calculation not to be found in books of general or specialized physics. We then tried to include it here by simplifying enormously and keeping only the simplest cases. The following calculation can be taken as an example of how physicists simplify life by making approximations and also as a masterful example of a common but complex phenomenon to be modelled.

We will not compute the wave equation. We must calculate the motion of the particles from the surface to the bottom of the water, since the movement extends to the bottom. But since particles describe ellipses, we need at least two variables per point: we need a vector field! We will therefore calculate the vector field of the velocities of the particles, but we will not calculate it directly. What we will find is a scalar potential of velocities whose gradient will be the vector field of velocities.

A final word on the waves that we will calculate. These waves are named "gravity waves" (not to be confused with "gravitational waves" in General Relativity), because it is the weight of the water that acts as a restoring force to bring down the summits and ascend the hollows.

Remark

I would like to thank Mr. Louis Peralta for his mathematical mastery and his pedagogy without which these exciting developments could never have been presented in this textbook. I am indebted to him, with his agreement, to copy / paste 99% of his course material.

We will make calculations in the simplest case: waves in a rectilinear channel of rectangular section and of constant width and depth... This reduces the dimensions of the problem to two (since the third one has an identical wave profile independently of where we are positioned in the width of the channel): the depth and direction of advance of the waves. Of course, we will neglect the friction on the bottom or sides of the canal and ... many other things.

The coordinate system chosen is then:

- x horizontal, positive in the direction of wave advancement (direction of channel length)
- y horizontal in the direction perpendicular to the advancement of the waves (direction of the width of the channel). Again, no variable will depend on y for the reasons already mentioned earlier
- z vertical and positive upwards. The zero is chosen on the surface of undisturbed water. Under water, z will therefore be negative. The depth of the channel being h, the bottom of the water will then be $z=-h$

Now, let us recall that we proved after very long developments in the section of Continuum Mechanics, that if the fluid is incompressible (divergence of the vector field of the velocities is therefore zero such that $\vec{\nabla}\circ\vec{v}=0$) and the dynamic viscosity is also ($\mu_d=0$), we then have the Euler equation of the first form (see page 3828):

$$\rho\mathrm{d}_t\vec{v}=-\vec{\nabla}p+\rho\vec{f}=-\vec{\nabla}p+\rho U=-\vec{\nabla}p-\rho gz \qquad (16.1.361)$$

because U is for recall of the scalar potential of the gravitational field.

What we will explicitly write in the following form in the case of our study of gravity waves:

$$\mathrm{d}_t\vec{v}=-\frac{1}{\rho}(\vec{\nabla}+\rho U) \qquad (16.1.362)$$

Before continuing, we will change the form of the term $\mathrm{d}_t\vec{v}$ which is a total derivative and not partial. Let us consider one of the two components (x or z) of this term. Let us take the component x of the velocity vector and use what we saw in the section of Differential and Integral Calculus (we omitted the y component since the system does not depend on it):

$$\mathrm{d}f(x,y)=\frac{\partial f}{\partial x}\mathrm{d}x+\frac{\partial f}{\partial y}\mathrm{d}y \qquad (16.1.363)$$

We have in our situation:

$$\mathrm{d}v_x(x,z,t)=\frac{\partial v_x}{\partial t}\mathrm{d}t+\frac{\partial v_x}{\partial x}\mathrm{d}x+\frac{\partial v_x}{\partial z}\mathrm{d}z \qquad (16.1.364)$$

Then we get:

$$\frac{\mathrm{d}v_x}{\mathrm{d}t}=\frac{\partial v_x}{\partial t}\frac{\mathrm{d}t}{\mathrm{d}t}+\frac{\partial v_x}{\partial x}\frac{\mathrm{d}x}{\mathrm{d}t}+\frac{\partial v_x}{\partial z}\frac{\mathrm{d}z}{\mathrm{d}t}=\frac{\partial v_x}{\partial t}+\frac{\partial v_x}{\partial x}v_x+\frac{\partial v_x}{\partial z}v_z \qquad (16.1.365)$$

The first term $\partial_t v_x$ is a linear term, whereas the other two are quadratic terms (as they include the product of a velocity by the derivative of a velocity) which are an infection (...) in all formal calculations. We shall therefore limit our calculations to cases where these quadratic terms are negligible relatively to the linear terms (implicitly implying that the speed must vary very little, otherwise this hypothesis is no longer valid). With this restriction, we then have:

$$\frac{\mathrm{d}\vec{v}}{\mathrm{d}t}\cong\frac{\partial\vec{v}}{\partial t} \tag{16.1.366}$$

We can then write:

$$\partial\vec{v}=-\frac{1}{\rho}(\vec{\nabla}p+\rho U) \tag{16.1.367}$$

We will add an additional restriction to our calculations. This restriction consists in imposing that the rotational velocity is zero:

$$\vec{\nabla}\times\vec{v}=\vec{0} \tag{16.1.368}$$

That is to say, as we have seen in the section of Continuum Mechanics, that there are no vortices in the fluid. We had already imposed that the velocity was zero in the y-direction, which prevents horizontal vortices horizontal axis of rotation). Now we eliminate the possibility of vortices with vertical axis of rotation also. It is not, in fact, too restrictive, we know that an object abandoned on the waves does not turn on itself unless it is caught in rolls. In the cases that we are going to calculate, the amplitudes are limited, we are in the linear case and, above all, not in the case of the rollers!!

We have proved in the section of Vector Calculus that when the curl of a vector variable is zero, the variable can be expressed as the gradient of a scalar potential:

$$\text{rot}\left[\overrightarrow{\text{grad}}\right]=\vec{\nabla}\times(\vec{\nabla}f)=\vec{0} \tag{16.1.369}$$

It comes then that we can write:

$$\vec{v}=\vec{\nabla}\phi \tag{16.1.370}$$

Then we get:

$$\partial_t(\vec{\nabla}\phi)=-\frac{1}{\rho}(\vec{\nabla}p+\rho U) \tag{16.1.371}$$

What can be written:

$$\vec{\nabla}\left(\partial_t\phi+\frac{1}{\rho}+gz\right)=0 \tag{16.1.372}$$

This equation acts as a wave equation, even if it does not directly describe the position or velocity of the particles. Once the equation of the function $\phi(x,z,t)$ are solved, we can deduce the velocities:

$$v_x=\frac{\partial\phi}{\partial x}\qquad v_z=\frac{\partial\phi}{\partial z} \tag{16.1.373}$$

It should not be forgotten that since the divergence of the vector field of the velocities is zero (incompressible field assumption):

$$\vec{\nabla}\circ\vec{v}=0=\vec{\nabla}(\vec{\nabla}\phi)=\vec{\nabla}^2\phi=\Delta\phi \tag{16.1.374}$$

Therefore the scalar Laplacian of ϕ is zero:

$$\Delta\phi = \frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial z^2} = 0 \qquad (16.1.375)$$

Therefore:

$$\frac{\partial^2\phi}{\partial x^2} = -\frac{\partial^2\phi}{\partial z^2} \qquad (16.1.376)$$

with $-h < z < 0$.

The solution must satisfy boundary conditions. The most obvious is that the vertical velocity must be zero at the bottom of the water:

$$v_z \underset{z=-h}{=} \frac{\partial\phi}{\partial z} = 0 \qquad (16.1.377)$$

To find the boundary conditions at the surface, we will define the variable $\xi(x,t)$ which is equal to the vertical displacement of a particle of water located on the surface of the water whose equilibrium position (in the absence of waves) is x (not to be confused with the other x...!). The height of the surface of the water, measured by reference to the level of the water without wave, will therefore be given by $\xi(x,t)$. Thus, the vertical velocity v_z at the surface of the water will be:

$$v_z \underset{z=0}{=} \frac{\partial\phi}{\partial z} = \frac{\partial\xi}{\partial t} \qquad (16.1.378)$$

This is a very subtle tip and not obvious at all to anticipate!

At the surface, we can consider that the pressure P is always equal to the atmospheric pressure for all the positions in x and in ξ. Hence, a priori nothing will change if the atmospheric pressure changes (...), and it is more convenient to consider it null. With this, the equation:

$$\vec{\nabla}\left(\partial_t\phi + \frac{1}{\rho}p + gz\right) = 0 \qquad (16.1.379)$$

Becomes:

$$\vec{\nabla}\left(\partial_t\phi + gz\right) = 0 \qquad (16.1.380)$$

From which we deduce:

$$\partial_t\phi = -gz \qquad (16.1.381)$$

If we place ourselves on the surface, which corresponds to $z = 0$, the preceding relation becomes:

$$\frac{\partial^2\phi}{\partial t^2} = -g\frac{\partial\xi}{\partial t} \qquad (16.1.382)$$

From which we deduce:

$$\partial_t\phi = -g\xi \qquad (16.1.383)$$

If we place ourselves on the surface, which corresponds to $z = 0$, the preceding relation becomes:

$$\partial_t \phi = -g\xi \tag{16.1.384}$$

and deriving this relation relatively to the time again, we get:

$$\frac{\partial^2 \phi}{\partial t^2} = -g\frac{\partial \xi}{\partial t} \tag{16.1.385}$$

Then using the relation proved just earlier above:

$$v_z \underset{z=0}{=} \frac{\partial \phi}{\partial z} = \frac{\partial \xi}{\partial t} \tag{16.1.386}$$

It comes:

$$\frac{\partial^2 \phi}{\partial t^2} = -g\frac{\partial \phi}{\partial z} \tag{16.1.387}$$

Let us sum up the conditions that the scalar potential ϕ must satisfy:

$$\begin{aligned} \frac{\partial^2 \phi}{\partial x^2} &= -\frac{\partial^2 \phi}{\partial z^2} & -h < z < 0 \\ \frac{\partial \phi}{\partial z} &= 0 & z = -h \\ \frac{\partial^2 \phi}{\partial t^2} &= -g\frac{\partial \phi}{\partial z} & z = 0 \end{aligned} \tag{16.1.388}$$

We will only look for solutions of the separable type (see section Differential and Integral Calculus page 1617). That is to say that ϕ, which is a function of x, z and t, will then be able to be written as the product of three functions, each of which depends on a single variable. Moreover, we will work only in sinusoidal regime (an intuition ... of the observation in real life) and using the formalism of the phasors (see section Wave Mechanics page 3510). Therefore, we have:

$$\phi(x, z, t) = \chi(x)\psi(z)e^{\mathrm{i}\omega t} \tag{16.1.389}$$

As usual, we will only keep the real part of the phasors of the solutions at the end.

Let us now calculate the second partial derivatives with respect to x and z:

$$\frac{\partial^2 \psi}{\partial x^2} = \chi''\psi e^{\mathrm{i}\omega t} \qquad \frac{\partial^2 \phi}{\partial z^2} = \chi\psi'' e^{\mathrm{i}\omega t} \tag{16.1.390}$$

The following equation:

$$\frac{\partial^2 \psi}{\partial x^2} = -\frac{\partial^2 \psi}{\partial z^2} \qquad -h < z < 0 \tag{16.1.391}$$

tells us that under the surface, these two expressions are equal to a given sign:

$$\chi''\psi e^{\mathrm{i}\omega t} = -\chi\psi'' e^{\mathrm{i}\omega t} \tag{16.1.392}$$

from which we deduce:

$$\frac{\chi''}{\chi}=-\frac{\psi''}{\psi}=\lambda \tag{16.1.393}$$

λ can only be a constant, since both sides of the expression depend on independent variables (which is very tricky for an observation!). This constant can take, in principle, any real or complex value.

This gives us the following system of two independent differential equations of the second order:

$$\begin{aligned}\chi''-\lambda\chi&=0\\ \psi''+\lambda\psi&=0\end{aligned} \tag{16.1.394}$$

It is therefore a system of differential equations of order 2 independent, almost identical to that solved in the section of Thermodynamics when we studied the equation of heat.

That being said, we do not know however the sign of the constant λ. What we know from what we have studied in the section of Differential and Integral Calculus is that if b is positive then the solution of the differential equation in z:

$$\psi''+\lambda\psi=0 \tag{16.1.395}$$

will have harmonic solutions. This would be very surprising ... and counter-intuitive with what we observe in reality. So we will impose λ as being negative and then we have seen in the section of Differential and Integral Calculus that we will have by adopting pretty much the same notations:

$$\begin{aligned}\chi&=Ae^{(\alpha+\mathrm{i}\beta)(x+\tau')}+Be^{(\alpha-\mathrm{i}\beta)(x+\tau')}\\ \psi&=Ce^{k_1(z+\tau)}+De^{k_2(z+\delta)}\end{aligned} \tag{16.1.396}$$

where we have the discriminant of the second differential equation (see section Differential and Integral Calculus page 1610) which holds:

$$k_{1,2}=\frac{-a\pm\sqrt{a^2-4b}}{2}=\pm\sqrt{\lambda} \tag{16.1.397}$$

So in other words:

$$k_1=-k_2=k \tag{16.1.398}$$

It then comes:

$$\begin{aligned}\chi&=Ae^{(\alpha+\mathrm{i}\beta)(x+\tau')}+Be^{(\alpha-\mathrm{i}\beta)(x+\tau')}\\ \psi&=Ce^{k(z+\tau)}+De^{-k(z+\delta)}\end{aligned} \tag{16.1.399}$$

and the discriminant of the first differential equation will be purely complex:

$$\alpha\pm\mathrm{i}\beta=\pm\mathrm{i}\sqrt{\lambda} \tag{16.1.400}$$

and therefore can be written:

$$\pm\mathrm{i}k \tag{16.1.401}$$

Our system is simplified even more:

$$\begin{aligned}\chi &= Ae^{\mathrm{i}k(x+\tau')}+Be^{-\mathrm{i}k(x+\tau')}\\ \psi &= Ce^{k(z+\tau)}+De^{-k(z+\delta)}\end{aligned} \tag{16.1.402}$$

If we consider the advance as zero (null phase shift) we have:

$$\begin{aligned}\chi &= Ae^{\mathrm{i}kx}+Be^{-\mathrm{i}kx}\\ \psi &= Ce^{kz}+De^{-kz}\end{aligned} \tag{16.1.403}$$

Since:

$$\phi(x,z,t)=\chi(x)\psi(z)e^{\mathrm{i}\omega t} \tag{16.1.404}$$

we have then:

$$\phi(x,z,t)=(Ce^{kz}+D^{-kz})(A'e^{\mathrm{i}(\omega t+kx)}+B'e^{\mathrm{i}(\omega t-kx)}) \tag{16.1.405}$$

So in the second parenthesis, we just have two waves that go in opposite directions. Let's keep one of the two to simplify the analysis (no matter what!):

$$\phi(x,z,t)=(Ce^{kz}+De^{-kz})(Ae^{\mathrm{i}(\omega t+kx)}) \tag{16.1.406}$$

To determine the constants, we will use the limit condition given above:

$$v_z \underset{z=-h}{=} = \frac{\partial\phi}{\partial z}=0 \tag{16.1.407}$$

Which in the present case gives us:

$$k(Ce^{-kh}-De^{kh})(A'e^{\mathrm{i}(\omega t+kx)})=0 \tag{16.1.408}$$

So of course we are not going to simplify totally so that k is zero otherwise it would not correspond with reality. On the other hand, we will simplify in the following way:

$$k(Ce^{-kh}-De^{kh})=0 \tag{16.1.409}$$

Which imposes in the non-trivial case that:

$$Ce^{-kh}=De^{kh} \tag{16.1.410}$$

So we can choose what we want, but if we want to simplify life by anticipating what is coming ... it would be better to take the following choice:

$$Ce^{-kh}=De^{kh}=\frac{1}{2} \tag{16.1.411}$$

Therefore:

$$C=\frac{1}{2}e^{kh} \qquad \text{and} \qquad D=\frac{1}{2}e^{-kh} \tag{16.1.412}$$

Therefore we get:

$$\phi(x,z,t)=(Ce^{kz}+De^{-kz})(A'e^{\mathrm{i}(\omega t+kx)})=\left(\frac{e^{k(z+h)}+e^{-k(z+h)}}{2}\right)(A'e^{\mathrm{i}(\omega t+kx)}) \tag{16.1.413}$$

Using the hyperbolic functions (see section Trigonometry page 2532) we have:

$$\phi(x,z,t)=\left(\frac{e^{k(z+h)}+e^{-k(z+h)}}{2}\right)(A'e^{\mathrm{i}(\omega t+kx)})=\cosh(k(z+h))(A'e^{\mathrm{i}(\omega t+kx)}) \quad (16.1.414)$$

We will continue to try to determine the constants using the second limit condition:

$$\frac{\partial^2\phi}{\partial t^2}=-g\frac{\partial\phi}{\partial z} \qquad z=0 \quad (16.1.415)$$

Then it comes (for the derivative of the hyperbolic cosine see the section of Differential and Integral Calculus at page 1475):

$$-\omega^2 A'\cosh(k(z+h))e^{\mathrm{i}(\omega t+kx)}=-gkA'\sinh(k(z+h))e^{\mathrm{i}(\omega t+kx)} \quad (16.1.416)$$

and therefore by putting $z=0$:

$$-\omega^2 A'\cosh(kh)e^{\mathrm{i}(\omega t+kx)}=-gkA'\sinh(kh)e^{\mathrm{i}(\omega t+kx)} \quad (16.1.417)$$

and simplifying:

$$-\omega^2\cosh(kh)=-gk\sinh(kh) \quad (16.1.418)$$

or written differently:

$$\tanh(kh)=\frac{\omega^2 h}{g}\frac{1}{kh}=\frac{\omega^2}{gk} \quad (16.1.419)$$

Let us recall that (see section Wave Mechanics page 3480):

$$k=\frac{\omega}{v_{\text{phase}}} \quad (16.1.420)$$

If we rearrange the above two relation we get the for irrational inviscid linear surface gravity waves the following phase velocity (remember that h is the water depth):

$$v_{\text{phase}}=\sqrt{\frac{g}{k}\tanh(kh)} \quad (16.1.421)$$

For fixed k then we note that $\tanh(hk)$ monotonically increases, hence the speed is greater for larger h. This answers the questions of why does the speed of a wave travelling in shallow water increase in deep water?

The relation:

$$\tanh(kh)=\frac{\omega^2}{gk} \quad (16.1.422)$$

does not, to my knowledge, have any solution for expressing the phase velocity directly from an analytic expression (it is therefore transcendent) as a function of the depth h and of the frequency f (implicitly the pulsation ω) of the wave without passing through a Maclaurin development (see section Sequences and Series page 1703) of the hyperbolic tangent for small values of kh such that:

$$\tanh(kh)\cong kh\Rightarrow kh\cong\frac{\omega^2 h}{g}\frac{1}{kh} \quad (16.1.423)$$

from which we derive when the depth h and k are also small by making an elementary simplification of the preceding relation:

$$\boxed{v_{\text{phase}} \cong \sqrt{gh} \qquad \text{(deep water)}} \tag{16.1.424}$$

Relation which is named "Lagrange celerity formula". For example, for a tsunami, the wavelengths λ are immense (on the order of a hundred kilometres) so the product hk is small (of the order of 0.25 in the oceans).

If, on the other hand, the depth h is very large as well as k then we have in Taylor development series (see section Sequences and Series page 1703):

$$\tanh(kh) \cong 1 \tag{16.1.425}$$

from which we derive also after an elementary simplification:

$$v_{\text{phase}} = \sqrt{\frac{g}{k}} \tag{16.1.426}$$

Relation which is named "Newton celerity formula". However we can numerically solve the relation:

$$\tanh(kh) = \frac{\omega^2 h}{g}\frac{1}{kh} \tag{16.1.427}$$

and then we have:

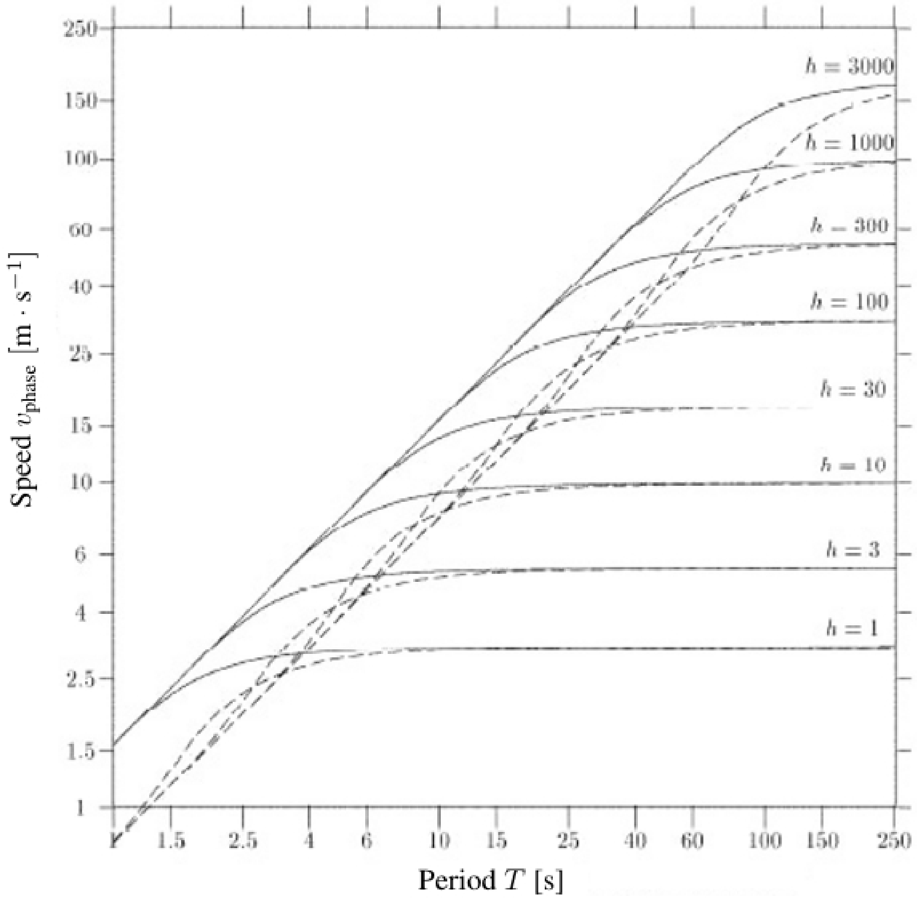


Figure 16.57: **Speed-Period gravity wave relation plot (source: LPFR)**

We can also by observing this plot understand why waves break (supercritical flux). Indeed, since the phase velocity for a given period increases as a function of the depth h, the upper part of the wave goes faster than the lower part and thus does not collapse due to lack of support. The supercritical part of the wave is destructive in the case of tsunamis because it is accelerated in its fall by gravity.

In the later case, as:

$$\tanh(kh)\cong 1\Rightarrow 1\cong\frac{\omega^2 h}{g}\frac{1}{kh} \tag{16.1.428}$$

Then we have:

$$\omega^2=gk \tag{16.1.429}$$

that is named the "dispersion relation". As k can be interpreted as the wave number, i.e.:

$$k=\frac{2\pi}{\lambda} \tag{16.1.430}$$

Hence:

$$\boxed{v_{\text{phase}}=\sqrt{\frac{g}{k}}=\sqrt{\frac{g\lambda}{2\pi}}\qquad\text{(deep water)}} \tag{16.1.431}$$

It also follows that the larger waves catch up with the small ones and that their amplitudes are superimposed over a certain distance. We will determine later the function linking the amplitude of the wave to the distance.

Figure 16.58: **Most common type of well-known gravity wave (source: ?)**

Why does the speed of a wave travelling in shallow water increase in deep water? Let us now return to:

$$\phi(x,z,t)=\cosh(k(z+h))(A'e^{\mathrm{i}(\omega t+kx)}) \tag{16.1.432}$$

by conserving only the real part:

$$\phi(x,z,t)=A'\cosh(k(z+h))\cos(\omega t+kx) \tag{16.1.433}$$

Let us recall that we saw at the beginning:

$$v_z=\frac{\partial\phi}{\partial z} \tag{16.1.434}$$

To get Z we must therefore derive the prior-previous relation with respect to z and then integrate the result with respect to time.

The derivative thus gives:

$$v_z=\frac{\mathrm{d}z}{\mathrm{d}t}=\frac{\partial\phi}{\partial z}=kA'\sinh(k(z+h))\cos(\omega t+kx) \tag{16.1.435}$$

Therefore:

$$\mathrm{d}z=kA'\sinh(k(z+h))\cos(\omega t+kx)\mathrm{d}t \tag{16.1.436}$$

The primitive gives:

$$\int \mathrm{d}z = \int kA' \sinh(k(z+h))\cos(\omega t+kx)\mathrm{d}t = kA' \sinh(k(z+h)) \int \cos(\omega t+kx)\mathrm{d}t \tag{16.1.437}$$

Therefore:

$$Z = \frac{k}{\omega}A' \sinh(k(z+h))\sin(\omega t+kx) \tag{16.1.438}$$

And placing ourselves on $z=0$ (on the surface) we get:

$$\xi = \frac{k}{\omega}A' \sinh(kh)\sin(\omega t+kx) \tag{16.1.439}$$

and by denoting by R the amplitude of the wave:

$$\xi = \frac{k}{\omega}A' \sinh(kh)\sin(\omega t+kx) = R\sin(\omega t+kx) \tag{16.1.440}$$

With this the vertical displacement Z becomes:

$$Z = R\frac{\sinh(k(z+h))}{\sinh(kh)}\sin(\omega t+kx) \tag{16.1.441}$$

and remembering that the potential of speeds is given by:

$$\phi(x,z,t) = A' \cosh(k(z+h))\cos(\omega t+kx) \tag{16.1.442}$$

we can then rewrite it with this new constant R as following:

$$\phi(x,z,t) = R\frac{\omega}{k}\frac{\cosh(k(z+h))}{\sinh(kh)}\cos(\omega t+kx) \tag{16.1.443}$$

The horizontal velocity of a particle of water will then be:

$$v_x = \frac{\partial\phi}{\partial x} = \frac{\mathrm{d}x}{\mathrm{d}t} = -R\omega\frac{\cosh(k(z+h))}{\sinh(kh)}\sin(\omega t+kx) \tag{16.1.444}$$

and the horizontal displacement will be the integral of the previous relation with respect to time:

$$\int v_x \mathrm{d}t = -R\omega\frac{\cosh(k(z+h))}{\sinh(kh)}\sin(\omega t+kx)\mathrm{d}t = -R\omega\frac{\cosh(k(z+h))}{\sinh(kh)}\int \sin(\omega t+kx)\mathrm{d}t \tag{16.1.445}$$

Therefore:

$$X = R\frac{\cosh(k(z+h))}{\sinh(kh)}\sin(\omega t+kx) \tag{16.1.446}$$

and at the surface $z=0$:

$$X = R\frac{\cosh(kh)}{\sinh(kh)}\sin(\omega t+kx) \tag{16.1.447}$$

16.1.10.1 Depth of a wave

It is now interesting to calculate the depth of penetration of the wave. Indeed, we know from experience that the waves are less and less visible as the water height is big (excepted for Rogue Wave that are special non-linear cases).

Remember that we have just proved:

$$Z = R\frac{\sinh(k(z+h))}{\sinh(kh)}\sin(\omega t + kx) \tag{16.1.448}$$

Which corresponds to the vertical displacement of the wave. If:

$$kh = \frac{2\pi}{\lambda} \gg 1 \tag{16.1.449}$$

where we will consider that the wavelength of the waves is small and that the depth h of the medium in which they propagate is large.

We then have:

$$\sin(kh) = \frac{e^{kh} - e^{-kh}}{2} \cong \frac{e^{kh}}{2} \tag{16.1.450}$$

and:

$$\sin(k(z+1h)) = \frac{e^{k(z+h)} - e^{-k(z+h)}}{2} = \frac{e^{k(z+h)} - e^{-kz}e^{-kh}}{2} \cong \frac{e^{k(z+h)}}{2} \tag{16.1.451}$$

and we see that for this approximation to be satisfied, it is necessary that:

$$e^{-kz}e^{-kh} \ll 1 \tag{16.1.452}$$

So that the remaining part of calculations to be valid, we will impose small values of z (i.e. close to the surface).

Since then:

$$\begin{aligned} Z &\cong R\frac{\dfrac{e^{k(z+h)}}{2}}{\dfrac{e^{kh}}{2}}\sin(\omega t + kx) = R\frac{e^{k(z+h)}}{e^{kh}}\sin(\omega t + kx) = Re^{kz}\sin(\omega t + kx) \\ &= R\frac{e^{k(z+h)}}{e^{kh}}\sin(\omega t + kx) = Re^{kz}\sin(\omega t + kx) \\ &= \frac{k}{\omega}A'\sinh(kh)e^{kz}\sin(\omega t + kx) \cong \frac{k}{2\omega}A'e^{2kz+kh}\sin(\omega t + kx) \end{aligned} \tag{16.1.453}$$

Without forgetting that $-h < z < 0$ (so z is negative for recall!). The amplitude of the movements thus decreases exponentially under these conditions with the depth. The reader can verify that for some values of small kh we have:

$$\frac{\sinh(k(z+h))}{\sinh(kh)} \rightarrow -\infty \tag{16.1.454}$$

which shows the limitations of the model with this approach...

16.1.10.2 Wave's amplitude

For the amplitude of the horizontal movement the situation is the same. That is to say:

$$kh=\frac{2\pi}{\lambda}h\gg 1 \tag{16.1.455}$$

where we will consider that the wavelength of the waves is small and that the depth h of the medium in which they propagate is large.

As we have proved earlier above that:

$$X=R\frac{\cosh(k(z+h))}{\sin(kh)}\cos(\omega t+kx) \tag{16.1.456}$$

It comes then:

$$\begin{aligned}X&=R\frac{\cosh(k(z+h))}{\sinh(kh)}\cos(\omega t+kx)=R\frac{\dfrac{e^{k(z+h)}+e^{-k(z+h)}}{2}}{\dfrac{e^{kh}-e^{-kh}}{2}}\cos(\omega t+kx)\\&=R\frac{e^{k(z+h)}}{e^{kh}}\cos(\omega t+kx)\cong Re^{kz}\cos(\omega t+kx)=\frac{k}{\omega}A'\sinh(kh)e^{kz}\cos(\omega t+kz)\\&\cong\frac{k}{2\omega}A'e^{k(z+h)}\cos(\omega t+kx)\end{aligned} \tag{16.1.457}$$

where for recall, we always have $-h<z<0$ and that this model is valid only near the surface.

So for these two approximations, we have then when z is small in absolute value with respect to h (therefore in shallow water):

$$\begin{aligned}Z&\cong\frac{k}{2\omega}A'e^{kh}\sin(\omega t+kx)\\X&\cong\frac{k}{2\omega}A'e^{kh}\cos(\omega t+kx)\end{aligned} \tag{16.1.458}$$

Thus we can observe that for the case of shallow water (for z small), the water particles describe a circular motion (since the two components Z and X have the same amplitude).

On the other hand, in the general case, we have:

$$\begin{aligned}Z&\cong R\frac{\sinh(k(z+h))}{\sinh(kh)}\sin(\omega t+kx)\\X&\cong R\frac{\cosh(k(z+h))}{\sinh(kh)}\cos(\omega t+kx)\end{aligned} \tag{16.1.459}$$

The amplitudes are therefore no longer the same and the movements are then elliptic.

16.2. Mechanical Engineering

MECHANICAL ENGINEERING is the set of knowledge related to mechanics, at the physical sense (sciences of movements) and at the technical sense (the study of mechanisms). This field of knowledge goes from design of mechanical product to the recycling of this latter through the way, of course, of production, maintenance, etc. Its applications are very important in many areas of everyday life either for the manufacture of machinery, toys, home appliances, medical devices or buildings or a variety of means of transport... and the list goes on...

Again, we will focus here only on the mathematical formalization of practical cases of current applications in the industry! So this section is only a general introduction to technical applications of mechanics and must be complemented by laboratory practices (or computer simulation with for the SimuLink™ MATLAB® toolbox and the SimDriveline™ MATLAB® toolbox) and by reading also the section of Thermodynamics where the solid state equation is treated (see page 3615) and the section of Continuum Mechanics where the Navier-Stokes equation is proved (see page 3811). The mix of mechanics and magnetism systems (AC motors for example) is treated in the section of Electrodynmics (see page 4094).

Remark

It would be pretentious to claim to do with this section as well and also as complete as two free French PDFs *Éléments de machine* and *Résistance des Matériaux* of Nicolet Gaston Raymond that are at our point of view unrivaled in content and quality at this date (compared to the same non-free books on the same subjects!). It is therefore strongly recommended to refer to them if you want to drive full information about mechanical engineering (see the download section of the companion website or directly his own website `http://www.raymondnicolet.ch`). Same recommendation applies to the reader about the master pieces that are the English books *Mechanics of Materials* ([246]) and *Structural and Stress Analysis* ([384])!

> *An engineer trying to tell a biologist that living things were designed is like a biologist trying to tell an engineer that machines are alive.*

quote
16.2:8359.#90

16.2.1 Mechanical Efficiency

Mechanical advantage is a measure of the force amplification achieved by using a tool, mechanical device or machine system. The device preserves the input power and simply trades off forces against movement to obtain a desired amplification in the output force. Machine components designed to manage forces and movement in this way are named "mechanisms".

Mechanical advantage that is computed using the assumption that no power is lost through deflection, friction and wear of a machine is the maximum performance that can be achieved. For this reason, it is often named the "ideal mechanical advantage" (IMA). In operation, deflection, friction and wear will reduce the mechanical advantage. The amount of this reduction from the ideal to the "actual mechanical advantage" (AMA) is defined by a factor named "efficiency", a quantity which is determined by experimentation.

The assumptions of an ideal machine are equivalent to the requirement that the machine does not store or dissipate energy; the power into the machine thus equals the power out. Therefore, the power P is constant through the machine and force times velocity into the machine equals the force times velocity out, that is:

$$P = F_{\text{in}} v_{\text{in}} = F_{\text{out}} v_{\text{out}} \tag{16.2.1}$$

The ideal mechanical advantage is the ratio of the force out of the machine (load) to the force into the machine (effort), or:

$$\boxed{\text{IMA} = \frac{F_{\text{out}}}{F_{\text{in}}}} \tag{16.2.2}$$

Applying the constant power relationship yields a formula for this ideal mechanical advantage in terms of the speed ratio:

$$\text{IMA} = \frac{F_{\text{out}}}{F_{\text{in}}} = \frac{v_{\text{in}}}{F_{\text{out}}} \tag{16.2.3}$$

The speed ratio of a machine can be calculated from its physical dimensions. The assumption of constant power thus allows use of the speed ratio to determine the maximum value for the mechanical advantage.

Figure 16.60: Some typical ideal mechanical advantages

Most of the IMA relations above are quite obvious. That of the incline plane has however already been proved in details in the section of Classical Mechanics. That for wheel and axle and (gears in general) will be proved just further below. The IMA for pulley will be developed in the section of Civil Engineering (see page 8542).

The AMA of a machine is calculated as the ratio of the measured force output to the measured force input:

$$\text{AMA} = \frac{\hat{F}_{\text{out}}}{\hat{F}_{\text{in}}} \tag{16.2.4}$$

where the input and output forces are determined experimentally.

The ratio of the experimentally determined mechanical advantage to the ideal mechanical advantage is the mechanical efficiency η_M of the machine (to not to be confused with the thermodynamical efficiency η):

$$\boxed{\eta_M = \frac{\text{AMA}}{\text{IMA}}} \tag{16.2.5}$$

16.2.2 Gears

A "gear" is a mechanical system consisting of two intermeshing gears for the transmission of the rotational movement therebetween or for the propulsion of a fluid (when the speak about: gear pump).

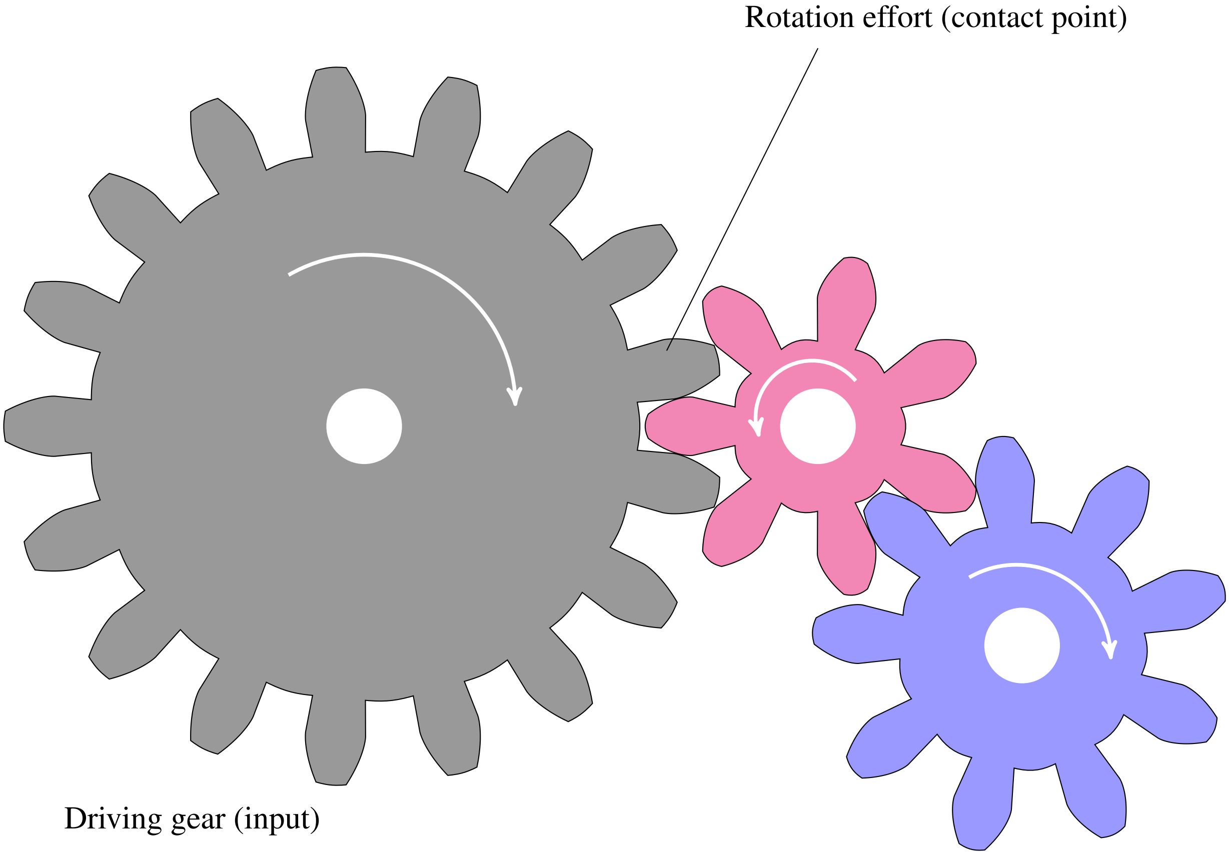

Figure 16.61: **Small gear train**

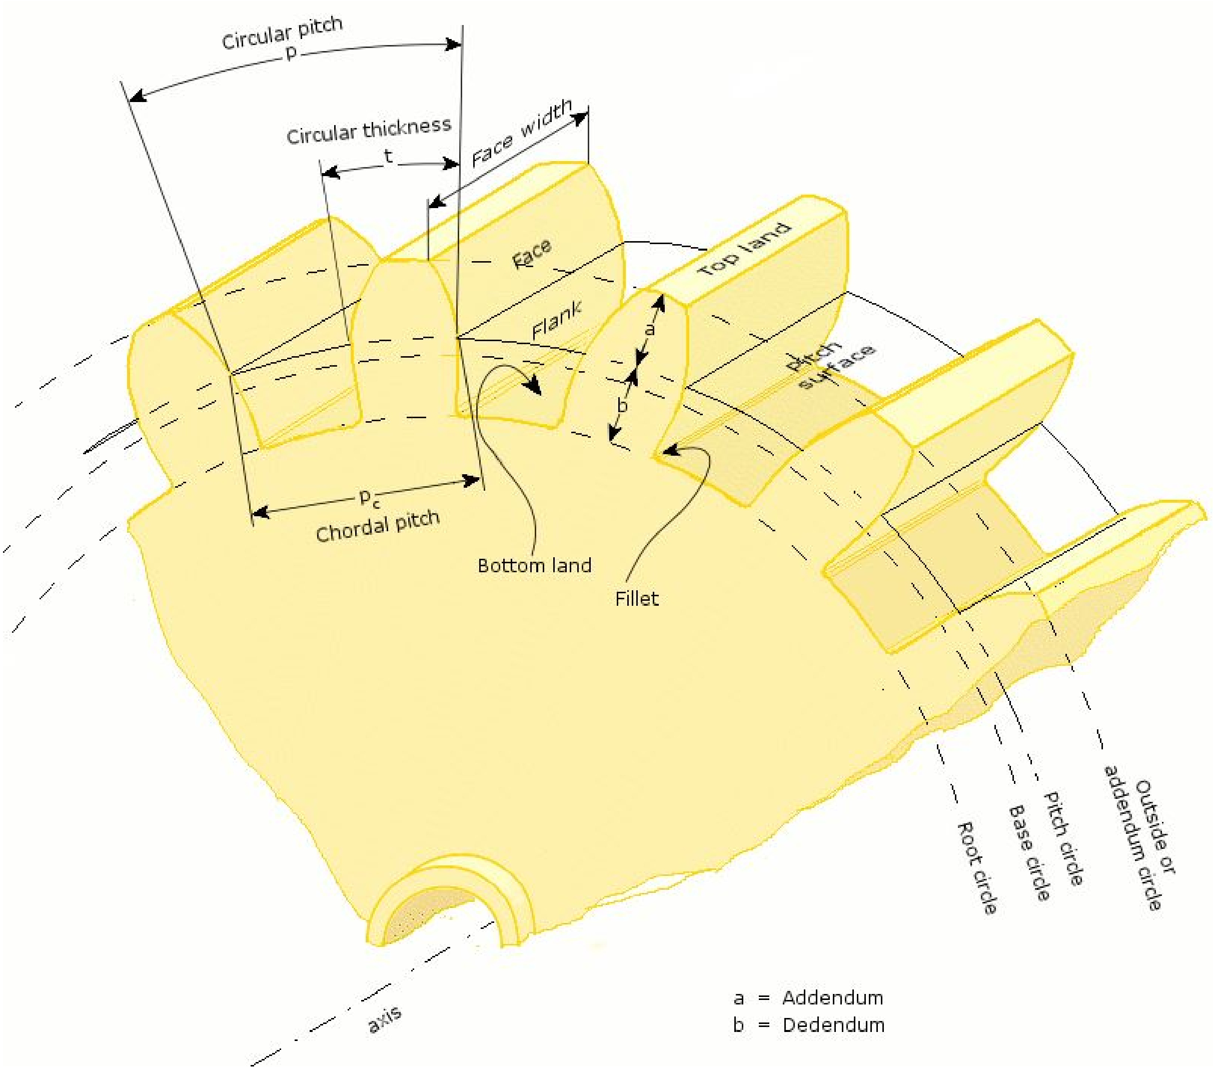
Two or more gears working in a sequence (train) are named a "gear train" or, in many cases, a "transmission"; such gear arrangements can produce a mechanical advantage through a gear ratio and thus may be considered a simple machine. Geared devices can change the speed, torque, and direction of a power source. The most common situation is for a gear to mesh with another gear; however, a gear can also mesh with a non-rotating toothed part, named a "rack", thereby producing translation instead of rotation.

The inventor of the cogwheel is considered by many practitioners as being no less than the famous mathematician, engineer and physicist Archimedes.

We find gears absolutely everywhere in our daily lives: cars, bicycles, watches, adjustable chairs, etc. We strongly recommend also the reader to think about the gears (trays and sprockets connected by a chain of transmission) of his bike to interpret the results that follow below.

The common vocabulary about a simple standard gear is given in the figure below:



Circular pitch
p
Circular thickness
t
Face width
Face
Flank
Top land
a
b
Pitch surface
p_c
Chordal pitch
Bottom land
Fillet
Root circle
Base circle
Pitch circle
Outside or addendum circle
axis
a = Addendum
b = Dedendum

Figure 16.62: Single Gear simple definitions (source: Wikipedia)

It seemed important to us to first introduce briefly how to calculate the tooth pitch of a cylindrical wheel depending on another one for the most famous type of gears is the "spur gear" like the one shown below:

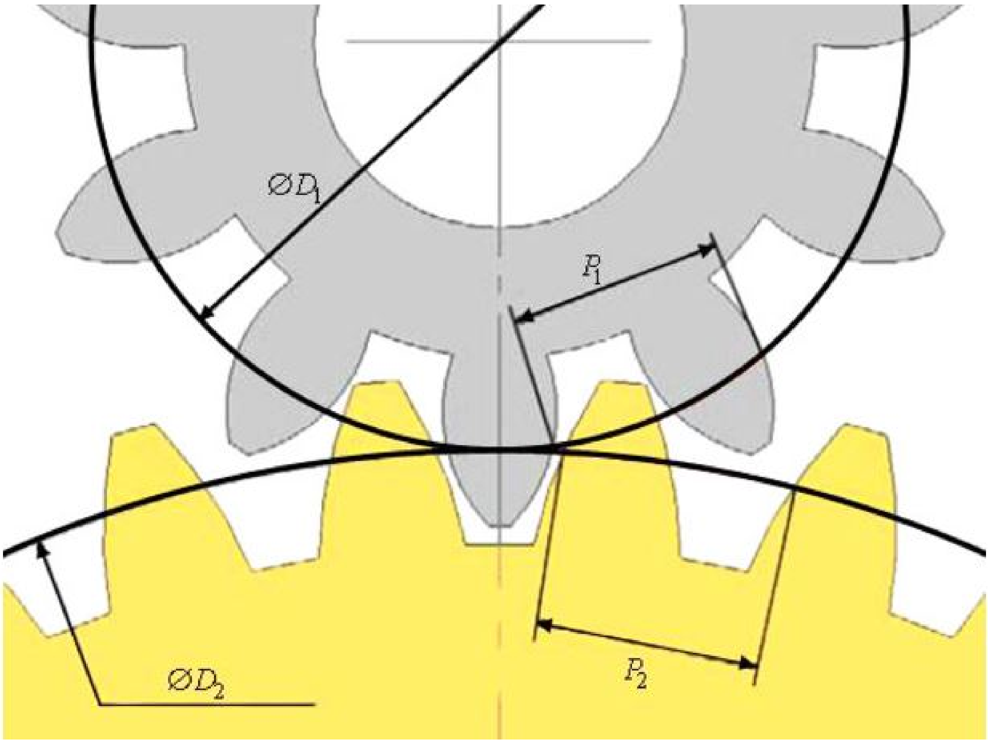


Figure 16.63: **Spur gear definitions for our analysis**

For the driving to operate so we must ensure that the teeth of a one of the cylindrical wheel of diameter $\varnothing = D_1$ well interspersed between the teeth of another wheel of diameter $\varnothing = D_2$. For this, we must introduce the concept of "circular pitch" from the teeth of each wheel which we will denote respectively by P_1 and P_2.

For this we will use the assumption that the teeth contact point can be assimilate to the diameters (represented above by black circles) that the cylindrical wheels would have if there were no slip (and therefore we would not need teeth ...) in the same way that the cog-wheel. These circles are named "primitive circles", or "primitive cylinders" or "primitive diameters".

The tooth pitch will thus be expressed as a function of the circumference and the number of teeth on each wheel. If we denote by Z_1 the number of teeth of a cylindrical gear 1 and Z_2 the number of teeth of a cylindrical gear 2, then we have the tooth pitch values that are equal respectively to:

$$\begin{aligned} P_1 &= \frac{2\pi R_1}{Z_1} = \frac{D_1}{Z_1} \\ P_2 &= \frac{2\pi R_2}{Z_2} = \frac{D_2}{Z_2} \end{aligned} \tag{16.2.6}$$

and as for the gear train to work we must have both tooth pitch to be equal such that:

$$P_1 = P_2 \tag{16.2.7}$$

Therefore we have:

$$\frac{D_1}{Z_1} = \frac{D_2}{Z_2} = m \tag{16.2.8}$$

where m is named the "tooth module". So we will retain that:

$$D_1 = mZ_1 \qquad D_2 = mZ_2 \tag{16.2.9}$$

We also observe by the above relation that the tooth pitch is not proportional to the tooth module (the choice of a large module provides a number of small teeth and the choice of a small module a large number of teeth).

Figure 16.64: **Spur Gear definitions**

16.2.2.1 Transmission ratios

The "transmission ratio" also named "reduction ratio" of a gear or a pulley system is very important in the field of mechanics and is defined by:

$$r = \frac{\omega_{\text{out}}}{\omega_{\text{in}}} = \frac{\dfrac{\mathrm{d}\theta_{\text{out}}}{\mathrm{d}t}}{\dfrac{\mathrm{d}\theta_{\text{in}}}{\mathrm{d}t}} = \frac{\mathrm{d}\theta_{\text{out}}}{\mathrm{d}\theta_{\text{in}}} \tag{16.2.10}$$

and therefore if the speed (pulsation) is constant (see the section of Classical Mechanics for the detailed calculations of the kinematics of the circular motion page 3280) and no longer varies between starting and nominal operation, it comes:

$$r = \frac{\omega_{\text{out}}}{\omega_{\text{in}}} = \frac{\theta_{\text{out}}}{\theta_{\text{in}}} = \frac{D_{\text{out}}}{D_{\text{in}}} \tag{16.2.11}$$

where for recall, D is the pitch circle diameter (diameter of the circle which passes through the center of all the studs, wheel bolts or wheel rim holes).

This is a widely used technology in everyday life but for people that like famous examples, we have such transmission ratios in cars (and generally almost all engines):

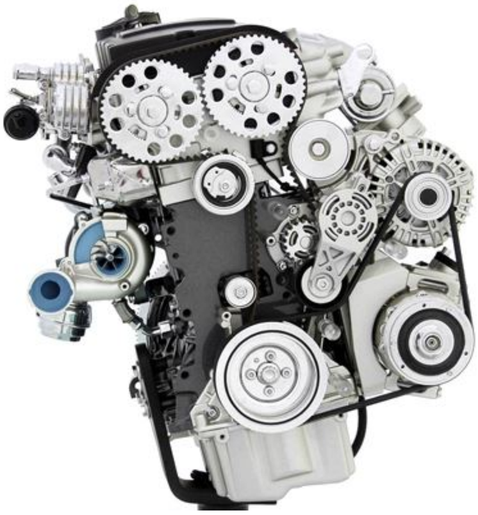

Figure 16.65: **Motor with few pulleys and drive belts**

as well as in almost all mechanical watches:

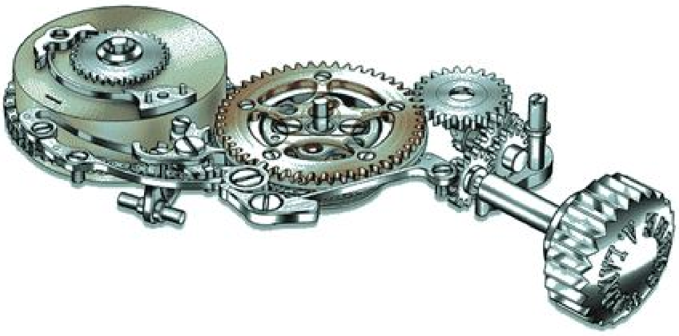

Figure 16.66: **A gear system with particular transmission ratio of a watch**

and bicycles:

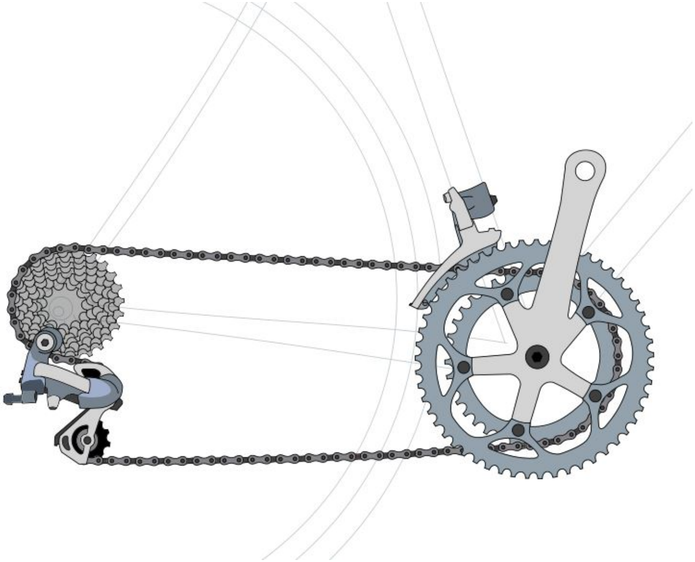

Figure 16.67: **Bicycle gears ratios**

We also of have of course:

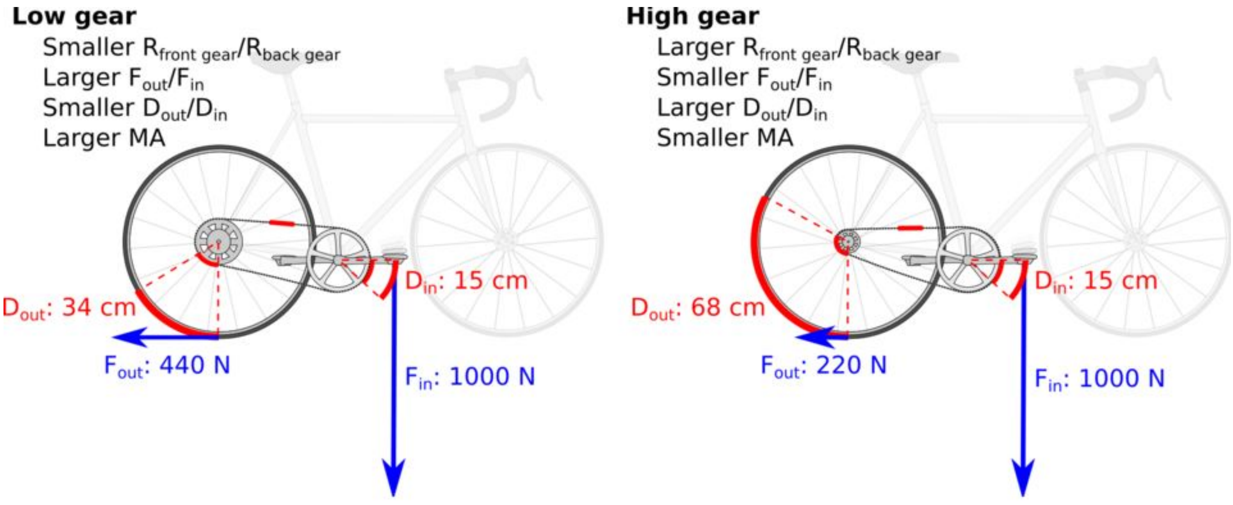
$$r=\frac{\omega_{\text{out}}}{\omega_{\text{in}}}=\frac{\dfrac{2\pi}{T_{\text{out}}}}{\dfrac{2\pi}{T_{\text{in}}}}=\frac{T_{\text{in}}}{T_{\text{out}}} \tag{16.2.12}$$

Therefore, the ratio of the rotational speed (angular frequency) between the output gear and the input gear is equal to the ratio of the angles travelled between the output gear and the input gear or the inverse ratio of their respective time period.

We even know by our study of kinematics of the circular motion (see section Classical Mechanics page 3280):

$$\boxed{r=\frac{\omega_{\text{out}}}{\omega_{\text{in}}}=\frac{T_{\text{in}}}{T_{\text{out}}}=\frac{\dfrac{v_s}{R_s}}{\dfrac{v_e}{R_e}}} \tag{16.2.13}$$

Thus, to use the example of the bicycle ... if we want to apply the greatest moment of force possible to the rear wheel by minimizing the moment of force we provide on the pedal so the best strategy according to the relationship given above is to take the smallest possible plate associated to the largest sprocket (the ideal would be to have a plate smaller than the largest sprockets for a transmission ratio greater than one).



Low gear
Smaller R_front gear/R_back gear
Larger F_out/F_in
Smaller D_out/D_in
Larger MA
D_out: 34 cm
F_out: 440 N
D_in: 15 cm
F_in: 1000 N
High gear
Larger R_front gear/R_back gear
Smaller F_out/F_in
Larger D_out/D_in
Smaller MA
D_out: 68 cm
F_out: 220 N
D_in: 15 cm
F_in: 1000 N

Figure 16.68: **Gear example with bicycle (source: Wikipedia)**

We also better understand why it is recommended for countries having periods of snow to maximize the transmission factor when driving car (on snows). As the moment of force will be minimized avoiding too much slipping.

It is important then to notice the gear ratio is also useful to play with the torque (moment of force) amplitude. Indeed, in the case of a simple system of spur gear of respectively radius R_{in} (for the input gear) and R_{out} (with $R_{\text{in}}<R_{\text{out}}$), then as the torque on the input gear on the output must be equal, we then have:

$$M_{\text{in}}=M_{\text{out}}\Leftrightarrow F_{\text{in}}R_{\text{in}}=F_{\text{out}}R_{\text{out}} \tag{16.2.14}$$

Hence:

$$\boxed{F_{\text{out}} = F_{\text{in}} \frac{R_{\text{out}}}{R_{\text{in}}}} \tag{16.2.15}$$

and we see that obviously, $F_{\text{out}} > F_{\text{in}}$ if $R_{\text{out}} > R_{\text{in}}$!

Then the ideal "ideal mechanical advantage of a simple spur gears system" is obviously given by:

$$\boxed{\text{IMA}_{\text{spur gears}} = \frac{R_{\text{out}}}{R_{\text{in}}}} \tag{16.2.16}$$

💣 Caution! The principle of pulley/gear with transmission ratio is a great force multiplicator but in no case it multiplies (increase or decrease) the work or the power as a simple calculation with the above figure can be done since for the work:

$$W = F_{\text{out}} D_{\text{out}} \tag{16.2.17}$$

is the same for the both situations.

Remark

The standard ISO 1122-1 provides the inverse definition and denotes the transmission ratio i instead of r:

$$i = \frac{\omega_{\text{in}}}{\omega_{\text{out}}} = \frac{\theta_{\text{in}}}{\theta_{\text{out}}} = \frac{M_{\text{out}}}{M_{\text{in}}} \tag{16.2.18}$$

16.2.2.2 Gears association

For reasons of geometrical or mechanical constraints, it is sometimes necessary to build gear stages as shown for example with the gear train of 4 wheels below:

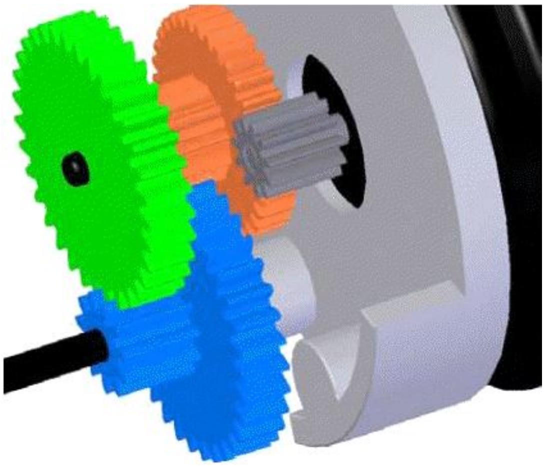


Figure 16.69: Gear train example in 3D with multiple wheels

Either into technical schematic form (not according to Swiss VSM Standards):

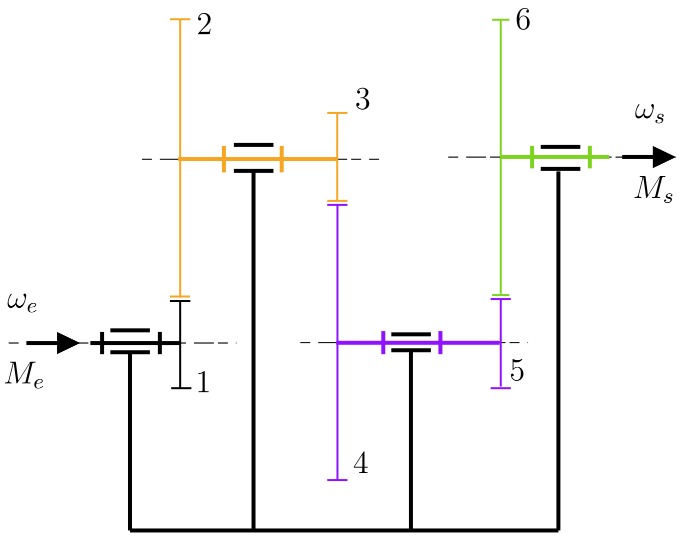

Figure 16.70: **Equivalent gear train example in 2D with multiple wheels**

The overall transmission ratio will then be given for the speed of rotation by:

$$r=r_{1-6}=\frac{\omega_{\text{out}}}{\omega_{\text{in}}}=\frac{\omega_6}{\omega_1}=\frac{\omega_2}{\omega_1}\frac{\omega_4}{\omega_3}\frac{\omega_6}{\omega_5}=\frac{\prod\omega_{\text{driven}}}{\prod\omega_{\text{leading}}} \tag{16.2.19}$$

where the fourth equality is simplified because in the case above:

$$\omega_5=\omega_4 \quad \text{and} \quad \omega_3=\omega_2 \tag{16.2.20}$$

We can also express the total transmission in terms of diameters. Since we have proven that:

$$r=\frac{\omega_{\text{out}}}{\omega_{\text{in}}}=\frac{Z_e}{Z_s} \tag{16.2.21}$$

it then comes immediately:

$$r=r_{1-6}=\frac{Z_1}{Z_2}\frac{Z_3}{Z_4}\frac{Z_5}{Z_6}=\frac{\prod Z_{\text{leading}}}{\prod Z_{\text{driven}}} \tag{16.2.22}$$

expression that we can not simplify!

Remark

Thus, in the context of a transmission of a watch with astronomical complication, the transmission ratio was obtained by determining the rational fraction $1802/217$. This being very difficult to implement with only two gears, we'll just build with three axes and four gears (with 7, 31, 34 and 53 teeth) the same ratio - which fortunately is not irreducible - as follows:

$$r=\frac{1802}{217}=\frac{34}{7}\frac{53}{31}=\frac{34}{7}\frac{53}{31}=\frac{\prod Z_{\text{leading}}}{\prod Z_{\text{driven}}} \tag{16.2.23}$$

✍**Example:**

We would like with a 4 wheel gear train on 2 axes, driven by the time axis (which spins through 12 hours), make a very precise transmission ratio r, to make a watch complication that shows a Moon phase with the classic disc having 2 Moons and turning behind a mask:

25
A. LANGE & SÖHNE
GLASHÜTTE I/SA
40
30
20
MADE IN GERMANY

As constraints the maximum number of teeth per wheel shall not exceed 300 teeth and do not fall below 7. The accuracy will be the best permitted within these numbers of teeth.

We will take 29 days 12 hours and 44 minutes for the lunar month.

The calculation of the desired ratio is relatively simple. The two Moons disc must make a full turn in $5,102,885.8$ seconds. The wheel of the timepiece makes one revolution in 12 hours, or $43,200$ seconds.

For a turn of the two Moons disc (leading axis) the axis of the 12h wheel (driven axis):

$$r=\frac{T_{\text{in}}}{T_{\text{out}}}=\frac{43,200}{5,102,588.8}\cong 0.008465798 \tag{16.2.24}$$

and rounding as below, we have an error of about 3 ten-thousandth of a second per 12 hours. Approximately 0.2 seconds per year of delay. What is acceptable for a mechanical watch.

By rounding:

$$r=\frac{T_{\text{in}}}{T_{\text{out}}}=\frac{43,200}{5,102,588.8}\cong 0.00846579 \tag{16.2.25}$$

we have an error of about 30 seconds per year, which is still acceptable for a mechanical watch. If we take again away one decimal place, then we have a delay of 6 minutes per year, even removing an additional decimal place, we would have a 49 minutes delay (which is still acceptable for many mechanical watches). By cons, beyond, this is no longer acceptable!

Now, to find the nearest decomposable rational fraction to this number there exist numerous empirical methods (by trial and error or by using a Brocot tree) and tables but the least worst ... for us ... is that using the continuous fractions (see section Number Theory page 369) when it is applicable...

Remember that we have proved that:

$$\begin{aligned}\frac{a}{b}&=q_1+\frac{1}{b/r_1}=q_1+\cfrac{1}{q_2+\cfrac{1}{r_1/r_2}}\\ &\vdots\\ &=q_1+\cfrac{1}{q_2+\cfrac{1}{q_3+\cfrac{1}{\cfrac{\ddots}{\cfrac{1}{q_{n+1}+\cfrac{1}{q_n}}}}}}\end{aligned}\tag{16.2.26}$$

considering:

$$\begin{aligned}&\frac{a}{b}=q_1+\frac{r_1}{b}\\ &\frac{b}{r_1}=q_2+\frac{r_2}{r_1}\\ &\frac{r_1}{r_2}=q_3+\frac{r_3}{r_2}\\ &\ldots\\ &\frac{r_{n-2}}{r_{n-1}}=q_n\end{aligned}\tag{16.2.27}$$

If we denote by x the ratio a/b then the relations above give us that q_1 is the integer part of x, q_2 the integer part of b/r_1 thus of $b/((x-q_1)b)=1/(x-q_1)$ either and so on...

We then have in our case:

$$\begin{aligned}
0.008465798 &\cong 0+\cfrac{1}{\cfrac{1}{0.008465798}}=0+\cfrac{1}{118.1223553881\ldots}\\
&=0+\cfrac{1}{118+\cfrac{1}{0.122355881\ldots}}=0+\cfrac{1}{118+8.17291347\ldots}\\
&=0+\cfrac{1}{118+\cfrac{1}{8+\cfrac{1}{0.17291347\ldots}}}=0+\cfrac{1}{118+\cfrac{1}{8+5.78323935\ldots}}\\
&=0+\cfrac{1}{118+\cfrac{1}{8+\cfrac{1}{5+\cfrac{1}{0.78323934\ldots}}}}=0+\cfrac{1}{118+\cfrac{1}{8+\cfrac{1}{5+1.2767489\ldots}}}\\
&=0+\cfrac{1}{118+\cfrac{1}{8+\cfrac{1}{5+\cfrac{1}{1+\ldots}}}}
\end{aligned}\tag{16.2.28}$$

Thus after we put everything to a common denominator:

$$0+\cfrac{1}{118+\cfrac{1}{8+\cfrac{1}{5+}}}=\cfrac{1}{118+\cfrac{1}{8+\cfrac{1}{6}}}=\cfrac{1}{118+\cfrac{6}{49}}=\frac{49}{5788}\tag{16.2.29}$$

If the difference (error) between this fraction and the exact value is acceptable (just have to calculate the error of time this causes after a year of operation of the watch for example), we stop ourselves here. But there is a second criterion ... the numerator and denominator must be decomposable in a satisfactory manner in relation to requirements of the number of teeth of the gears. Or in this case, the denominator (5788) can not be decomposed satisfactorily in relation to our constraints (do the decomposition with the command `ifactor` of Maple™ 4.00b and you will see!).

If we continue to develop our continued fraction, we will not find an acceptable solution before the numerator or the denominator exceeds the maximum permissible value of 300^2.

Thus, we return for example to our fraction (well this is not an acceptable approximation because in reality the maladjustment of the watch will be too fast):

$$\frac{49}{5788}\tag{16.2.30}$$

and we cheat a bit by trial and error to find a good ratio:

$$\frac{49}{5792}\tag{16.2.31}$$

Then, as we have a four gears train, we must have:

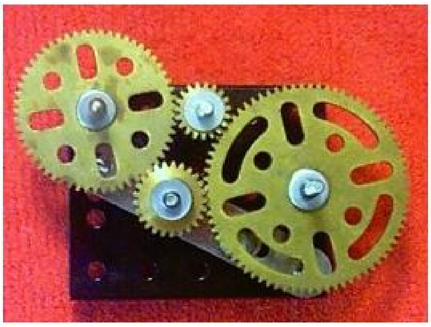
$$r \cong \frac{\prod Z_{\text{leading}}}{\prod Z_{\text{driven}}} = \frac{Z_1}{Z_2}\frac{Z_3}{Z_4} \qquad (16.2.32)$$

and then we take (always helping with the function `ifactor` of Maple™ 4.00b):

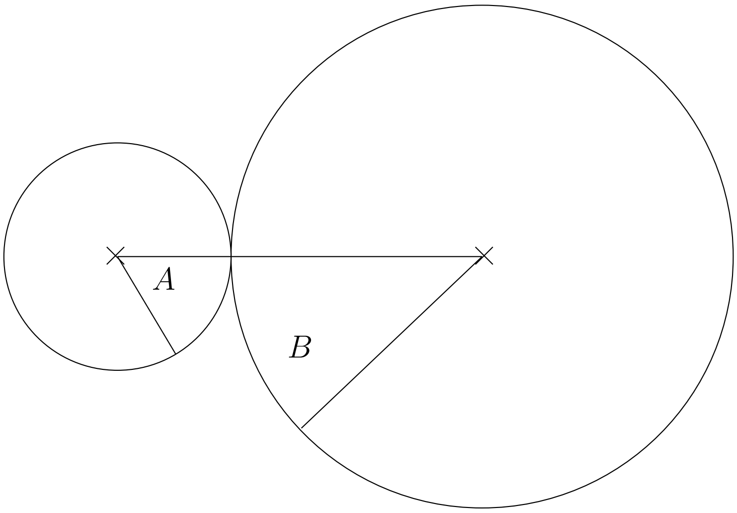
$$r \cong \frac{Z_1}{Z_2}\frac{Z_3}{Z_4} = \frac{7}{32}\frac{7}{181} \qquad (16.2.33)$$

16.2.2.2.1 Odd/Even Gear "problem"

The gear association below has a closed loop of four different gears. No two of them have the same diameter, and no two have the same number of teeth. They turn smoothly. Any even number of gears, with parallel axles, or even smooth wheels, can be put into such a loop, and they will turn freely, no matter what their tooth count or size. There's a simple way to prove this, using elementary geometry.



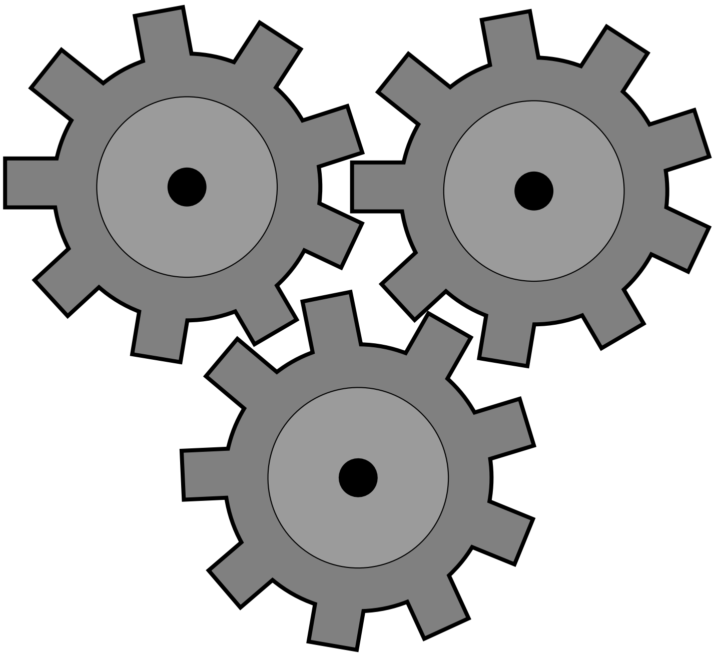
The underlying principle isn't physics, but geometry, and it applies not only to gears, but to smooth friction wheels as well. The figure shows two friction wheels of different diameter. When they turn without slipping, the two circles must turn through the same arc, but in opposite sense of rotation. That is, if the left wheel turns clockwise through arc A, the right wheel turns counter-clockwise through arc B, and $B = -A$:



If these were gears, then if one gear turns through N teeth, the other gear turns through N teeth in the other direction. It follows that if you had a string of an odd number of gears and tried to make a loop by meshing the gears at the end of the loop, their points of contact would be moving in opposite directions. If you closed a loop of an even number of gears, they would all turn quite smoothly through the same arc.

There are even exotic gears that have non-circular perimeters, such as oval or elliptical. You could make a model with an even number of these in a loop, and the gears in the model would turn smoothly.

A typical mistake is to think that the following will work:



16.2.2.3 Types of Gears

Here are some basic types of gears and how they are different from each other.

- The most common gears are "spur gears" and are used as we have seen previously in series for large gear reductions along a same plane! The teeth on spur gears are straight and are mounted in parallel on different shafts. These are particularly loud, due to the gear tooth engaging and colliding. Each impact makes loud noises and causes vibration, which is why spur gears are not used in machinery like cars.
- "Helical gears" operate more smoothly and quietly compared to spur gears due to the way the teeth interact. The teeth on a helical gear cut at an angle to the face of the gear. When two of the teeth start to engage, the contact is gradual–starting at one end of the tooth and maintaining contact as the gear rotates into full engagement. Helical is the most commonly used gear in transmissions.
- "Bevel gears" are used to change the direction of a shaft's rotation (bevel gears are most often mounted on shafts that are 90 degrees apart). Bevel gears have teeth that are avail-

able in straight, spiral, or hypoid shape. Straight teeth have similar characteristics to spur gears and also have a large impact when engaged.

- "Worm gears" are used in large gear reductions. The setup is designed so that the worm can turn the gear, but the gear cannot turn the worm. The angle of the worm is shallow and as a result the gear is held in place due to the friction between the two. The gear is found in applications such as conveyor systems in which the locking feature can act as a brake or an emergency stop.
- "Geneva gears" or "Maltese cross gears" are gears mechanism that translates a continuous rotation into an intermittent rotary motion. The rotating drive wheel has a pin that reaches into a slot of the driven wheel advancing it by one step. The drive wheel also has a raised circular blocking disc that locks the driven wheel in position between steps. In the most common arrangement, the driven wheel has four slots and thus advances by one step of 90° for each rotation of the drive wheel. If the driven wheel has n slots, it advances by $360^\circ/n$ per full rotation of the drive wheel.
- ...

In the figure below the reader can see a photo and the name of the nine most common types of gears used in engineering:

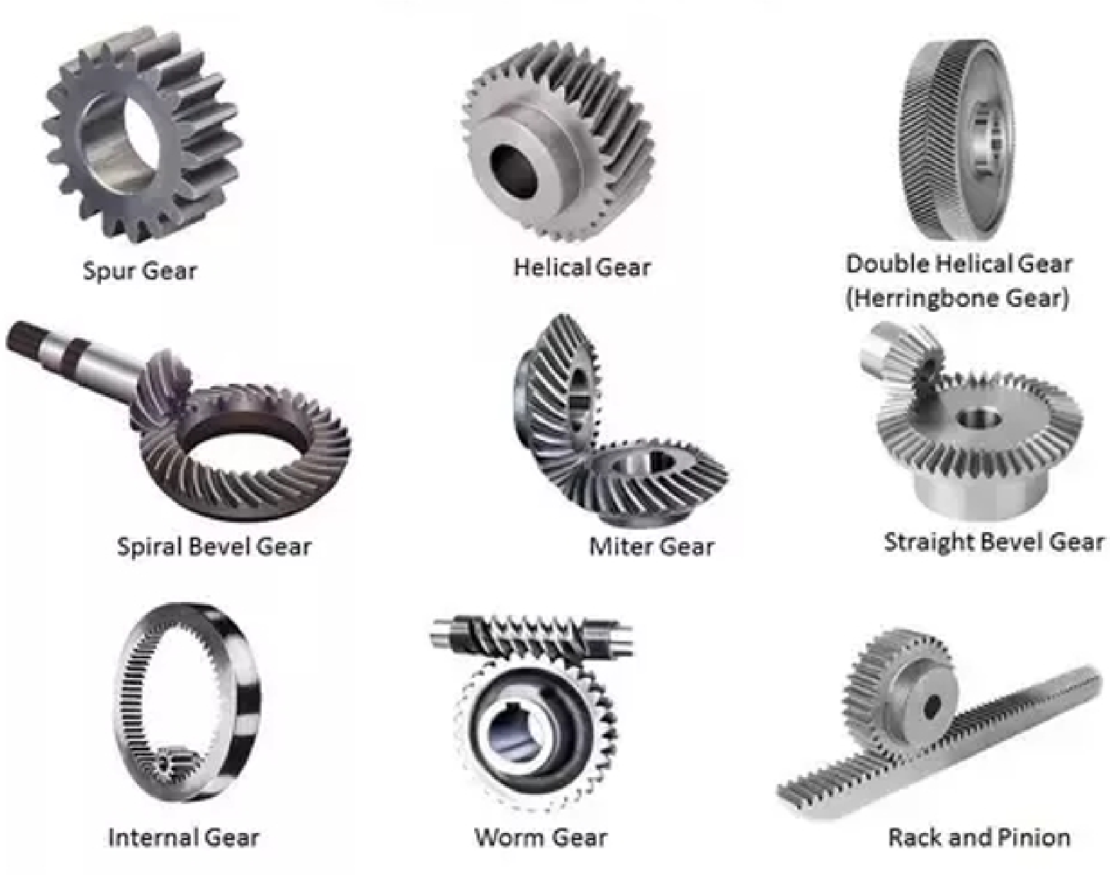


Figure 16.72: **Most common types of gears**

While manual transmissions (manually shifting a gear selector mechanism that disengages one gear and selects another) have remained relatively unchanged over the years, electronically controlled automatic, semi-automatic, and continuously variable transmissions (CVTs) have become increasingly complex, but also easier to use than ever before. However, modern transmissions of all types have become more prone to failure, primarily because of this higher level of complexity.

The Continuously Variable Transmissions (CVT) is a transmission mechanism that doesn't use gears as its means of producing various vehicle speeds at different engine speeds. Instead of gears, the system relies on a rubber or metal belt running over pulleys that can vary their effective diameters:

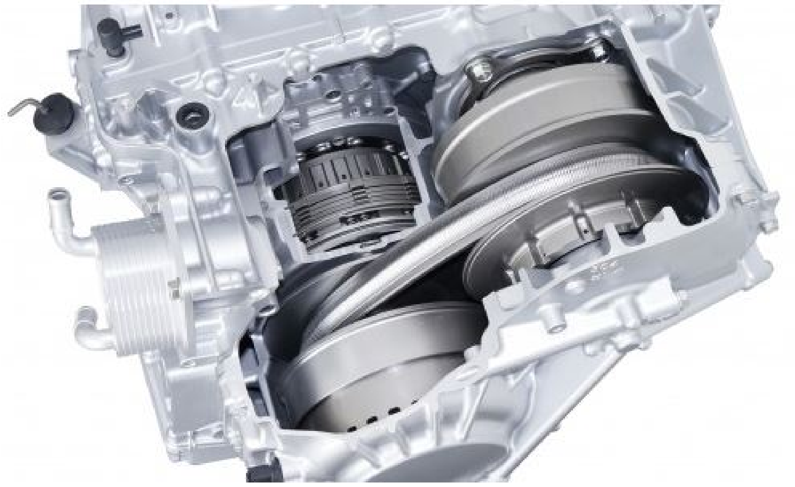

Figure 16.73: **Continuously Variable Transmissions (CVT)**

To keep the belt at its optimum tension, one pulley will increase its effective diameter, while the other decreases its effective diameter by exactly the same amount. This action is exactly analogous to the effect produced when gears of different diameters are engaged.

Now just a word about epicyclic gears!

Definition (#16.2.726): An "epicyclic gear train" or "planetary gear" consists of two gears mounted so that the center of one gear revolves around the center of the other. A carrier connects the centers of the two gears and rotates to carry one gear, named the "planet gear", around the other, named the "sun gear". The planet and sun gears mesh so that their pitch circles roll without slip. A point on the pitch circle of the planet gear traces an epicycloid curve. In this simplified case, the sun gear is fixed and the planetary gear(s) roll around the sun gear.

The epicyclic gear train below consists of a sun gear (yellow), planet gears (blue) supported by the carrier (green) and an annular gear (pink). The red marks show the relative displacement of the sun gear and carrier, when the carrier is rotated 45° clockwise and the annular gear is held fixed:

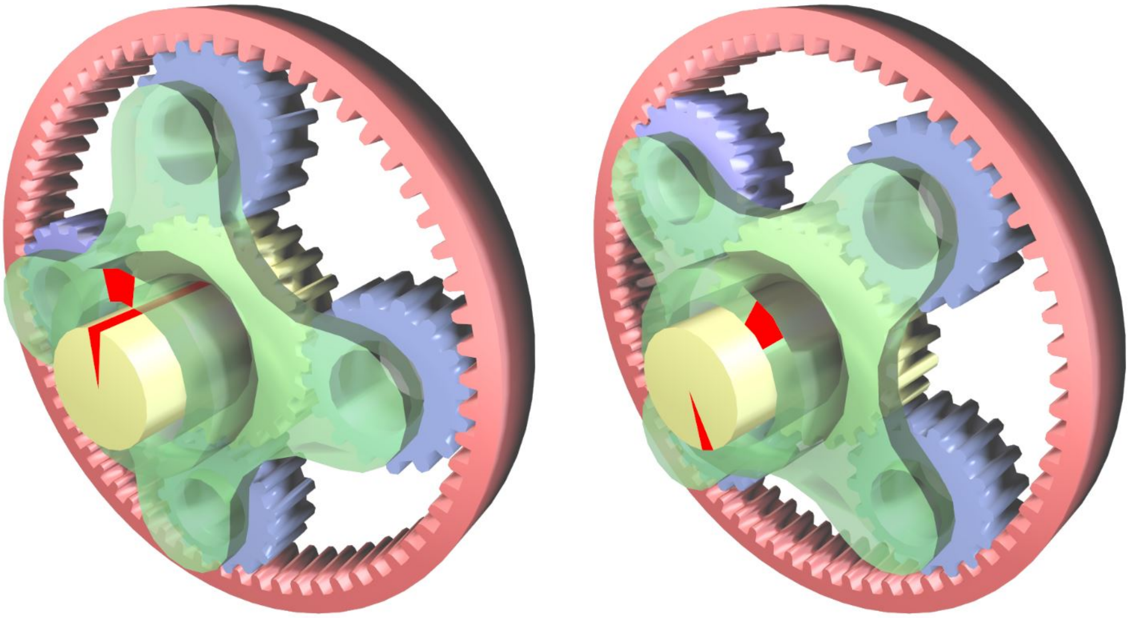

Figure 16.74: **Epicyclic gear (source: Wikipedia)**

Yes ok... but why use a epicyclic train gear excepted in watches knowing that the latter or not one of the most important thing in life!

There is one well known example: modern cars using CVT (and not only) have epicyclic gears and also almost all bicycles:

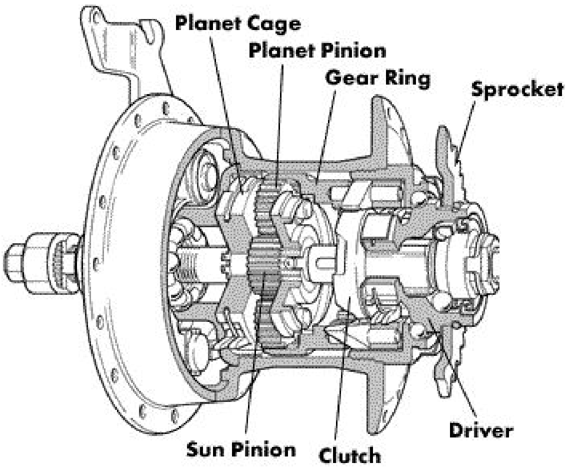

Figure 16.75: **Bicycle hub gear (special example)**

Why do CVT and bicycles use this type of gear?

First because this type of gear is very compact in surface and in volume and as forces are distributed across 4 planets gears (sometimes more!) the effort on the sun gear is divided. This is for the technical point of view...

Now for the utility point of view: Consider the figure above, where for example the sun gear is driven by the motor of the car and the annular gear is connected in one way or another to the transmission of the car. Therefore if we make the sun gear and the carrier solidary (connected) they turn together in the same direction. Then we speak of "forward gear" as the whole mechanism move as a single unique gear. If we remove what makes the sun gear and annular solidary than as it is a double epicyclic gear, the sun gear will force the annular gear to turn in the reverse direction and then we get a "reverse gear".

Remark

If the reader wants to see such a gear in action he can take a look to YouTube where there is a ton of video on this subject.

The gear ratio of an epicyclic gearing system is somewhat non-intuitive, particularly because there are several ways in which an input rotation can be converted into an output rotation. Indeed, in some hybrid vehicle transmissions, two of the components are used as inputs with the third providing output relative to the two inputs!!

OK let us now introduce some mathematical properties of this gear. For this let us consider the following figure where for simplification purposes our epicyclic has its planetary gears that are horizontal:

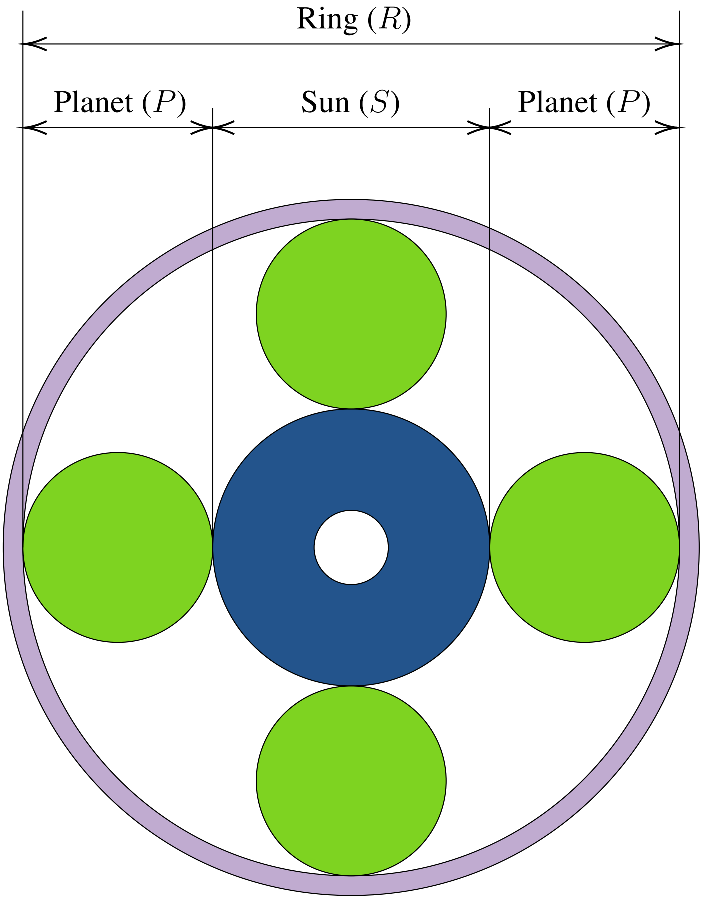

Figure 16.76: **Epicyclic gear simplified schema**

From the figure above we want to prove a canonical relation for the tooth counts. For this purpose let us denote the number of teeth of the ring gear by N_r, of the sun gear by N_s, and of the planet gears by N_p.

We will assume that our planetary gear to work out is that all teeth have the same pitch, or tooth spacing (this ensures that the teeth mesh).

The determination of a canonical between all teeth can be made more clear by imagining "gears" that just roll (no teeth), and imagine an even number of planet gears. From the illustration above we can see that the diameters of the sun gear, plus two planet gears be must equal to the ring gear size. That is:

$$\varnothing_r = 2\varnothing_p + \varnothing_s \tag{16.2.34}$$

And if we assume that all teeth have the same pitch that we will denote here by P, that is:

$$\dfrac{2\varnothing_r}{P} = N_r \qquad \dfrac{2\varnothing_p}{P} = N_p \qquad \dfrac{2\varnothing_s}{P} = N_s \tag{16.2.35}$$

Therefore injecting and simplifying in the prior-previous relation we get:

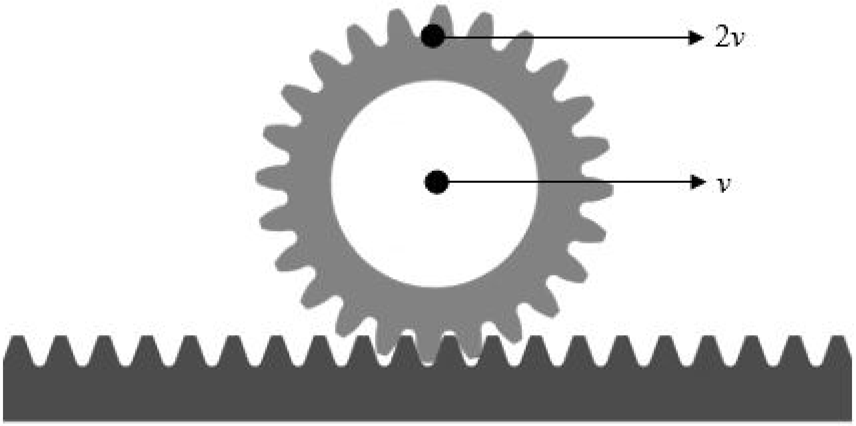
$$\boxed{N_r = 2N_p + N_s} \tag{16.2.36}$$

That is to say, the number of teeth in the ring gear is equal to the number of teeth in the middle sun gear plus twice the number of teeth in the planet gears.

We see also that the special case $N_p = 0$ brings us to the obvious result: $N_r = N_s$.

Let us denote first by $\omega_r, \omega_s, \omega_p, \omega_c$ the angular velocity of respectively the Ring (annulus) gear (pink color in the first figure), Sun gear (yellow color in the first figure), Planet gears (blue color in the first figure) and Carrier (green color in the first figure) and N_r, N_s, N_p the corresponding number of teeth of each gear (the Carrier no have teeth of sure!).

To continue let us consider the following figure:



A wheel (or gear) rolling without slipping as above means, any point on the circumference of the wheel will have both rotatory motion and translatory motion. Due to translation, if the velocity of the vehicle is v, then all the points of the wheel will have v linear velocity in the forward direction. Then due to the rotatory motion, each point will have a linear velocity of $v = r\omega$, where ω is the angular velocity. For the top most point at a particular instant, the linear velocity will be horizontal forward. So at any instant, a top most point on the wheel will have two linear velocities of same magnitude:

$$v_T = v + v = 2v \tag{16.2.37}$$

Now we have obviously (remember that r denotes here the transmission ratio!):

$$r = \frac{\omega_s}{\omega_c} \tag{16.2.38}$$

But we have immediately:

$$v_c = \omega_c(R_s + R_p) \tag{16.2.39}$$

We obviously have:

$$v_s = \omega_s R_s \tag{16.2.40}$$

But as just seen earlier above, we have:

$$v_s = 2v_c \tag{16.2.41}$$

Therefore:

$$v_s = 2\omega_c(R_s + R_p) \tag{16.2.42}$$

Hence an important relation for the planetary gear:

$$\boxed{\omega_s R_s = 2\omega_c(R_s + R_p)} \tag{16.2.43}$$

From that latter we get:

$$\begin{aligned}\frac{\omega_s}{\omega_c} &= \frac{2(R_s + R_p)}{R_s} = \frac{2R_s + 2R_p}{R_s} = \frac{2R_s + (R_r - R_s)}{R_s} \\ &= \frac{R_s + R_r}{R_s} = 1 + \frac{R_r}{R_s} = 1 + \frac{N_r}{N_s}\end{aligned} \tag{16.2.44}$$

This latter relation is in fact a special case of a more general one named the "Willis equation" or "fundamental formula of planetary gears" for the case where the ring gear is fixed (blocked).

Let us prove this equation:

Proof 16.0.1. If the sun gear stands still and the planet gear is locked firm on the carrier, then the swept angle of the carrier θ_c corresponds to the angular position of one of the planetary gear. Let us denoted this angular position θ_{p1}.

In fact, the planet gear will roll on the sun gear when mounted rotatable on the carrier and thus rotate around its own center of gravity. The planet gear will thus rotate by an additional angle θ_{p2}.

However we must not forget we have proved at the beginning of our study of simple gears systems:

$$\frac{\theta_{\text{in}}}{\theta_{\text{out}}} = \frac{D_{\text{in}}}{D_{\text{out}}} \tag{16.2.45}$$

Therefore considering sill the sun gear as fix and the carrier gear as moving, we have:

$$D_p\theta_{p2}=D_s\theta_c \tag{16.2.46}$$

Therefore:

$$\theta_{p2}=\frac{D_s}{D_p}\theta_c \tag{16.2.47}$$

Let us now consider that the carrier is held in position and the sun gear is rotated clockwise by an angle θ_s. In this case, the planet gear will turn counter-clockwise by an angle θ_{p3}. Analogous to the case before, the following statement applies (obviously the negative sign indicates that the motion of the planet gear is in the opposite direction to the motion of the sun gear):

$$D_p\theta_{p3}=-D_s\theta_s \tag{16.2.48}$$

Therefore:

$$\theta_{p3}=-\frac{D_s}{D_p}\theta_s \tag{16.2.49}$$

The motions of the planet gear according which have been considered separately so far, can now be superposed to the total motion:

$$\theta_p=\theta_{p1}+\theta_{p2}+\theta_{p3}\Leftrightarrow\theta_p=\theta_c+\frac{D_s}{D_p}\theta_c-\frac{D_s}{D_p}\theta_s \tag{16.2.50}$$

All this can be rearranged to the final relation we were looking for:

$$\boxed{D_p\theta_p=(D_p+D_s)\theta_c-D_s\theta_s} \tag{16.2.51}$$

That can also be rewritten as:

$$Z_p\omega_p=(Z_p+Z_s)\omega_c-Z_s\omega_s \tag{16.2.52}$$

■ Q.E.D.

There are many other relations that we can derive for the planetary gear (we could write a whole book on the subject). But we will stop our investigations here because we are not big fans of the subject...

16.2.3 Strength of materials

Strength of materials (or SoM for the intimates...) is, like all the other sections of this textbook, an extremely vast area which level of detail and complexity of the calculations can explode rather quickly. We will in the following paragraphs focus on the essentials that the engineer (in business) needs to know. The developments are oversimplified for trivial special cases (straight bars and beams). In reality, we use the tensor calculus, design of experiments or computer modelling experience with FEM (finite element methods).

Definitions (#16.2.727): "resistance of materials" also known as "mechanics of materials" or "strength of materials" - is a branch of engineering mechanics that studies the behavior of solid objects subject to various forces and deformations. It examines how materials react to external loads, stresses, and strains, ensuring structures and mechanical components maintain stability and integrity under the presence or not of gravity. This field encompasses fundamental concepts such as elasticity, plasticity, fatigue, and failure analysis, which are critical in designing safe and durable engineering systems.

Before we begin to study some simple concrete cases let us de some reminders of the proofs we have proceed during our study of this subject in the section of Continuum Mechanics:

- A solid considered as rigid does not exist, it is only a convenient approximation. Experience shows that a solid is in fact still slightly deformable under the effect of external forces.
- Relationships between deformations and tensions are usually complicated due to the anisotropy of the crystal lattices. However, the solids are generally not single crystals but polycrystalline substances consisting of assemblies of microcrystals associated randomly, they can be thus considered as isotropic.

Then, we should consider globally the following assumptions relatively to the developments that will follow:

H1. Matter is homogeneous, that is to say for recall that it has the same physical constitution and the same structure throughout all its volume.

H2. Matter is isotropic, that is to say for recall that its mechanical properties are the same in any point of the volume.

H3. The material is perfectly elastic, that is to say, for recall that after removal of the external forces, the volume immediately takes back its original dimensions (unlike the plastic limit!).

H4. The deformations (displacements of the points of the characteristics line) are small compared with the dimensions of the objects studied.

H5. Any straight section (cross-sections) before deformation remain straight after deformation (i.e. "Navier-Bernoulli hypothesis").

H6. The results obtained in material strength theory can only be applies to a sufficient distance from the concentrated efforts applied on the volume (i.e. "Barré Saint Venant hypothesis").

H7. In the elastic range, matter obeys the law of proportionality and then the deformations are given by Hooke's law already proved in the section of Continuum Mechanics. This linear law allows us to apply the principle of superposition to forces and to resistive deformations.

We proved in the section of Continuum Mechanics (see page 3744) that Hooke's law states, when the deformations are reversible, that there is proportionality between tension and deformation (it's a variation formulation of Hooke's law):

$$F=k|\Delta L|=\frac{ES}{L_0}|\Delta L|=ES\varepsilon=ES\varepsilon \tag{16.2.53}$$

or:

$$\frac{F}{S}=\sigma=E\varepsilon \tag{16.2.54}$$

where E is the Young's modulus, ε the normal deformation and σ the normal stress.

Let us indicate that the ratio:

$$\frac{ES}{L_0} \tag{16.2.55}$$

is often named "stiffness (rigidity) of the bar" in the literature and is often denoted by k.

We have also proved in the section of Continuum Mechanics that the shear stress was given by (see page 3760):

$$\tau=\frac{E}{1+2\eta}\gamma=G\gamma \tag{16.2.56}$$

where G is the "shear modulus", γ the angle of deformation, and η the Poisson's ratio that is a dimensionless number. thus we have a relation between the modulus of elasticity and rigidity in the case of small deformations.

We have proved also in the same section that for a solid or a liquid subjected to a uniform isotropic pressure we had (see page 3761):

$$\frac{\Delta V}{V_0}=\sigma\frac{3(1-2\eta)}{E}=\sigma\kappa=\kappa\Delta P \tag{16.2.57}$$

The compressibility coefficient κ is therefore a positive number, so using the above relation, we have:

$$\kappa>0\Rightarrow(1-2\eta)>0\Rightarrow 2\eta<1 \tag{16.2.58}$$

and then comes a known result:

$$\eta<\frac{1}{2} \tag{16.2.59}$$

So the Poisson coefficient can not be bigger than $1/2$ and can be negative (in the latter case we speak then of "auxetic materials").

Finally, let us recall that we saw in the section of Continuum Mechanics (see page 3751) that the unit contraction along the z-axis was given during a traction along the x-axis by:

$$\varepsilon_z = -\eta\frac{\sigma_x}{E} = -\eta\varepsilon_x \tag{16.2.60}$$

That is to say when written differently (focusing on the XZ plane):

$$\frac{|\Delta L_z|}{L_{0z}} = -\eta\frac{|\Delta L_x|}{L_{0x}} \tag{16.2.61}$$

Therefore:

$$\eta = -\frac{\dfrac{|\Delta L_z|}{L_{0z}}}{\dfrac{|\Delta L_x|}{L_{0x}}} = \frac{(L_z - L_{0z})/L_{0z}}{(L_x - L_{0x})/L_{0x}} \tag{16.2.62}$$

and that is what shows the figure below:

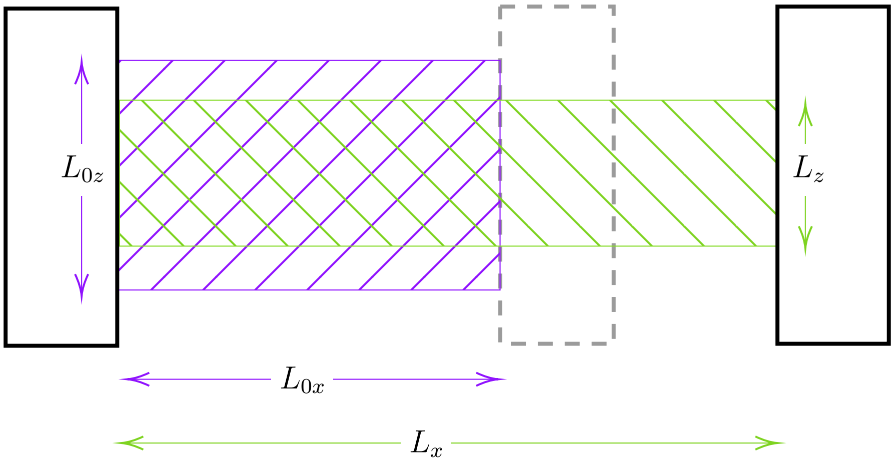


Figure 16.77: Traction on a test piece

We also proved in the section of Continuum Mechanics the following relation during our study of flexural modulus (see page 3762):

$$M = \frac{EI}{R} = \frac{E\displaystyle\int y^2 \mathrm{d}S}{R} = \frac{-\sigma I}{y} \tag{16.2.63}$$

which expresses the bending moment for a beam under a moment of force M (torque), then the span describes an arc of with a curvature of radius R and where I characterizes the "shape stiffness (rigidity)" of the material having a given cross sectional area S. This is a very important relation in many areas of mechanical and civil engineering (shipbuilding, automobile, architecture, etc.).

Remark

I is named the "static moment of inertia" or "quadratic moment" as we have already specified it in the section of Continuum Mechanics.

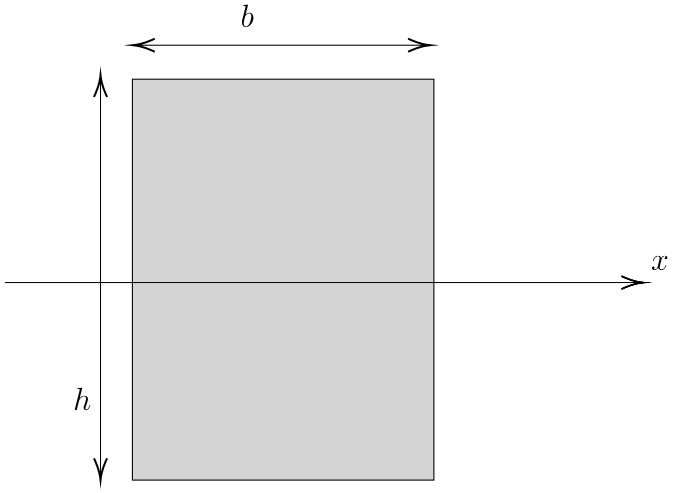
16.2.3.1 Quadratic moments

Let us see the three conventional static moments of inertia I in the field of Material Strengths because they are often encountered in practice (construction).

Remark

The theory of moments of inertia is presented for recall in the section of Classical Mechanics (3297). In the section on Geometric Shapes (see page 2886) we proved in detail the moments of inertia of the most common volumes.

Let us see first the quadratic moment of inertia I_x of a rectangular plate of side b and height h:



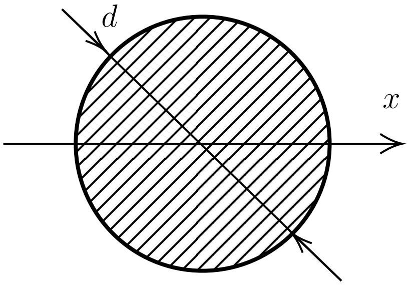
The domain occupied by the plate is given by:

$$S=\left\{(x,y)\in\mathbb{R}^2\left|-\frac{b}{2}\leq x\leq\frac{b}{2},-\frac{h}{2}\leq y\frac{h}{2}\right.\right\} \tag{16.2.64}$$

Then we have:

$$I_x=\int\limits_{-h/2}^{h/2}\int\limits_{-b/2}^{b/2}y^2\mathrm{d}x\mathrm{d}y=\int\limits_{-h/2}^{h/2}y^2x\Big|_{-b/2}^{b/2}\mathrm{d}y=\int\limits_{-h/2}^{h/2}by^2\mathrm{d}y=\frac{b}{3}y^3\Big|_{-h/2}^{h/2}=\frac{bh^3}{12} \tag{16.2.65}$$

And now let us study the quadratic static moment of a disc of diameter:



Here the domain of integration is:

$$S=\left\{(x,y)\in\mathbb{R}^2|x^2+y^2\leq\frac{d^2}{4}\right\}\qquad(16.2.66)$$

where d is the diameter of the disc.

To calculate this integral, we use polar coordinates that are for recall given by (see section Vector Calculus page 1863):

$$x=r\cos(\theta)\qquad y=r\sin(\theta)\qquad(16.2.67)$$

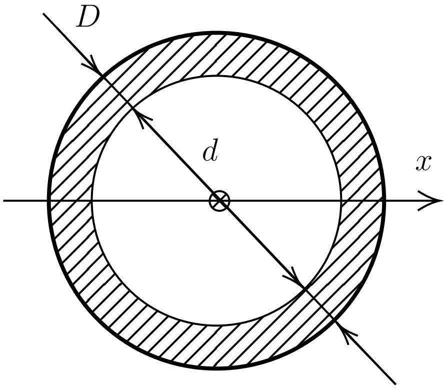
We always have:

$$I_x=\int_S y^2\mathrm{d}x\mathrm{d}y\qquad(16.2.68)$$

The Jacobian of the transformation is equal to r (see section Differential and Integral Calculus page 1528). We get:

$$I_x=\int\limits_0^{d/2}\int\limits_0^{2\pi}r^3(\sin(\theta))^2\mathrm{d}\theta\mathrm{d}r=\pi\int\limits_0^{d/2}r^3\mathrm{d}r=\frac{\pi d^4}{64}\qquad(16.2.69)$$

Now let us calculate the quadratic static inertia of a ring of external diameter D and internal diameter d:



Here is the domain of integration is:

$$S=\left\{(x,y)\in\mathbb{R}^2|\frac{d^2}{4}\leq x^2+y^2\leq\frac{D^2}{4}\right\}\qquad(16.2.70)$$

where D and d are the diameters of the large and small discs.

If we denote by S_1 the domain of the large disc and S_2 that of the small disk then:

$$I_x = \int_{S_1} y^2 \mathrm{d}x\mathrm{d}y - \int_{S_2} y^2 \mathrm{d}x\mathrm{d}y = \frac{\pi(D^4 - d^4)}{64} \tag{16.2.71}$$

using the quadratic static moment of inertia of the disk.

For summary, we have therefore:

$$\begin{aligned} I_x &= \int_S y^2 \mathrm{d}s = \iint_S y^2 \mathrm{d}x\mathrm{d}y \\ I_y &= \int_S x^2 \mathrm{d}s = \iint_S x^2 \mathrm{d}x\mathrm{d}y \end{aligned} \tag{16.2.72}$$

and finally there exist also the static polar quadratic moment of S with respect to a point O:

$$I_0 = \int_S r^2 \mathrm{d}s = \iint_S (x^2 + y^2) \mathrm{d}x\mathrm{d}y = I_x + I_y \tag{16.2.73}$$

It is therefore easy in simple cases to know the static polar moment of inertia and it is very useful for the study of torsion.

It follows from these tools as more elements of the section are located away from the axis, the more the static quadratic moment will be important and the more (we will prove it just further below) the "arrows" will be weak.

16.2.3.2 Equation of the elastic line

For this case study example, widely used in practice, we will first have to obtain mathematically the geometric form that takes the neutral axis of a beam subjected to bending forces.

Remark

If all the reactions of a solicited system can be found from the static equilibrium equations, the problem is say to be "statically determined" or "isostatic". When the equations of static fail to find the equilibrium of a system, the system is say to be "hyperstatic" or "statically indeterminate". We also say that while there is "freedom of movement" despite of n connection points, we are in isostatic situation.

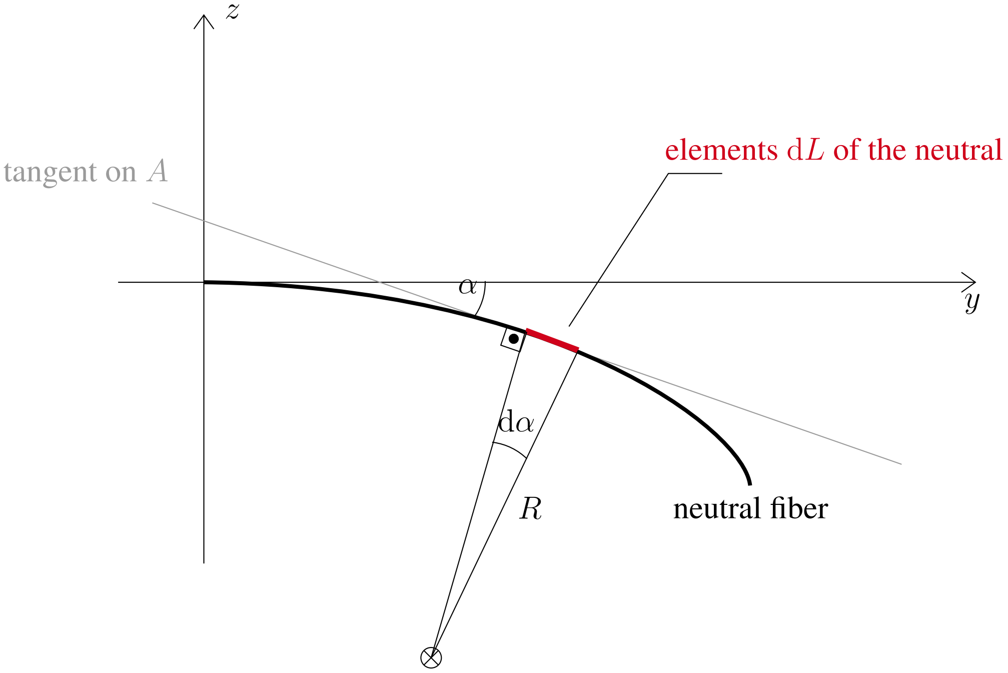


Figure 16.78: Beam (simplified ...) subjected to a force

By definition of the derivative and under the assumption of small deformations (however that still works well up to 45°...):

$$\frac{\mathrm{d}z}{\mathrm{d}y} \cong \tan(\alpha) \cong \alpha \qquad (16.2.74)$$

Or by derivating once again:

$$\frac{\mathrm{d}^2 z}{\mathrm{d}y^2} = \frac{\mathrm{d}\alpha}{\mathrm{d}y} \qquad (16.2.75)$$

Moreover, the figure shows that (see section Trigonometry page 2542):

$$\mathrm{d}L = R\mathrm{d}\alpha \Rightarrow \frac{1}{R} = \frac{\mathrm{d}\alpha}{\mathrm{d}L} \qquad (16.2.76)$$

But the fact that the neutral fiber curve deviates little from the y axis (small deformations), we can write:

$$\mathrm{d}y \cong \mathrm{d}L \qquad (16.2.77)$$

Therefore:

$$\frac{1}{R}\cong\frac{\mathrm{d}\alpha}{\mathrm{d}y} \tag{16.2.78}$$

Therefore we can write using the relationships obtained above:

$$\boxed{\frac{\mathrm{d}^2 z}{\mathrm{d}y^2}=\frac{1}{R}=\frac{M}{EI}} \tag{16.2.79}$$

which is the differential equation giving $z=f(y)$, named "equation of the elastic line".

Another common but less intuitive approach to get the same relation is to start from:

$$M=\frac{EI}{R} \tag{16.2.80}$$

and to recall that the radius of curvature R is given by (see section Differential Geometry page 2875):

$$R=\frac{1}{C}=\frac{\left(1+\left(\dfrac{\mathrm{d}y}{\mathrm{d}y}\right)^2\right)^{3/2}}{\left|\dfrac{\mathrm{d}^2 y}{\mathrm{d}x^2}\right|}=\frac{(1+y'^2)^{3/2}}{|y''|} \tag{16.2.81}$$

Either by adapting the notation to our context:

$$M=\frac{EI}{R}=\frac{EI}{\dfrac{(1+z'^2)^{3/2}}{|z''|}} \tag{16.2.82}$$

and neglecting the first derivative for the small deformations we find indeed:

$$M=\frac{EI}{R}=\frac{EI}{\dfrac{(1+z'^2)^{3/2}}{|z''|}}\cong EI|z''|=EI\frac{\mathrm{d}^2 z}{\mathrm{d}y^2} \tag{16.2.83}$$

✍**Examples:**

E1. Cantilevered beam (only at one side) that is classic case in construction and housing) with concentrated load (punctual) at the end:

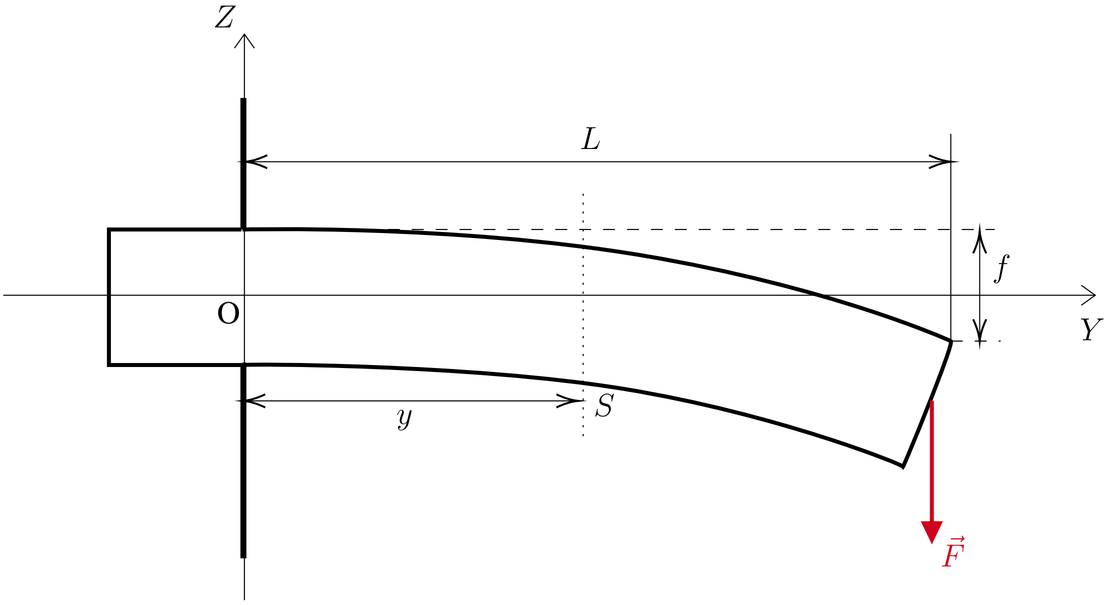

Figure 16.79: **Cantilevered beam with punctual force on extremity**

In the section S at any point, the moment of force (bending) is therefore:

$$M(y) = F(L-y) = \frac{EI}{R} \Rightarrow \frac{F(L-y)}{EI} = \frac{1}{R} \tag{16.2.84}$$

On the other hand:

$$\frac{\mathrm{d}^2 z}{\mathrm{d}y^2} = \frac{1}{R} \tag{16.2.85}$$

By eliminating R between these two relations, it remains:

$$\frac{\mathrm{d}^2 z}{\mathrm{d}y^2} = \frac{F}{EI}(L-y) \tag{16.2.86}$$

The figure shows that the boundary conditions are:

$$y = 0 \Rightarrow \begin{cases} z = 0 \\ \dfrac{\mathrm{d}z}{\mathrm{d}z} = 0 \end{cases} \tag{16.2.87}$$

We get after integration:

$$\begin{aligned} \frac{\mathrm{d}z}{\mathrm{d}z} &= \frac{F}{EI}\left(Ly - \frac{1}{2}y^2\right) \\ z &= \frac{F}{EI}\left(L\frac{1}{2}y^2 - \frac{1}{2}\frac{1}{3}y^3\right) \end{aligned} \tag{16.2.88}$$

Therefore:

$$z=\frac{FL}{EI}\frac{y^2}{2}-\frac{F}{2EI}\frac{y^3}{3} \tag{16.2.89}$$

If $y=L$ the deformation is maximum and z therefore takes the maximum value f named the "arrow" or deflection" (distance between the top initial position of the cantilever and the top of the final position in the above example). It follows:

$$z=f=\frac{FL}{EI}\frac{L^2}{2}-\frac{F}{2EI}\frac{L^3}{3}=\frac{FL^3}{3EI} \tag{16.2.90}$$

This gives us finally the maximum vertical deflection of the end to a beam fixed on one side:

$$\boxed{f=\frac{FL^3}{3EI}} \tag{16.2.91}$$

All data from this relation are known to us (force, length, Young's modulus, static momentum) and it is then possible to determine whether the bar will break or not because we simply need to apply the relation proved above:

$$M=\frac{-\sigma I}{y}\Rightarrow|\sigma|=\frac{yM}{I}=\frac{fM}{I} \tag{16.2.92}$$

So thanks to the relation:

$$\boxed{\sigma=\frac{fM}{I}} \tag{16.2.93}$$

and knowing experimentally from what experimental value of σ the material breaks down we will know when the beam will also break down (at least approximately!) knowing the arrow f, the bending moment M and the static quadratic moment I.

So we have a result that will be useful to us later:

$$\mathrm{d}f=F\frac{1}{EI}y^2\mathrm{d}y \tag{16.2.94}$$

and integrating from 0 to L we find the arrow of our previous beam!

E2. The sustained beam (also named "beam two times supported" or "isostatic beam") is the most classic example in construction and therefore architecture (and for those who played during childhood to put wooden slats to move over a small river). This is a homogeneous beam, of constant section, resting on two free bearings at its ends and subjected to a load F at the center:

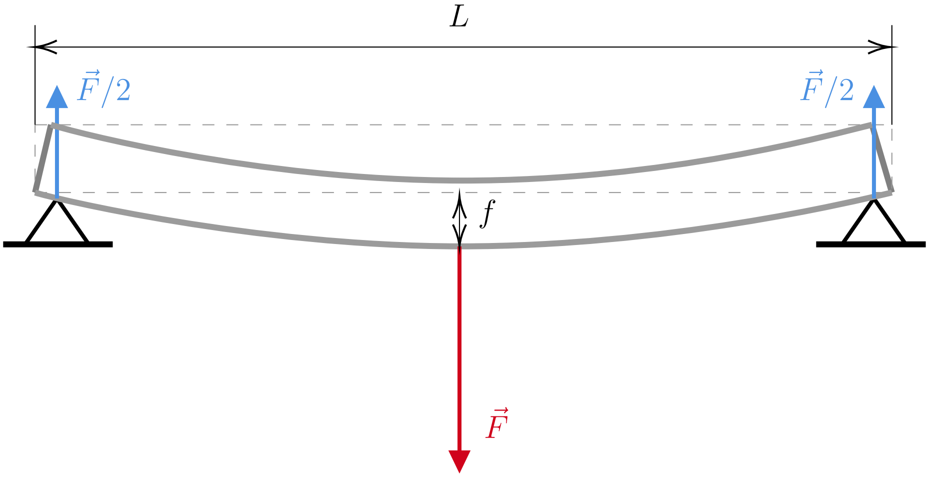

Figure 16.80: **Sustained beam with punctual centered force**

We can therefore consider that it is as if we had $F/2$ at both ends of two beams of length $L/2$ (thus the sum is indeed equal to F, that is to say, the bending moment). Notice that we neglect the weight of the beam relatively to that of F, but F may be simply the weight of the beam! Using the last relation of the previous example, we have:

$$\mathrm{d}f=\frac{F}{2}\frac{1}{EI}y^2\mathrm{d}y \tag{16.2.95}$$

Therefore:

$$f=\frac{F}{2}\frac{1}{EI}\int_0^{L/2}y^2\mathrm{d}y=\frac{FL^3}{48EI} \tag{16.2.96}$$

Thus the maximum vertical deflection of a beam connected on both sides is finally (changing a bit the notation):

$$\boxed{f=\frac{FL^3}{48EI}} \tag{16.2.97}$$

Thus, for a same length of beam, at identical F the arrow is 16 times smaller than for a fixed beam! It was intuitive that it was lower for the same force but hard to guess that it would be of a factor 16...!

It is this relationship that is also used for IPN beams (famous beams in building construction!).

E3. Beam built only one side still named "cantilever beam" (also classic case in the construction and housing) but now with a constant line load denoted w:

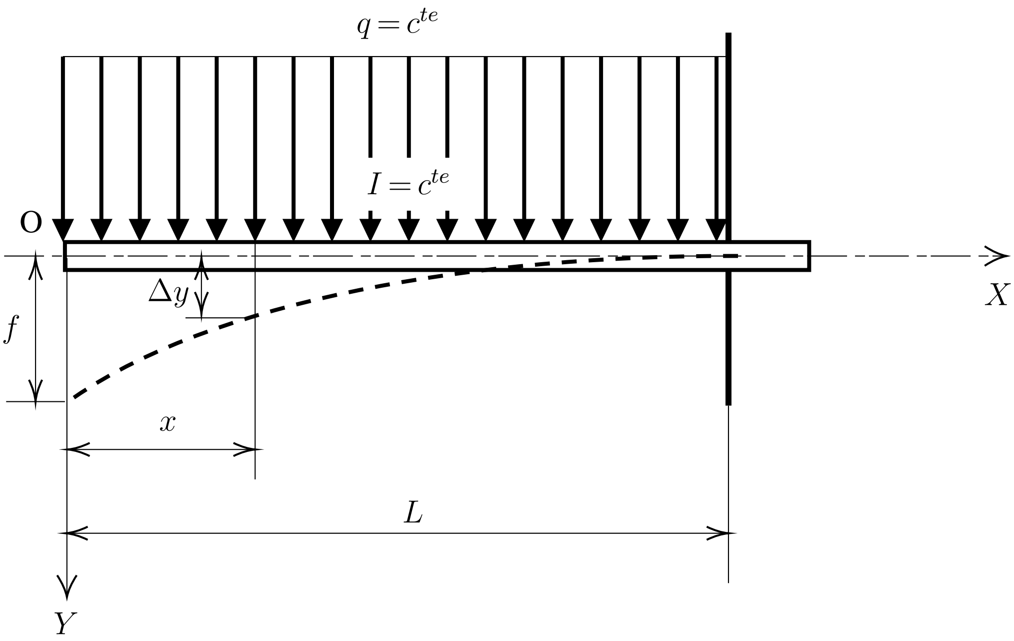

Figure 16.81: Beam fixed on one side with constant line load

The development is simple but some simplifications are smart to get at the end an elegant result. So we always start from the equation of the elastic line by adopting the notations relatively to the selected configuration (see figure above):

$$\frac{\mathrm{d}^2y}{\mathrm{d}x^2} = \frac{M}{EI} \tag{16.2.98}$$

Thus explicitly:

$$\frac{\mathrm{d}^2y}{\mathrm{d}x^2} = \frac{\displaystyle\int F\mathrm{d}x}{EI} = \frac{\displaystyle\int\left(\int q\mathrm{d}x\right)\mathrm{d}x}{EI} = \frac{\displaystyle\int wx\mathrm{d}x}{EI} = \frac{w\dfrac{x^2}{2} + c^{te}}{EI} \tag{16.2.99}$$

As the moment of force M is zero at $x = 0$, we have the constant that is zero. Since then:

$$\frac{\mathrm{d}^2y}{\mathrm{d}x^2} = \frac{w\dfrac{x^2}{2}}{EI} \tag{16.2.100}$$

Integrating again, we get:

$$y' = \frac{\mathrm{d}y}{\mathrm{d}x} = \frac{w}{EI}\int\frac{x^2}{2}\mathrm{d}x = \frac{w}{EI}\frac{x^3}{6} + c^{te} \tag{16.2.101}$$

As for $x = L$ by hypothesis the deformation is zero, we have then the constant that is given by:

$$y' = \frac{w}{EI}\frac{L^3}{6} + c^{te} = 0 \Rightarrow = -\frac{wL^3}{6EI} \tag{16.2.102}$$

Therefore:

$$y' = \frac{w}{EI}\frac{x^3}{6} - \frac{wL^3}{6EI} = \frac{wL^3}{6EI}\left(\left(\frac{x}{L}\right)^3 - 1\right) \tag{16.2.103}$$

By integrating a last time:

$$y=\frac{w}{6EI}\int(x^3-L^3)\mathrm{d}x=\frac{w}{6EI}\left(\frac{x^4}{4}-L^3x\right)+\frac{wL^4}{8EI} \tag{16.2.104}$$

And as on $x=L$ we have y that is also zero, it comes for the constant:

$$y=\frac{w}{EI}\left(\frac{L^4}{4}-L^3L\right)+c^{te}=0\Rightarrow=\frac{wL^4}{8EI} \tag{16.2.105}$$

Therefore:

$$y=\frac{w}{EI}\left(\frac{x^4}{4}-L^3x\right)+\frac{wL^4}{8EI} \tag{16.2.106}$$

And as the arrow is anyway on $x=0$, we have then:

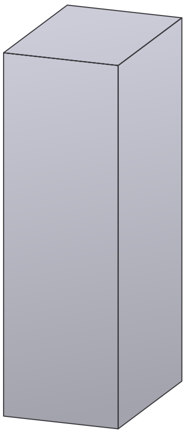
$$f=\frac{wL^4}{8EI} \tag{16.2.107}$$

16.2.3.2.1 Euler-Bernoulli Beam equation

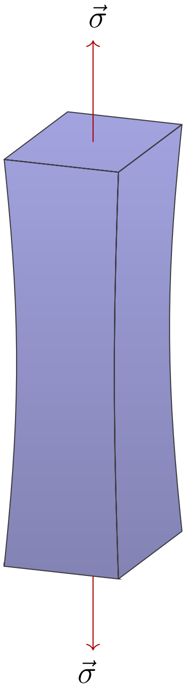
Let us now consider the case of a beam fixed on both sides (case even more common that the three previous examples!). The analysis will be a bit more difficult and we will have to introduce several new concepts.

A beam in practice must withstand at least the following efforts:

- Unloaded (normal):

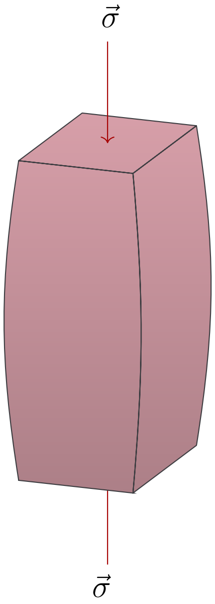


- Tension:



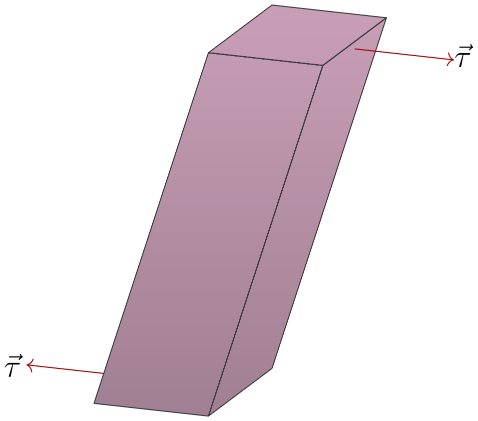
$\vec{\sigma}$
$\vec{\sigma}$

- Compression:



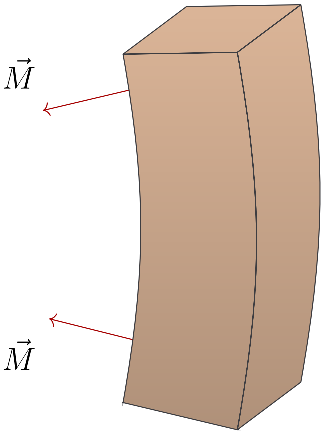
$\vec{\sigma}$
$\vec{\sigma}$

- Shearing (shear):

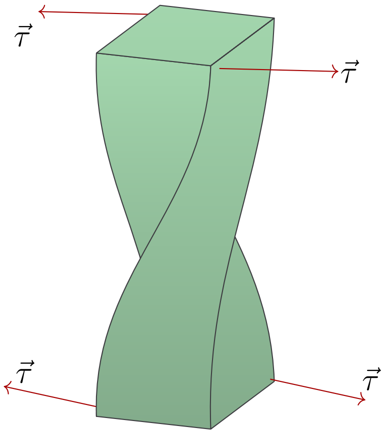


$\vec{\tau}$
$\vec{\tau}$

- Flexion (bending stress):

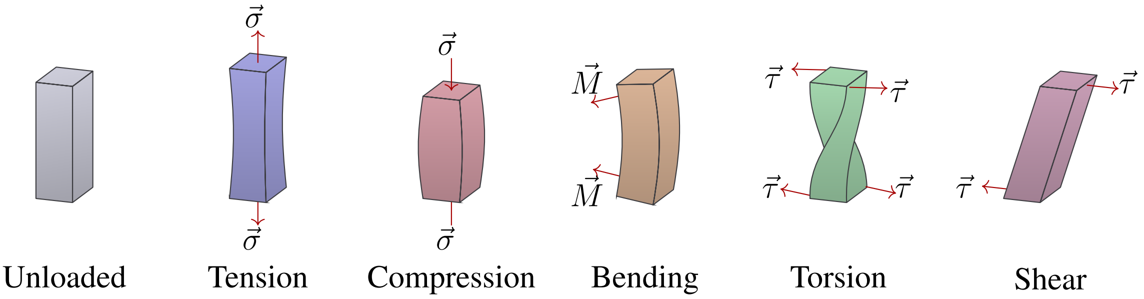


- Torsion:



$\vec{\tau}$
$\vec{\tau}$
$\vec{\tau}$
$\vec{\tau}$

Or to summarize in a single figure:



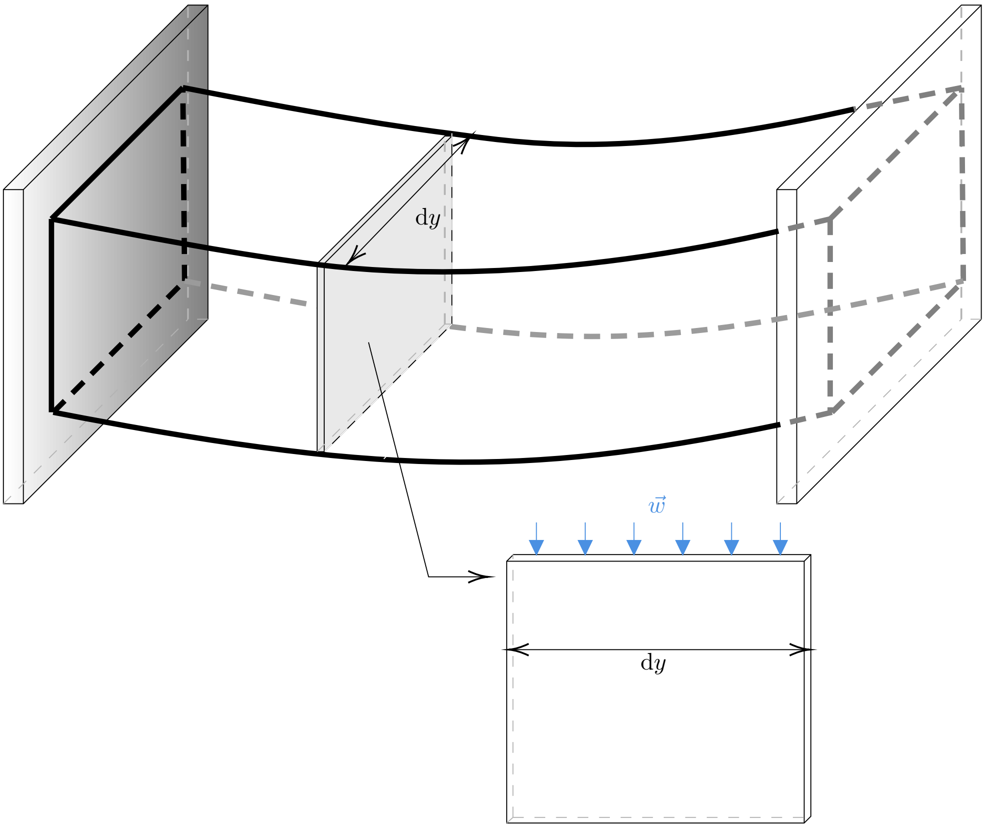
Unloaded Tension Compression Bending Torsion Shear

Figure 16.82: Most common types of material deformations (author: Izaak Neutelings)

If a beam is in equilibrium, then the internal forces must satisfy at all points the following relations:

$$\begin{gathered}\sum\vec{F}_{\text{horizontal}}=\sum\vec{F}_{\text{stress/compression}}=\vec{0}\\ \sum\vec{F}_{\text{horizontal}}=\sum\vec{F}_{\text{shear}}=\vec{0}\\ \sum\vec{M}=\sum\vec{M}_{\text{bending}}=\vec{0}\end{gathered}\tag{16.2.108}$$

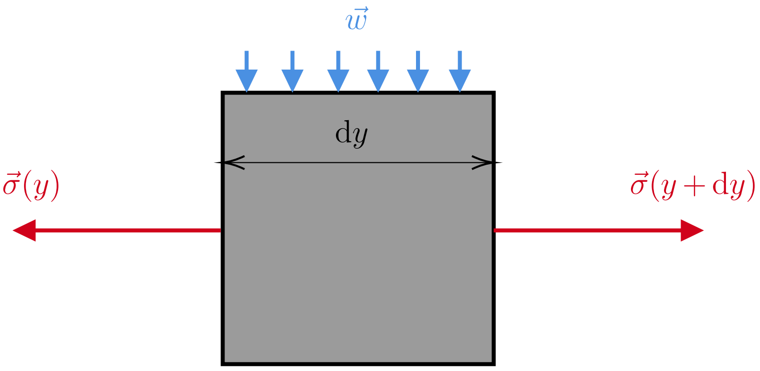
Let us consider now a beam embedded at its two ends (dual-embedded beam) and let us take in a slice of infinitesimal length $\mathrm{d}y$ such that locally its curvature is zero. The beam will be assumed to be subjected to a uniform force over its entire length (a force which can also be assimilated to its own weight, as already mentioned above). It is then customary to denote by $\vec{w}$ the force per unit length (total weight divided by the length) which is obviously a linear load:



If the beam is at equilibrium once deformed (weakly or strongly deformed, this does not matters

!) then the sums of the forces of tension, compression, shear and bending must be zero at each point as we have already said! This does not however mean that at each point of the elastic line the values of each of the forces is equal! On the contrary! There are of course differences (if not, there would be no deformation...!).

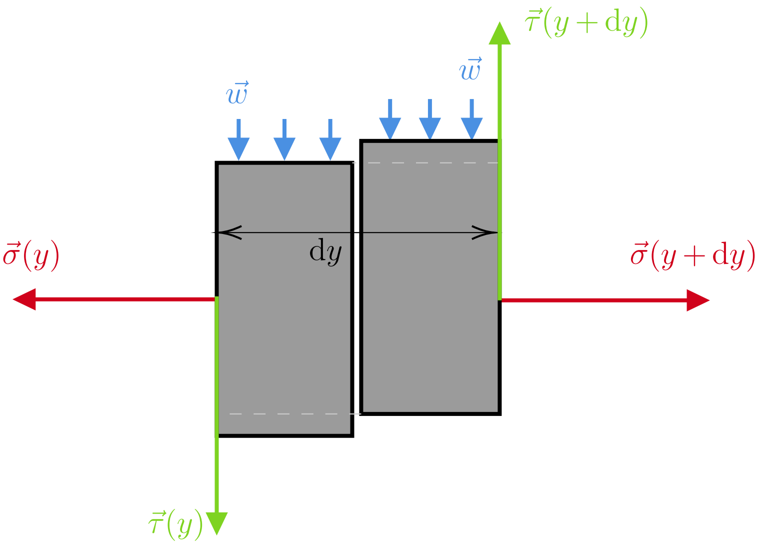
Let us first sum the local forces of tension and compression (horizontal) of the element of length $\mathrm{d}y$. We then have schematically:



That is to say algebraically (the variational can be negative or positive whatever!):

$$\sum \vec{F}_{\text{horizontal}} = \vec{\sigma}(y+\mathrm{d}y) - \vec{\sigma}(y) = \vec{\sigma} + \mathrm{d}\vec{\sigma} - \vec{\sigma} = \mathrm{d}\vec{\sigma} = \vec{0} \qquad (16.2.109)$$

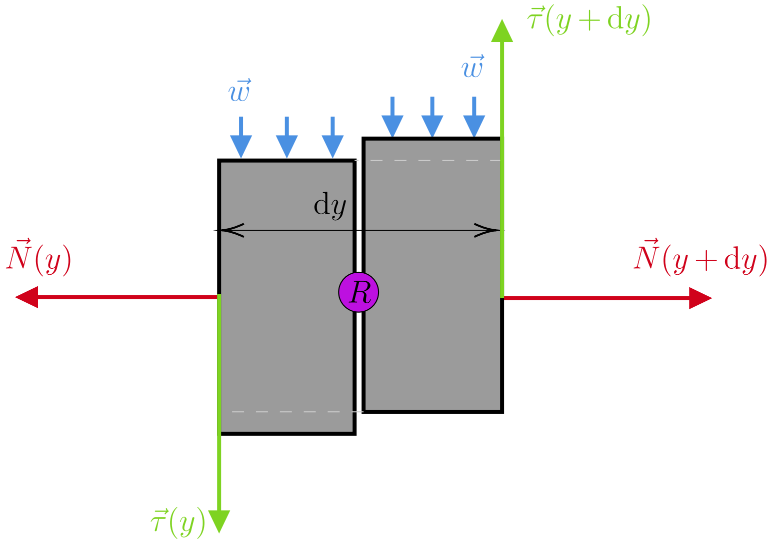
If now we take care of the vertical forces at the source of the shear then we have schematically:



That is to say algebraically (the variational can be negative or positive whatever!):

$$\sum \vec{F}_{\text{vertical}} = \vec{\tau}(y+\mathrm{d}y) - \vec{\tau}(y) = \vec{\tau} + \mathrm{d}\vec{\tau} - \vec{\tau} - \vec{w}\mathrm{d}y = \mathrm{d}\vec{\tau} - \vec{w}\mathrm{d}y = \vec{0} \qquad (16.2.110)$$

And finally for the bending moments the sum is also necessarily zero at equilibrium. However, in contrast to the two preceding algebraic sums where we could only use the differential, we have to choose a reference point R for the bending moments since, for recall... the moment of force is by definition the product of a force by a distance. We will therefore naturally choose the center of gravity:



The uniform linear load $\vec{w}$ on the length $\mathrm{d}y$ generates a force at mid distance of:

$$\vec{F}_{\vec{w}}=(\vec{w}(y)\mathrm{d}y)\frac{1}{2}\mathrm{d}y=\frac{1}{2}\vec{w}(y)\mathrm{d}y^2 \tag{16.2.111}$$

but as it is confounded with the choices of our reference point, then its moment of strength is zero!

We then have algebraically:

$$\begin{aligned}\sum\vec{M}&=\vec{M}(y)+\vec{M}(-y)+\vec{\tau}(y)\frac{\mathrm{d}y}{2}+\vec{\tau}(-y)\frac{\mathrm{d}y}{2}\\&=\underbrace{\vec{M}+\mathrm{d}\vec{M}}_{=\vec{M}(y)}-\underbrace{\vec{M}}_{=\vec{M}(-y)}\frac{\mathrm{d}y}{2}+\underbrace{\vec{\tau}}_{=\vec{\tau}(-y)}\frac{\mathrm{d}y}{2}=\mathrm{d}\vec{M}+\vec{\tau}\frac{\mathrm{d}y}{2}+\mathrm{d}\vec{\tau}\frac{\mathrm{d}y}{2}+\vec{\tau}\frac{\mathrm{d}y}{2}\\&=\mathrm{d}\vec{M}+\vec{\tau}\mathrm{d}y+\mathrm{d}\vec{\tau}\frac{\mathrm{d}y}{2}=\vec{0}\end{aligned} \tag{16.2.112}$$

And if we neglect the differentials of order two it remains only:

$$\mathrm{d}\vec{M}+\vec{\tau}\mathrm{d}y=\vec{0} \tag{16.2.113}$$

Finally, we have:

$$\boxed{\left.\begin{aligned}&\mathrm{d}\vec{\sigma}=\vec{0}\\&\mathrm{d}\vec{\tau}-\vec{w}\mathrm{d}y=\vec{0}\\&\mathrm{d}\vec{M}+\vec{\tau}\mathrm{d}y=\vec{0}\end{aligned}\right\}\Leftrightarrow\left\{\begin{aligned}&\frac{\mathrm{d}\vec{\sigma}}{\mathrm{d}y}=\vec{0}\\&\frac{\mathrm{d}\vec{\tau}}{\mathrm{d}y}=\vec{w}\\&\frac{\mathrm{d}\vec{M}}{\mathrm{d}y}=-\vec{\tau}\end{aligned}\right.} \tag{16.2.114}$$

To determine the bending moment from the linear load (which is of primary interest to the practitioner), we derive the third relation twice and make a substitution:

$$\frac{\mathrm{d}}{\mathrm{d}y}\left(\frac{\mathrm{d}\vec{M}}{\mathrm{d}y}\right)=-\frac{\mathrm{d}}{\mathrm{d}y}\vec{\tau}=-\vec{w} \tag{16.2.115}$$

Hence:

$$\frac{\mathrm{d}^2\vec{M}}{\mathrm{d}y^2}=-\vec{w} \tag{16.2.116}$$

The problem with this last relation is the knowledge of the moments. We should get rid of this term absolutely. What we know easily is the deformation function and we have proved earlier above that:

$$\frac{\mathrm{d}^2 z}{\mathrm{d}y^2}=\frac{1}{R}=\frac{M}{EI} \tag{16.2.117}$$

It then comes immediately by substituting the preceding relation in the prior previous one:

$$\boxed{EI\frac{\mathrm{d}^4 z}{\mathrm{d}y^4}=-w(y)} \tag{16.2.118}$$

where the product EI is known as the "flexural rigidity".

This is the most important elementary relation of the theory of beams, that covers the case for small deflections of a beam that is subjected to lateral loads only, because it allows by knowing the linear load to determine the function of deformation or conversely! It is so important to know that it is named the "static beam equation" or in honour to those who have determined it: "Euler-Bernoulli equation". It seemed it was first enunciated circa 11750 (holocene calendar), but was not applied on a large scale until the development of the Eiffel Tower and the Ferris wheel in the late 119th century (holocene calendar).

Since it is a differential equation of order 4 that will generate four constants at each integration, we will then need 4 initial conditions to solve it completely.

Remark

The Euler-Bernoulli equation by its assumptions is only a special case of a more general theory named the "Timoshenko beam theory" published in 11921 (holocene calendar).

✍**Example:**

We would like to calculate the deformation of a beam fixed on both sides and loaded uniformly knowing its length L, its modulus of elasticity E, its moment of inertia I.

We start from (we change the notations only to show that according to some textbooks the axes can be denoted differently):

$$EI\frac{\mathrm{d}^4y}{\mathrm{d}x^4}=-w(x) \tag{16.2.119}$$

With the initial conditions:

$$y(x=0)=0 \qquad y(x=L)=0 \qquad \frac{\mathrm{d}y}{\mathrm{d}x}(x=0)=0 \qquad \frac{\mathrm{d}y}{\mathrm{d}y}(x=L)=0 \tag{16.2.120}$$

And integrating by repetition, we have:

$$\begin{gathered}\frac{\mathrm{d}^3y}{\mathrm{d}x^3}=\frac{-wx}{EI}+C_1\Rightarrow\frac{\mathrm{d}^2y}{\mathrm{d}x^2}=\frac{-wx^2}{2EI}+C_1x+C_2\Rightarrow\frac{\mathrm{d}y}{\mathrm{d}x}=\frac{-wx^2}{6EI}+\frac{C_1x^2}{2}+C_2x+C_2\\ y(x)=\frac{-wx^4}{24EI}+\frac{C_1x^3}{6}+\frac{C_2x^2}{2}+C_3x+C_4\end{gathered} \tag{16.2.121}$$

From the two initial conditions:

$$y(x=0)=0 \qquad \frac{\mathrm{d}y}{\mathrm{d}x}(x=0)=0 \tag{16.2.122}$$

It follows that:

$$C_3=C_4=0 \tag{16.2.123}$$

With the other two remaining conditions, we obtain the following system which must allow us to determine the two remaining constants:

$$\begin{cases}\dfrac{-wL^4}{24EI}+\dfrac{C_1L^3}{6}+\dfrac{C_2L^2}{2}=0\\ \dfrac{-wL^3}{6EI}+\dfrac{C_1L}{2}+C_2L=0\end{cases} \tag{16.2.124}$$

Then it is simply a matter of solving a simple linear system (see section Linear Algebra page 1929):

$$\begin{cases}\dfrac{-wL^4}{24EI}+\dfrac{C_1L^3}{6}+\dfrac{C_2L^2}{2}=0\Big|\cdot\dfrac{24}{L^2}\\ \dfrac{-wL^3}{6EI}+\dfrac{C_1L}{2}+C_2L=0\Big|\cdot\dfrac{6}{L}\end{cases}\Rightarrow\begin{cases}\dfrac{-wL^2}{EI}+4C_1L+12C_2=0\Big|\cdot\dfrac{24}{L^2}\\ \dfrac{-2wL^2}{EI}+6C_1L+12C_2=0\Big|\cdot\dfrac{6}{L}\end{cases} \tag{16.2.125}$$

Subtracting both relation in the simple adequate way we get immediately:

$$\begin{cases}C_1&=\dfrac{wL}{2EI}\\ C_2&=\dfrac{-wL}{12EI}\end{cases} \tag{16.2.126}$$

Therefore for an ideal beam embedded on both sides subjected to a uniform load and described by:

$$y(x)=\frac{-wx^4}{24EI}+\frac{wLx^3}{12EI}-\frac{wL^2x^2}{24EI}=\frac{-wx^2}{24EI}(x^2-2Lx+L^2)=\frac{-wx}{24EI}(x-L)^2 \tag{16.2.127}$$

To determine the arrow, we must therefore look for the point x where this relation has an optimum. We then have:

$$\begin{aligned}f'(x)&=\left[x^2(x-L)^2\right]'=2x(x-L)^2+2x^2(x-L)\\&=2x(x-L)(x-L+x)=2x(x-L)(2x-L)=0\end{aligned} \tag{16.2.128}$$

It follows that the arrow has a maximum at $x=L/2$. Injecting this into $y(x)$ we get the famous relation often given in the literature but rarely proved:

$$\boxed{f=\frac{w}{24EI}\frac{L^4}{16}=\frac{wL^4}{384EI}} \tag{16.2.129}$$

It follows that the arrow of a beam is proportional to the fourth power of the length of the beam! Such high dependence imposes significant limitations on Civil Engineering structures based on beams.

Remark

The constant linear load, either over the total length of the beam or in successive sections, is a frequent observed type of stress in horizontal axis of pieces. It may come from the weight of the pieces with a constant section or from a load caused by an external force (eg gravity).

16.2.3.2.2 Potential elastic energy

After a quick overview of the various elastic deformations of the parts stressed by the fundamental forces, we will establish here the general expression of the elastic energy accumulated in a beam of any shape stressed by external forces.

Let us recall for this study that we can write Hook's law (see section Continuum Mechanics page 3744) in the following form:

$$|\Delta L| = \frac{FL_0}{ES} = \frac{F}{k} \tag{16.2.130}$$

and the elastic potential energy of a spring proved in the section of Classical Mechanics (see page 3418) is given by:

$$E_{\text{elastic}} = \frac{1}{2}kx^2 \tag{16.2.131}$$

Or in relative displacement:

$$E_{\text{elastic}} = \frac{1}{2}k\Delta x^2 \tag{16.2.132}$$

In the traction domain (or compression) of the beams, it is customary to consider the beam as a spring (...) and then to use the stiffness constant of Hook's law ... hoping that this is conforming to experimental observations...:

$$E_{\text{elastic}} = \frac{1}{2}k\Delta x^2 = \frac{1}{2}\frac{ES}{L_0}\Delta x^2 = \frac{ES}{2L_0}\Delta L^2 \tag{16.2.133}$$

Where, according to usage, we denote the longitudinal displacement L instead of x. By injecting Hook's law (yes ... it turns a little bit a loop... but that's engineering...):

$$E_{\text{elastic}} = \frac{ES}{2L_0}\left(\frac{FL_0}{ES}\right)^2 = \frac{F^2L_0}{2ES} \tag{16.2.134}$$

It is then sufficient to divide by the length of the bar to have the elastic linear energy denoted:

$$\boxed{\bar{E}_{\text{elastic}} = \frac{F^2}{2ES}} \tag{16.2.135}$$

The energy density, noted conventionally denoted as in thermodynamics by a minuscule letter, is then:

$$\boxed{e = \frac{E_{\text{elastic}}}{V} = \frac{F^2L_0}{2ESV} = \frac{F^2L_0}{2ESSL_0} = \frac{F^2}{2ES^2} = \left(\frac{F}{S}\right)^2\frac{1}{2E} = \frac{\sigma^2}{2E}} \tag{16.2.136}$$

16.2.3.3 Torsion

Let us recall first to the reader a study we made in the section on Classical Mechanics on the torsional pendulum where some elements had deliberately been muted.... Let's study this in more detail as it is very useful for transmission shafts or springs in everyday life.

Let us consider for this a cylindrical wire fixed at its base and subjected to a torsion moment $\vec{M}$. Under the effect of this torsion moment, the upper face of the wire is offset by an angle θ with respect to the lower face, the material undergoing a torsion stress (or shearing τ):

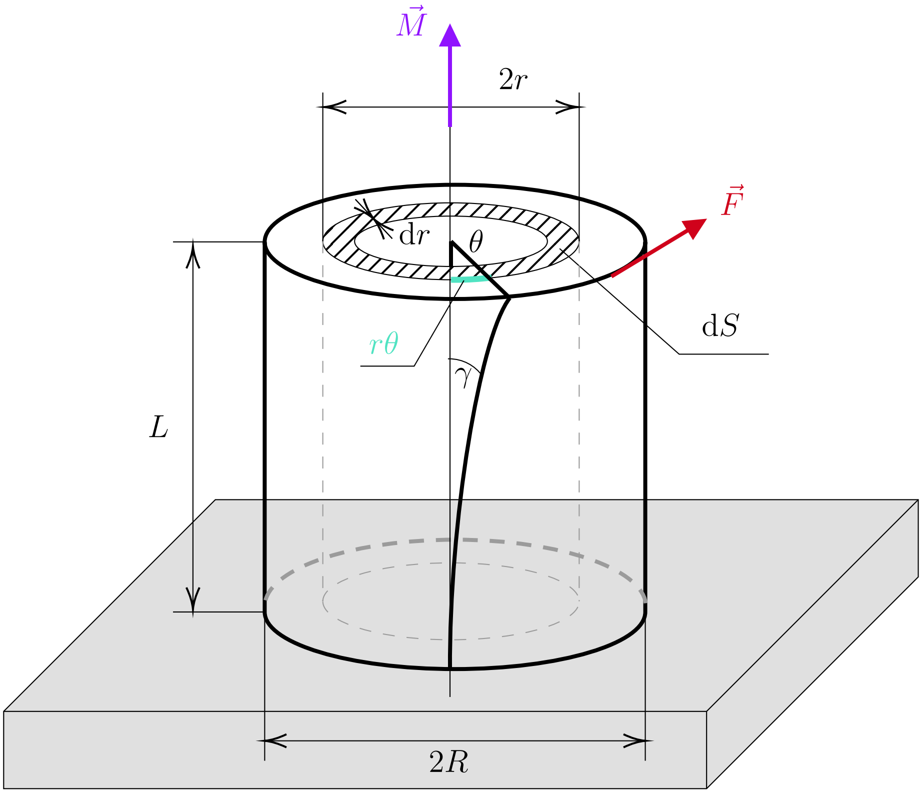


Figure 16.83: **Wire under torsion**

Let us imagine an extraction of the inside the wire an elementary tube of radius r, of thickness $\mathrm{d}r$, and let us observe the effect of the torsion on this tube unrolled (this will allow us an approximate approach of the concerned phenomenon):

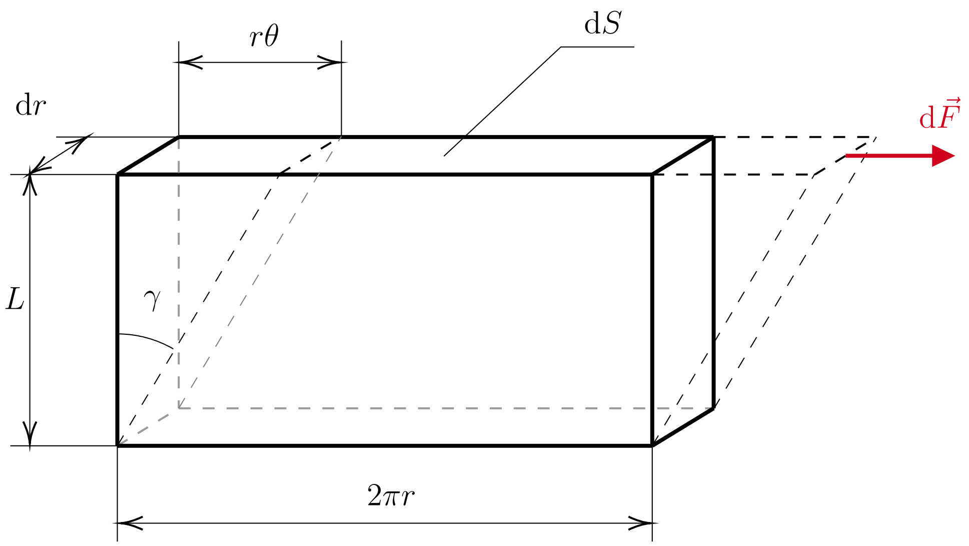

Figure 16.84: **Extraction an unroll of an element of the wire**

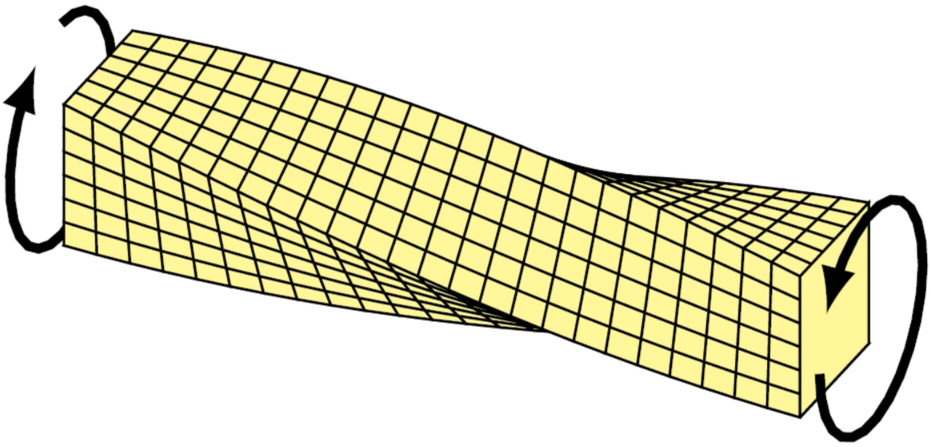
Let us look for a relation between torsion moment $\vec{M}$ and torsion angle θ that would therefore also apply to a beam as below:



For the unrolled tube, let us apply the shear relations as proved and introduced in the section of Continuum Mechanics (see page 3760):

$$G\gamma = \tau = \frac{\mathrm{d}F}{\mathrm{d}S} \Rightarrow \mathrm{d}F = \gamma G \mathrm{d}S \tag{16.2.137}$$

but the figure shows that (the deformations being weak) to the first order in Taylor series (see section Sequences and Series page 1703):

$$\gamma = \arctan\left(\frac{r\theta}{L}\right) \cong \frac{r\theta}{L} \tag{16.2.138}$$

hence:

$$\mathrm{d}F = \frac{r\theta}{L} G \mathrm{d}S \tag{16.2.139}$$

The elementary moment due to this force is by definition of the moment of force (torque):

$$\mathrm{d}\vec{M}=\vec{r}\times\mathrm{d}\vec{F} \tag{16.2.140}$$

Since $\vec{r}$ and $\vec{F}$ are perpendicular:

$$\mathrm{d}M=\frac{\theta G}{L}r^2\mathrm{d}S \tag{16.2.141}$$

The total moment (torque) is then equal to:

$$M=\int\limits_{r=0}^{r=R}\mathrm{d}M=\frac{\theta G}{L}\int\limits_{r=0}^{r=R}r^2\mathrm{d}S=\frac{\theta G}{L}I_0 \tag{16.2.142}$$

therefore:

$$M=\left(\frac{GI_0}{L}\right)\theta=-\left(\frac{GI_0}{L}\right)\theta=-k\theta \tag{16.2.143}$$

We thus fall back on the relation of the torsional pendulum that we had found during our study of the torsional pendulum in the section of Classical Mechanics (see page 3425):

$$\boxed{M=-k\theta} \tag{16.2.144}$$

with the difference that this time the constant k, the "torsion constant" is explicit!!!!

The numerator of the constant k is named in the domain of the strength of materials the "torsional rigidity" or "torsional stiffness" and the constant k itself is often referred to as "shaft rigidity" instead of "torsional constant". In practice, the main aim is to find the numerical value of the following expression:

$$\boxed{\theta=\frac{ML}{GI_0}} \tag{16.2.145}$$

since this will give the angular amplitude of the torsion.

Let us see therefore a very important application to the compression spring of helical type (the approach is approximate again...) working in torsion.

First, it must be realized that when a force is applied to the spring, the ends will rotate by a small angle θ (torsion) corresponding to the movement by a distance x which itself corresponds to the narrowing of the spring (yes indeed! this length must be taken somewhere....).

Given then a spring of external radius R (or of diameter D), of shear modulus G, with a body diameter d (diameter of the folded cylinder of which the spring is composed):

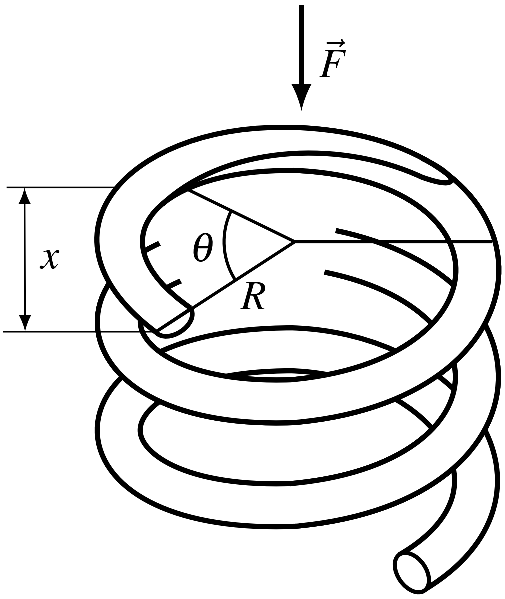


Figure 16.85: Spiral spring under load (author: H. Zeljko)

For the analysis we will simply need to mix several of the relations proved so far. In the first place, the torsion angle of a beam of length L (length of the spring in this case!):

$$\theta = \frac{ML}{GI_0} \tag{16.2.146}$$

With:

$$I_0 = I_x + I_y = \frac{\pi d^4}{64} + \frac{\pi d^4}{64} = \frac{\pi d^4}{32} \tag{16.2.147}$$

and:

$$L = n\pi D \tag{16.2.148}$$

Moreover, the moment of torsion is written:

$$M = FR = F\frac{D}{2} \tag{16.2.149}$$

We thus arrive at:

$$\theta = \frac{ML}{GI_0} = \frac{F\dfrac{D}{2}n\pi D}{G\dfrac{\pi d^4}{32}} = \frac{16FnD^2}{Gd^4} \tag{16.2.150}$$

Remark

It would be pretentious to claim to do with this section as well and also as complete as the *Statique* free French PDF of Nicolet Gaston Raymond that is a priori unrivaled in content and quality to this date (even compared to non-free textbooks on the subject!). It is therefore strongly recommended to refer to it if the reader wants to drive full information about civil engineering (see the download section of the companion website or directly his own website `http://www.raymondnicolet.ch`). Same recommendation applies to the reader about the master pieces that are the English books *Mechanics of Materials* ([246]) and *Structural and Stress Analysis* ([384])!

The ratio M/θ, as well as for the drive shaft, is named the "spring stiffness" or "spring rigidity".

The displacement (deformation) x is equal to (see section Trigonometry page 2542):

$$x=R\theta=\frac{D}{2}\theta \tag{16.2.151}$$

We finally arrive at:

$$x=\frac{D}{2}\frac{16FnD^2}{Gd^4}=\frac{8FnD^3}{Gd^4} \tag{16.2.152}$$

Which brings us to the worldwide known relation in the world in the strength of material regarding to springs:

$$\boxed{F=\left(\frac{Gd^4}{8nD^3}\right)x=kx} \tag{16.2.153}$$

where k is the "spring stiffness" constant also named "spring rigidity"! If now we use the expression of the elastic potential energy of a spring proved in the section of Classical Mechanics:

$$E_{\text{elastic}}=\frac{1}{2}kx^2 \tag{16.2.154}$$

We can then determine the energy a spiral spring can absorb.

16.2.3.4 Buckling

We conclude this study of the material strengths in this textbook for now, with "buckling" (classical study case in construction and mechanics) which consists in determining (in a special simple case) the minimum force F_0 from which a bar of length L, of Young's modulus E fixed at its two ends can fold (with a curvature radius R) until it breaks without the need to increase the force F_0 (this is again an indication value!).

Buckling is characterized by a sudden sideways failure of a structural member subjected to high compressive stress, where the compressive stress at the point of failure is less than the ultimate compressive stress that the material is capable of withstanding. Mathematical analysis of buckling often makes use of an "artificial" axial load eccentricity that introduces a secondary bending moment that is not a part of the primary applied forces being studied. As an applied load is increased on a member, such as a column, it will ultimately become large enough to cause the member to become unstable and is said to have buckled. Further load will cause significant and somewhat unpredictable deformations, possibly leading to complete loss of the member's load-carrying capacity. If the deformations that follow buckling are not catastrophic the member will continue to carry the load that caused it to buckle. If the buckled member is part of a larger assemblage of components such as a building, any load applied to the structure beyond that which caused the member to buckle will be redistributed within the structure. Theoretically, buckling is caused by a bifurcation in the solution to the equations of static equilibrium. At a certain stage under an increasing load, further load is able to be sustained in one of two states of equilibrium: a purely compressed state (with no lateral deviation) or a laterally-deformed state.

The ratio of the effective length of a column to the least radius of gyration of its cross section is named the "slenderness ratio λ". This ratio affords a means of classifying columns. Slenderness ratio is important for design considerations. All the following are approximate values used for convenience:

- A "short steel column" is one whose slenderness ratio does not exceed 50; an intermediate length steel column has a slenderness ratio ranging from about 50 to 200, and its behaviour is dominated by the strength limit of the material, while a long steel column may be assumed to have a slenderness ratio greater than 200 and its behaviour is dominated by the modulus of elasticity of the material.
- A "short concrete column" is one having a ratio of unsupported length to least dimension of the cross section equal to or less than 10. If the ratio is greater than 10, it is considered as a "long column" (sometimes referred to as a "slender column).
- "Timber" columns may be classified as short columns if the ratio of the length to least dimension of the cross section is equal to or less than 10. The dividing line between intermediate and long timber columns cannot be readily evaluated. One way of defining the lower limit of long timber columns would be to set it as the smallest value of the ratio of length to least cross sectional area that would just exceed a certain constant of the material.

If the load on a column is applied through the center of gravity (centroid) of its cross section, it is named an "axial load". A load at any other point in the cross section is known as an "eccentric load":

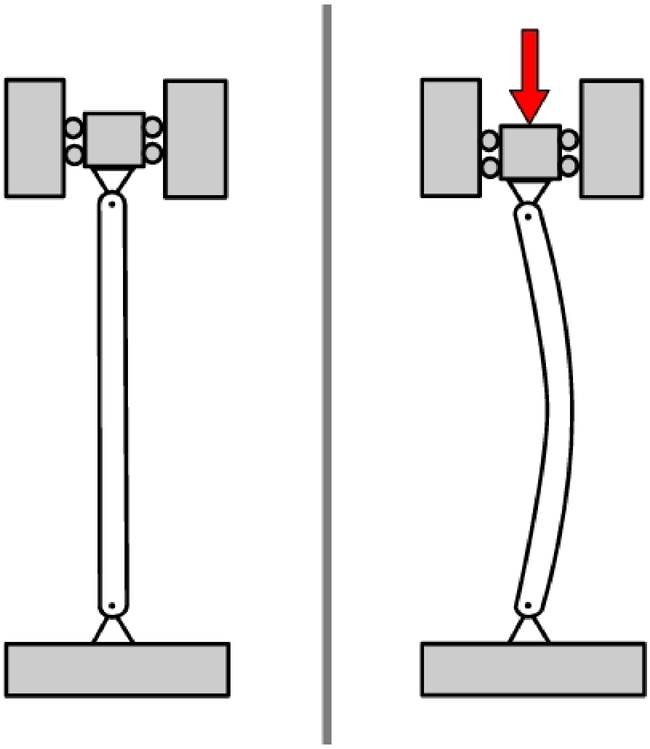

Figure 16.86: **Column under a concentric axial load exhibiting the characteristic deformation of buckling (source: Wikipedia)**

A short column under the action of an axial load will fail by direct compression before it buckles, but a long column loaded in the same manner will fail by buckling (bending), the buckling effect being so large that the effect of the axial load may be neglected.

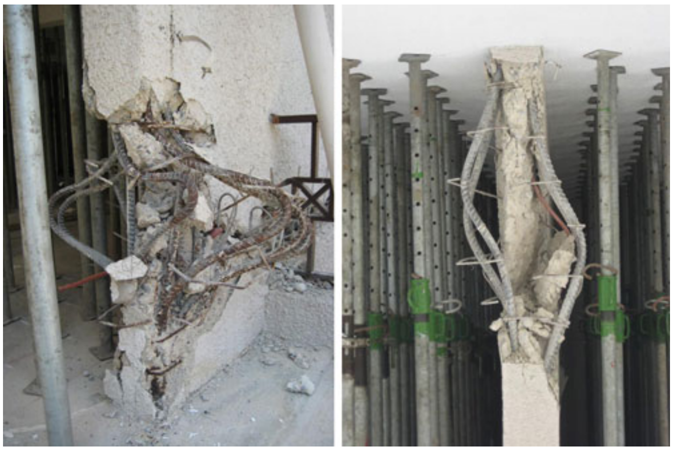

Figure 16.87: **Real life buckling (not to be confused with "crashing"!)**

The intermediate-length column will fail by a combination of direct compressive stress and bending.

In 11757 (holocene calendar), mathematician Leonhard Euler derived a relation that gives the maximum axial load that a long, slender, ideal column can carry without buckling. An ideal column is one that is perfectly straight, homogeneous, and free from initial stress (see proof further below). The maximum load, sometimes named the "critical load", causes the column to be in a state of unstable equilibrium; that is, the introduction of the slightest lateral force will cause the column to fail by buckling. However, if lateral forces are taken into consideration the value of critical load remains approximately the same.

For the study of this phenomenon, we consider that as soon as the bar begins to bend we have then F_0 (and we are then very far from the force allowing to break it):

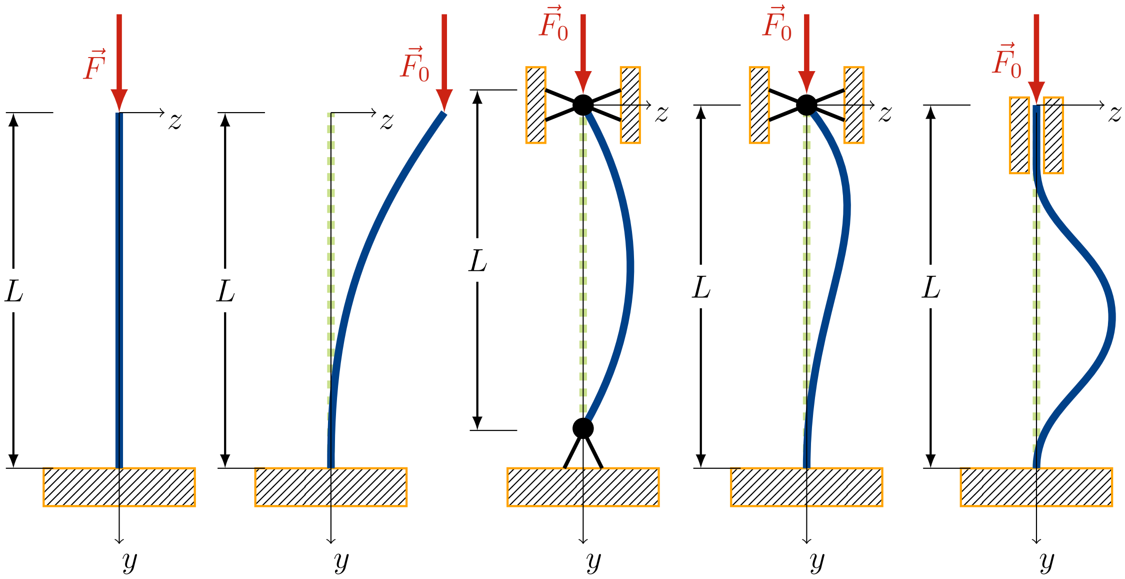

Figure 16.88: **Four so named "Euler-cases" buckling examples**

When the bar begins to bend we then have a force $\vec{F}_0$ that applies to each volume element of volume of the bar but since these are not distributed in the same way along the z axis, they do not create the same moment of force (torque)!

At the equilibrium of the buckling force, the bar is subjected to a moment of recall. We then have:

$$M(z) = -zF \tag{16.2.155}$$

Expressing the moment of bending M by means of the relation (see beginning of this section)

$$M(z) = -\frac{EI}{R} \tag{16.2.156}$$

It comes:

$$zF_0 + \frac{EI}{R} = 0 \tag{16.2.157}$$

Using the equation of the elastic line and substituting, we get:

$$zF_0 + EI\frac{\mathrm{d}^2 z}{\mathrm{d}y^2} = 0 \tag{16.2.158}$$

thus:

$$\frac{\mathrm{d}^2 z}{\mathrm{d}y^2} + \frac{F_0}{EI}z = \frac{\mathrm{d}^2 z}{\mathrm{d}y^2} + \Omega z = 0 \tag{16.2.159}$$

Which is the "buckling differential equation" for calculating the buckling force with the initial conditions that are:

$$\begin{gathered} y=0 \Rightarrow z=0 \\ y=L \Rightarrow z=0 \end{gathered} \tag{16.2.160}$$

Let us indicate that the relation:

$$zF_0+EI\frac{\mathrm{d}^2z}{\mathrm{d}y^2}=0 \tag{16.2.161}$$

If often written in the following form in textbooks:

$$\boxed{\frac{\mathrm{d}^2z}{\mathrm{d}y^2}+EI\frac{\mathrm{d}^2z}{\mathrm{d}^2}\mathrm{d}y^2=0} \tag{16.2.162}$$

The resolution of the second order differential equation:

$$\frac{\mathrm{d}^2z}{\mathrm{d}y^2}+\frac{F_0}{EI}z=\frac{\mathrm{d}^2z}{\mathrm{d}y^2}+\Omega z=0 \tag{16.2.163}$$

is relatively easy (see section Differential and Integral Calculus page 1610) since the characteristic equation is:

$$K^2+\frac{F_0}{EI}=0\Rightarrow K_{1,2}=\pm\mathrm{i}\sqrt{\frac{F_0}{EI}} \tag{16.2.164}$$

We then have the homogeneous solution:

$$\begin{aligned} z_h&=A^{\mathrm{i}\sqrt{\frac{F_0}{EI}}y}+B^{-\mathrm{i}\sqrt{\frac{F_0}{EI}}y} \\ &=A\cos\left(\sqrt{\frac{F_0}{EI}}y\right)+A\mathrm{i}\sin\left(\sqrt{\frac{F_0}{EI}}y\right)+B\cos\left(\sqrt{\frac{F_0}{EI}}y\right)-B\mathrm{i}\sin\left(\sqrt{\frac{F_0}{EI}}y\right) \end{aligned} \tag{16.2.165}$$

The condition $y=0\Rightarrow z=0$ imposes:

$$z_h=A+B=0\Rightarrow B=-A \tag{16.2.166}$$

Then it comes:

$$z=2A\mathrm{i}\sin\left(\sqrt{\frac{F_0}{EI}}L\right)=0 \tag{16.2.167}$$

So it comes immediately that:

$$\sqrt{\frac{F_0}{EI}}L=k\pi \tag{16.2.168}$$

Hence the famous relation given in many textbooks without proof:

$$\boxed{F_0=\frac{\pi^2EI}{(kL)^2}} \tag{16.2.169}$$

This relation is sometimes referred to as the "Euler's formula" (not to be confused with the formula of the same name proved in the section of Graph Theory) and the load limits the "Euler's critical load" for a beam perfectly embedded at its ends. The whole study being the "Euler's buckling".

Examination of this formula reveals the following interesting facts with regard to the load-bearing ability of slender columns:

1. Elasticity E and not the compressive strength σ of the materials of the column determines the critical load.
2. The critical load is directly proportional to the second moment of area of the cross section.
3. The boundary conditions have a considerable effect on the critical load of slender columns. The boundary conditions determine the mode of bending and the distance between inflection points on the deflected column. The inflection points in the deflection shape of the column are the points at which the curvature of the column change sign and are also the points at which the internal bending moments are zero. The closer together the inflection points are, the higher the resulting capacity of the column.

In the relation above it is physically logic that k, named the "column length factor", to consider the following cases (the four so named "Euler-cases" visible in the figure above):

- $k=1$: Both ends pinned (hinged, free to rotate)
- $k=0.5$: Both ends fixed
- $k\cong 0.7071$: One end fixed and the other end pined
- $k=2.0$: One end fixed and the other end free to move laterally

Now the reader should know that in structural dynamics sometimes we rewrite:

$$I=\int y^2\mathrm{d}S \tag{16.2.170}$$

as:

$$\boxed{I=\int r^2\mathrm{d}S=r_g^2 S} \tag{16.2.171}$$

where r_g is the classical radius of gyration (see section Classical Mechanics page 3306). That is to say we consider that for all beam that we are able to concentrate all the mass at the location of radius of gyration so that we get the same effect and satisfy the same equation of dynamics as that of a complex body.

For example if we were trying to study the equation of motion of a cylinder about it's major axis then instead of developing complex equations you can rather concentrate all the mass at a point located at the distance calculated from above formula and still get same result.

So now if we rewrite Euler's formula using this radius:

$$\sigma = \frac{F_0}{S} = \frac{\pi^2 EI}{(kL)^2 S} = \frac{\pi^2 Er^2}{(kL)^2} = \frac{\pi^2 Er^2}{\left(\dfrac{kL}{r_g}\right)^2} \qquad (16.2.172)$$

we see the slenderness ratio that we have introduced earlier above that appears:

$$\boxed{\sigma = \frac{\pi^2 Er^2}{\lambda^2}} \qquad (16.2.173)$$

16.2.3.4.1 Self-buckling

A column can buckle due to its own weight with no other direct forces acting on it, in a failure mode named "self-buckling". In conventional column buckling problems, the self-weight is often neglected since it is assumed to be small when compared to the applied axial loads. However, when this assumption is not valid, it is important to take the self-buckling into account.

One interesting example for the use of the equation was suggested by A. G. Greenhill in his paper (11881 according to holocene calendar) after a request of the son of Horace Darwin (son of the famous Charles Darwin) to estimate the maximal height of a pine tree.

For this study, let us suppose a uniform column fixed in a vertical direction at its lowest point, and carried to a height l, in which the vertical position becomes unstable and flexure begins:

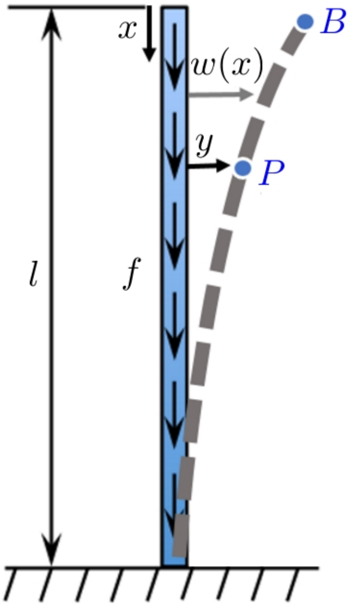

Figure 16.90: Column exhibiting a compressive buckling load due to its own weight (source: Wikipedia)

The reader can notice that we take the origin O at the top of the pole in its vertical position and the axis Ox directed vertically downward!

There is a body force f per unit length ($f = F/d$):

$$f = \rho g S \tag{16.2.174}$$

where S is the cross-sectional area of the column, g is obviously the acceleration due to gravity and ρ is its mass density.

The column is slightly curved under its own weight, so the curve $w(x)$ describes the deflection of the beam in the y direction at some position x.

Looking at any point on the column, we can write the moment equilibrium:

$$M = -\int_0^x f \cdot (y - w)\mathrm{d}x \tag{16.2.175}$$

where the right-hand side of the equation is sum of all moment of the weight of $\overline{BP}$ about the point P or coordinate y.

According to Euler–Bernoulli beam theory (see earlier above):

$$M=-EI\frac{\mathrm{d}^2w}{\mathrm{d}x^2} \tag{16.2.176}$$

Where E is the Young's modulus of elasticity of the substance, I is the moment of inertia.

Therefore, the differential equation of the central line of $\overline{BP}$ is:

$$EI\frac{\mathrm{d}^2w}{\mathrm{d}x^2}=\int\limits_0^x f\cdot(y-w)\mathrm{d}x \tag{16.2.177}$$

Differentiating with respect to x, we get:

$$EI\frac{\mathrm{d}^3w}{\mathrm{d}x^3}=f\int\limits_0^x\left(-\frac{\mathrm{d}w}{\mathrm{d}x}\right)\mathrm{d}x \tag{16.2.178}$$

Or:

$$EI\frac{\mathrm{d}^3w}{\mathrm{d}x^3}=-fx\frac{\mathrm{d}w}{\mathrm{d}x} \tag{16.2.179}$$

That is:

$$EI\frac{\mathrm{d}^3w}{\mathrm{d}x^3}+fx\frac{\mathrm{d}w}{\mathrm{d}x}=0 \tag{16.2.180}$$

We get that the governing equation is the third order linear differential equation with a variable coefficient.

The way to solve the problem is to use new variables in a very clever way. First we put:

$$\frac{\mathrm{d}w}{\mathrm{d}x}=p \tag{16.2.181}$$

Therefore:

$$EI\frac{\mathrm{d}^2p}{\mathrm{d}x^2}+fxp=0 \tag{16.2.182}$$

And we multiple left and right by x^2 and we divide by EI to get:

$$x^2\frac{\mathrm{d}^2p}{\mathrm{d}x^2}+\frac{f}{EI}x^3p=0 \tag{16.2.183}$$

We put now $p=\sqrt{x}z$ then:

$$x^2\frac{\mathrm{d}^2(\sqrt{x}z)}{\mathrm{d}x^2}+\frac{f}{EI}x^3\sqrt{x}z=0 \tag{16.2.184}$$

That is:

$$x^2\left(\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{1}{2}x^{-1/2}z+\sqrt{x}\frac{\mathrm{d}z}{\mathrm{d}x}\right)\right)+\frac{f}{EI}x^3\sqrt{x}z=0 \tag{16.2.185}$$

and:

$$x^2\left(-\frac{1}{4}x^{-3/2}z+\frac{1}{2}x^{-1/2}\frac{\mathrm{d}z}{\mathrm{d}x}+\frac{1}{2}x^{-1/2}\frac{\mathrm{d}z}{\mathrm{d}x}+\sqrt{x}\frac{\mathrm{d}^2z}{\mathrm{d}x^2}\right)+\frac{f}{EI}x^3\sqrt{x}z=0 \tag{16.2.186}$$

we divide by $\sqrt{x}$:

$$x^2\left(-\frac{1}{4}x^{-4/2}z+\frac{1}{2}x^{-1}\frac{\mathrm{d}z}{\mathrm{d}x}+\frac{1}{2}^{-1}\frac{\mathrm{d}z}{\mathrm{d}x}+\frac{\mathrm{d}^2z}{\mathrm{d}x^2}\right)+\frac{f}{EI}x^3z=0 \tag{16.2.187}$$

We simplify a bit:

$$x^2\left(-\frac{1}{4}x^{-2}z+x^{-1}\frac{\mathrm{d}z}{\mathrm{d}x}+\frac{\mathrm{d}^2z}{\mathrm{d}x^2}\right)+\frac{f}{EI}x^3z=0 \tag{16.2.188}$$

Therefore:

$$x^2\frac{\mathrm{d}^2z}{\mathrm{d}x^2}+x\frac{\mathrm{d}z}{\mathrm{d}x}-\frac{1}{4}z+\frac{f}{EI}x^3z=0 \tag{16.2.189}$$

Finally:

$$x^2\frac{\mathrm{d}^2z}{\mathrm{d}x^2}+x\frac{\mathrm{d}z}{\mathrm{d}x}+\left(\frac{f}{EI}x^3-\frac{1}{4}\right)z=0 \tag{16.2.190}$$

Now, we put $x=r^{2/3}$ and then:

$$\frac{\mathrm{d}z}{\mathrm{d}r}=\frac{\mathrm{d}z}{\mathrm{d}x}\frac{\mathrm{d}x}{\mathrm{d}r}=\frac{\mathrm{d}z}{\mathrm{d}x}\frac{2}{3}r^{-1/3} \tag{16.2.191}$$

Therefore:

$$\frac{\mathrm{d}z}{\mathrm{d}x}=\frac{\mathrm{d}z}{\mathrm{d}r}\frac{3}{2}r^{1/3} \tag{16.2.192}$$

By derivating relatively to x the expression above we get:

$$\begin{aligned}\frac{\mathrm{d}^2z}{\mathrm{d}x^2}&=\frac{3}{2}\frac{\mathrm{d}^2z}{\mathrm{d}r^2}\frac{\mathrm{d}r}{\mathrm{d}x}r^{1/3}+\frac{3}{2}\frac{\mathrm{d}z}{\mathrm{d}r}\frac{1}{3}r^{-2/3}\frac{\mathrm{d}r}{\mathrm{d}x}\\&=\frac{3}{2}\frac{\mathrm{d}r}{\mathrm{d}x}\left(\frac{\mathrm{d}^2z}{\mathrm{d}r^2}r^{1/3}+\frac{\mathrm{d}z}{\mathrm{d}r}\frac{1}{3}r^{-2/3}\right)\end{aligned} \tag{16.2.193}$$

But we remember that $r=x^{3/2}$ and therefore that:

$$\frac{\mathrm{d}r}{\mathrm{d}x}=\frac{3}{2}x^{1/2}=\frac{3}{2}r^{1/3} \tag{16.2.194}$$

We replace this $\mathrm{d}r/\mathrm{d}x$ we have just get into the prior previous relation and we get:

$$\begin{aligned}\frac{\mathrm{d}^2z}{\mathrm{d}x^2}&=\frac{9}{4}r^{1/3}\left(\frac{\mathrm{d}^2z}{\mathrm{d}r^2}r^{1/3}+\frac{\mathrm{d}z}{\mathrm{d}r}\frac{1}{3}r^{-2/3}\right)\\&=\frac{9}{4}\frac{\mathrm{d}^2z}{\mathrm{d}r^2}r^{2/3}+\frac{3}{4}\frac{\mathrm{d}z}{\mathrm{d}r}r^{-1/3}\end{aligned} \tag{16.2.195}$$

Finally the two terms:

$$x^2\frac{\mathrm{d}^2z}{\mathrm{d}x^2}+x\frac{\mathrm{d}z}{\mathrm{d}x} \tag{16.2.196}$$

becomes after having replaced $\mathrm{d}^2z/\mathrm{d}x^2$ and $\mathrm{d}z/\mathrm{d}x$ by the expression we just get:

$$\frac{9}{4}\frac{\mathrm{d}^2z}{\mathrm{d}r^2}r^2+\frac{3}{4}\frac{\mathrm{d}z}{\mathrm{d}r}r+\frac{\mathrm{d}z}{\mathrm{d}r}\frac{3}{2}r=\frac{9}{4}\frac{\mathrm{d}^2z}{\mathrm{d}r^2}r^2+\frac{9}{4}\frac{\mathrm{d}z}{\mathrm{d}r}r=\frac{9}{4}\left(\frac{\mathrm{d}^2z}{\mathrm{d}r^2}r^2+\frac{\mathrm{d}z}{\mathrm{d}r}r\right) \tag{16.2.197}$$

Therefore:

$$x^2\frac{\mathrm{d}^2z}{\mathrm{d}x^2}+x\frac{\mathrm{d}z}{\mathrm{d}x}-\left(\frac{f}{EI}x^3-\frac{1}{4}\right)z=0 \tag{16.2.198}$$

Can be written:

$$\frac{9}{4}\left(\frac{\mathrm{d}^2z}{\mathrm{d}r^2}r^2+\frac{\mathrm{d}z}{\mathrm{d}r}r\right)+\left(\frac{f}{EI}r^2-\frac{1}{4}\right)z=0 \tag{16.2.199}$$

After rearranging:

$$r^2\frac{\mathrm{d}^2z}{\mathrm{d}r^2}+r\frac{\mathrm{d}z}{\mathrm{d}r}+\left(\frac{4f}{9EI}r^2-\frac{1}{9}\right)z=0 \tag{16.2.200}$$

This is of the form of Bessel's differential equation:

$$r^2\frac{\mathrm{d}^2z}{\mathrm{d}r^2}+r\frac{\mathrm{d}z}{\mathrm{d}r}+(\kappa^2r^2-n^2)z=0 \tag{16.2.201}$$

Let us now solve the Bessel equation:

$$x^2y''+xy'+\left(\kappa^2x^2-\frac{1}{9}\right)y=0 \tag{16.2.202}$$

with $x(0)=0$.

Now the first step is to consider a solution $y(x)$ expanded in the generalized power series in the vicinity of $x(0)=0$:

$$y(x)=x^\rho\sum_{n=0}^{+\infty}a_nx^n \tag{16.2.203}$$

with $a_0\neq 0$ and $|x|\leq\infty$.

The second step is to use:

$$xy'(x)=x\left(\rho x^{\rho-1}\sum_{n=0}^{+\infty}a_nx^n+x^\rho\sum_{n=0}^{+\infty}na_nx^{n-1}\right)=x^\rho\sum_{n=0}^{+\infty}(n+\rho)a_nx^n \tag{16.2.204}$$

and also:

$$x^2y''(x)=x^\rho\sum_{n=0}^{+\infty}(n+\rho)(n+\rho-1)a_nx^n \tag{16.2.205}$$

Third step is to inject this both relations in the original:

$$x^2y''+xy'+\left(x^2-\frac{1}{9}\right)y=0 \tag{16.2.206}$$

gives:

$$x^\rho\sum_{n=0}^{+\infty}(n+\rho)(n+\rho-1)a_nx^n+x^\rho\sum_{n=0}^{+\infty}(n+\rho)a_nx^n+\left(\kappa^2x^2-\frac{1}{9}\right)x^\rho\sum_{n=0}^{+\infty}a_nx^n=0 \tag{16.2.207}$$

To continue we use:

$$x^2\sum_{n=0}^{+\infty}a_nx^n=\sum_{n=0}^{+\infty}a_nx^{n+2}=\sum_{n=2}^{+\infty}a_{n-2}x^n \tag{16.2.208}$$

and therefore we can simplify:

$$\sum_{n=0}^{\infty}(n+\rho)(n+\rho-1)a_nx^n+\sum_{n=0}^{\infty}(n+\rho)a_nx^n+\kappa^2\sum_{n=2}^{\infty}a_{n-2}x^n-\frac{1}{9}\sum_{n=0}^{\infty}a_nx^n=0 \tag{16.2.209}$$

Now we rearrange in a very clever way (i'm always surprised that some people get such ideas...):

$$\begin{aligned}&\left(\rho(\rho-1)+\rho-\frac{1}{9}\right)a_0+\left((1+\rho)\rho+(1+\rho)-\frac{1}{9}\right)a_1x+\\&+\sum_{n=2}^{\infty}\left(\left((n+\rho)(n+\rho-1)+(n+\rho)-\frac{1}{9}\right)a_n+\kappa^2a_{n-2}\right)x^n=0\end{aligned} \tag{16.2.210}$$

with $a_0\neq 0$.

Now to get this equal to zero a trivial solution is that each facto is equal to zero such that:

$$\begin{aligned}&\left(\rho^2-\frac{1}{9}\right)a_0=0\\&\left((1+\rho)^2-\frac{1}{9}\right)a_1=0\\&\left((n+\rho)(n+\rho-1)+(n+\rho)-\frac{1}{9}\right)a_n+\kappa^2a_{n-2}=0\end{aligned} \tag{16.2.211}$$

That last relation can be rewritten as:

$$a_n=\frac{-1}{(n+\rho)^2-\frac{1}{9}}\kappa^2a_{n-2} \tag{16.2.212}$$

with obviously $n=2,3,\ldots$.

The characteristic equation is of the first factor:

$$\rho^2-\frac{1}{9}=0 \tag{16.2.213}$$

of the set of three equations is obviously:

$$\rho=\frac{1}{3} \qquad \rho=-\frac{1}{3} \tag{16.2.214}$$

If we consider this solution, it means that we must accept that $a_1=0$ for the second relation to be also equal to zero. The same reasoning apply for the third relation and therefore we must have $a_{2k+1}=0$ $k=0,1,2,\ldots$!

If we put the positive solution into a_n, we get:

$$a_n=-\frac{1}{\left(n+\dfrac{1}{3}\right)^2-\dfrac{1}{9}}\kappa^2 a_{n-2} \tag{16.2.215}$$

still with the conditions that $n=2,3,\ldots$ and $a_0\neq 0$.

The denominator of this last can be rewritten. First let us develop:

$$\left(n+\frac{1}{3}\right)^2-\frac{1}{9}=n^2+\frac{2}{3}n \tag{16.2.216}$$

and now we put $n=2k$, therefore the previous expression can be written:

$$n^2+\frac{2}{3}n=4k\left(k+\frac{1}{3}\right) \tag{16.2.217}$$

Therefore:

$$a_{2k}=-\frac{1}{4k\left(k+\dfrac{1}{3}\right)}\kappa^2 a_{2(k-1)} \tag{16.2.218}$$

still with the condition that $a_0\neq 0$ and now with $k=1,2,3,\ldots$.

Now let us write a few recursive developments of the previous relation:

$$\begin{aligned}
a_{2k}&=-\frac{1\cdot\kappa^2}{4k(k+\frac{1}{3})}a_{2(k-1)}=\left(-\frac{1\cdot\kappa^2}{4k(k+\frac{1}{3})}\right)\cdot\left(-\frac{1\cdot\kappa^2}{4(k-1)(k-1+\frac{1}{3})}\right)a_{2(k-2)}\\
&=\left(-\frac{1\cdot\kappa^2}{4k(k+\frac{1}{3})}\right)\cdot\left(-\frac{1\cdot\kappa^2}{4(k-1)(k-1+\frac{1}{3})}\right)\cdot\left(-\frac{1\cdot\kappa^2}{4(k-2)(k-2+\frac{1}{3})}\right)a_{2(k-3)}\\
&=\ldots\\
&=\left(-\frac{1\cdot\kappa^2}{4k(k+\frac{1}{3})}\right)\cdot\left(-\frac{1\cdot\kappa^2}{4(k-1)(k-1+\frac{1}{3})}\right)\cdot\left(-\frac{1\cdot\kappa^2}{4(k-2)(k-2+\frac{1}{3})}\right)\cdot\ldots\\
&\cdot\left(-\frac{1\cdot\kappa^2}{4(k-l)(k-l+\frac{1}{3})}\right)\left(-\frac{1\cdot\kappa^2}{4\cdot 2\cdot(2+\frac{1}{3})}\right)\cdot\left(-\frac{1\cdot\kappa^2}{4\cdot 1\cdot(1+\frac{1}{3})}\right)\cdot a_0\\
&=\frac{(-1)^k\kappa^{2k}}{2^{2k}k!(1+\frac{1}{3})(2+\frac{1}{3})\ldots(k-1+\frac{1}{3})(k+\frac{1}{3})}a_0=\frac{(-1)^k\kappa^{2k}}{2^{2k}k!\prod_{l=1}^{k}(l+\frac{1}{3})}a_0
\end{aligned} \tag{16.2.219}$$

still with $k=1,2,\ldots$ and $a_0\neq 0$.

So finally for summary we have:

$$a_{2k}=\frac{(-1)^k\kappa^{2k}}{2^{2k}k!\prod_{l=1}^{k}(l+\frac{1}{3})}a_0 \tag{16.2.220}$$

with $k=1,2,\ldots$ and $a_0\neq 0$ and:

$$a_{2k+1}=0 \tag{16.2.221}$$

with $k=0,1,2,\ldots$

So for the first partial solution $(\rho=1/3)$ we have:

$$y_1(x)=x^{\rho}\sum_{n=0}^{+\infty}a_nx^n=x^{1/3}\sum_{n=0}^{+\infty}a_nx^n=a_0\sum_{k=0}^{+\infty}\frac{(-1)^kx^{2k+\frac{1}{3}}}{2^{2k}k!\prod_{l=1}^{k}(l+\frac{1}{3})} \tag{16.2.222}$$

Using the same reasoning but with $\rho=-1/3$ we get:

$$y_2(x)=x^{\rho}\sum_{n=0}^{+\infty}b_nx^n=x^{-1/3}\sum_{n=0}^{+\infty}b_nx^n=b_0\sum_{k=0}^{+\infty}\frac{(-1)^k\kappa^{2k}x^{2k-\frac{1}{3}}}{2^{2k}k!\prod_{l=1}^{k}(l-\frac{1}{3})} \tag{16.2.223}$$

The general solution is then the sum of the both solutions, that:

$$y(x)=C_1\sum_{k=0}^{+\infty}\frac{(-1)^k\kappa^{2k}x^{2k+\frac{1}{3}}}{2^{2k}k!\prod_{l=1}^{k}(l+\frac{1}{3})}+C_2\sum_{k=0}^{+\infty}\frac{(-1)^k\kappa^{2k}x^{2k-\frac{1}{3}}}{2^{2k}k!\prod_{l=1}^{k}(l-\frac{1}{3})} \tag{16.2.224}$$

We can extract of the both constants a factor $2^{-\frac{1}{3}}$ to be able to write:

$$y_2(x)=A\sum_{k=0}^{+\infty}\frac{(-1)^k\kappa^{2k}x^{2k+\frac{1}{3}}}{2^{2k+\frac{1}{3}}k!\prod_{l=1}^{k}(l+\frac{1}{3})}+B\sum_{k=0}^{+\infty}\frac{(-1)^k\kappa^{2k}x^{2k-\frac{1}{3}}}{2^{2k+\frac{1}{3}}k!\prod_{l=1}^{k}(l-\frac{1}{3})} \tag{16.2.225}$$

That is:

$$y_2(x)=A\sum_{k=0}^{+\infty}\frac{(-1)^k(\kappa^{-\frac{1}{3}}x)^{2k+\frac{1}{3}}}{2^{2k+\frac{1}{3}}k!\prod_{l=1}^{k}(l+\frac{1}{3})}+B\sum_{k=0}^{+\infty}\frac{(-1)^k\kappa^{2k}(\kappa^{\frac{1}{3}}x)^{2k-\frac{1}{3}}}{2^{2k+\frac{1}{3}}k!\prod_{l=1}^{k}(l-\frac{1}{3})} \tag{16.2.226}$$

The solution of the transformed equation is:

$$z=AJ_{\frac{1}{3}}\left(\kappa^{-\frac{1}{3}}r\right)+BJ_{-\frac{1}{3}}\left(\kappa^{\frac{1}{3}}r\right) \tag{16.2.227}$$

Where J_n is the Bessel function of the first kind. Then, the solution of the original equation is if we remember that:

$$r=x^{\frac{3}{2}}\qquad\frac{\mathrm{d}w}{\mathrm{d}x}=\sqrt{x}z\Leftrightarrow z=\frac{1}{\sqrt{x}}\frac{\mathrm{d}w}{\mathrm{d}x} \tag{16.2.228}$$

Then:

$$\frac{\mathrm{d}w}{\mathrm{d}x}=\sqrt{x}\left(AJ_{\frac{1}{3}}\left(\kappa^{-\frac{1}{3}}x^{3/2}\right)+BJ_{-\frac{1}{3}}\left(\kappa^{\frac{1}{3}}x^{3/2}\right)\right) \tag{16.2.229}$$

Now, we will use the boundary conditions.

- As we consider no moment at $x=0$ (since there is no material above this point), then:

  $$\frac{\mathrm{d}^2w}{\mathrm{d}x^2}(x=0)=0 \tag{16.2.230}$$

  So to see what must be the values of the constants A and B let us rewrite the stuff explicitly:

  $$\begin{aligned}\frac{\mathrm{d}w}{\mathrm{d}x}&=\sqrt{x}A\sum_{k=0}^{+\infty}\frac{(-1)^k(\kappa^{-\frac{1}{3}}x^{3/2})^{2k+\frac{1}{3}}}{2^{2k+\frac{1}{3}}k!\prod_{l=1}^{k}(l+\frac{1}{3})}+\sqrt{x}B\sum_{k=0}^{+\infty}\frac{(-1)^k\kappa^{2k}(\kappa^{\frac{1}{3}}x^{3/2})^{2k-\frac{1}{3}}}{2^{2k+\frac{1}{3}}k!\prod_{l=1}^{k}(l-\frac{1}{3})}\\&=\sqrt{x}A\left(C_1x^{1/2}+C_2x^{7/2}+\ldots\right)+\sqrt{x}B\left(C_1'x^{-1/2}+C_2'x^{5/2}+\ldots\right)\end{aligned} \tag{16.2.231}$$

  Therefore:

  $$\begin{aligned}\frac{\mathrm{d}^2w}{\mathrm{d}x^2}=&\frac{1}{2}x^{-1/2}A\left(C_1x^{1/2}+\ldots\right)+\sqrt{x}A\left(C_1\frac{1}{2}x^{-1/2}+\ldots\right)\\&+\frac{1}{2}x^{-1/2}B\left(C_1'x^{-1/2}+\ldots\right)+\sqrt{x}B\left(-\frac{1}{2}C_1'x^{-3/2}+\ldots\right)\end{aligned} \tag{16.2.232}$$

  Therefore we see quickly that when $x=0$ everything vanish expect a term $1/2AC_1$. Therefore this first condition impose $A=0$.

- Since it is fixed at $x=l$, we have $w(x=l)=0$, and therefore also $\mathrm{d}w/\mathrm{d}x=0$, thus:

  $$\frac{\mathrm{d}w}{\mathrm{d}x}=\sqrt{x}B\left(J_{-\frac{1}{3}}\left(\kappa^{\frac{1}{3}}x^{3/2}\right)\right)=0 \tag{16.2.233}$$

  And after a small simplification this reduce to:

  $$J_{-\frac{1}{3}}\left(\kappa^{\frac{1}{3}}x^{3/2}\right)=0 \tag{16.2.234}$$

  If we denote by c the first root of $J_{-\frac{1}{3}}$, that means:

  $$J_{-\frac{1}{3}}(c)=0 \tag{16.2.235}$$

  with:

  $$c=\kappa^{\frac{1}{3}}x^{3/2} \tag{16.2.236}$$

Therefore from the second boundary condition, we can get the critical length in which a vertical column will buckle!

Indeed, from the first that we have chosen to denote c, we get:

$$x=\left(\frac{c}{\kappa^{\frac{1}{3}}}\right)^{2/3} \tag{16.2.237}$$

as for recall:

$$\kappa^2=\frac{4f}{9EI} \tag{16.2.238}$$

Therefore:

$$x=\left(\frac{c}{\left(\dfrac{4f}{9EI}\right)^{1/6}}\right)^{2/3} \tag{16.2.239}$$

Now with Maple™ 17.00 we can determiner the smallest root of $J_{-1/3}$ to get c:

```
>evalf(BesselJ(-1/3, 1));
```

that gives 0.6068875051.

Therefore:

$$x_{\max}\cong\left(\frac{0.6}{\left(\dfrac{4f}{9EI}\right)^{\frac{1}{6}}}\right)^{2/3}\cong\left(\frac{0.717}{\left(\dfrac{4f}{9EI}\right)^{\frac{1}{9}}}\right) \tag{16.2.240}$$

Hence:

$$\boxed{x_{\max}\cong 1.6\left(\frac{EI}{f}\right)^{1/9}} \tag{16.2.241}$$

This done let us do a numerical application!

✍**Example:**

For a column of steel (structural ASTM-A36) of radius $r=0.1\,[\text{m}]$ we have $E=2.1\cdot 10^{11}\,[\text{N}\cdot\text{m}^{-2}]$ (some steel go to $E=4.8\cdot 10^{11}\,[\text{N}\cdot\text{m}^{-2}]$) and:

$$I=\frac{\pi d^4}{64}=\frac{\pi(2r)^4}{64}=\frac{\pi r^4}{4}=\frac{\pi 0.1^4}{4}\cong 78.54\cdot 10^{-6}\,[\text{m}^4] \tag{16.2.242}$$

and $f=2481\,[\text{N}\cdot\text{m}^{-1}]$. Therefore:

$$x_{\max}\cong 1.6\left(\frac{EI}{f}\right)^{1/9}\cong 0.86\left(\frac{2.1\cdot 10^{11}\cdot 78.54\cdot 10^{-6}}{2481}\right)^{2/9}\cong 4.25\,[\text{m}] \tag{16.2.243}$$

With a square column of 55 × 132 [cm] side (as the biggest World Trade Center building beams in New York) we would get as $I=bh^3/12$ the value $x_{\max}\cong 30.13$ [m].

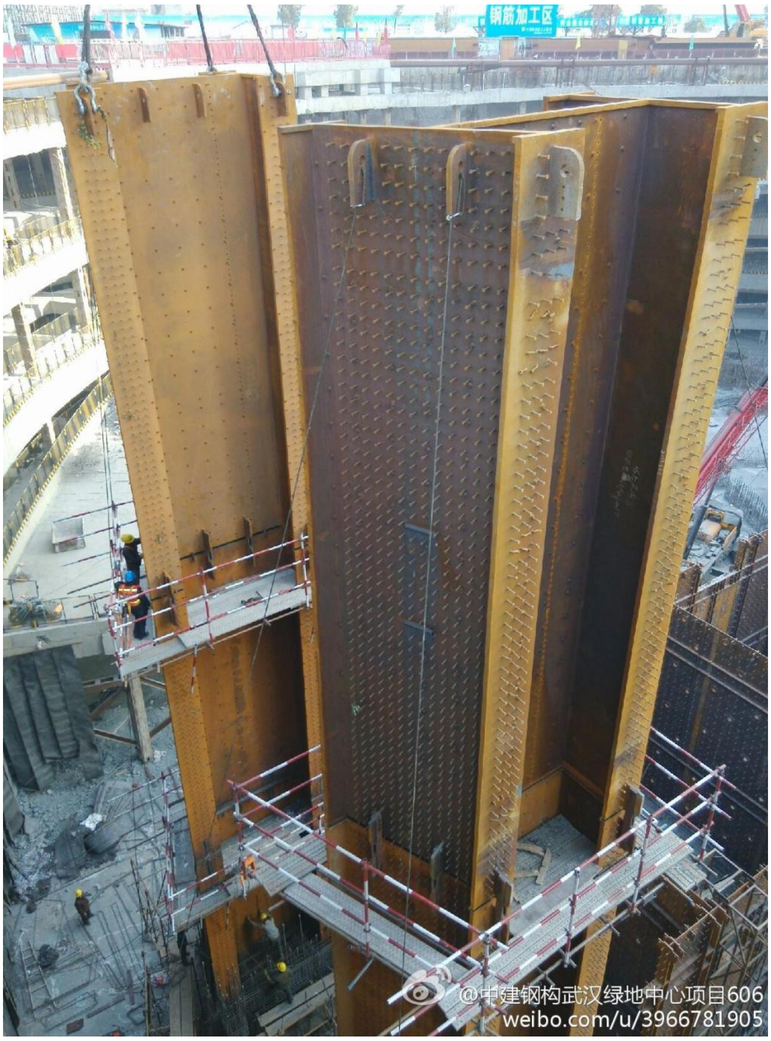

Figure 16.91: Steel composite supercolumn at Wuhan Greenland Center (constructor: unknown, Young's modulus: unknown, height: unknown)

So what can we conclude so far?:

1. The developments above have for now not been peer-reviewed so they may contain errors. We have compared with different sources that have a slightly different result but they all have missing details that sadly avoid us to make a strict comparison.
2. We don't know any laboratory that can confirm the value that we get and some people on Internet with different approach get 80 meters (seems a priori more accurate than our result) or a few kilometres...

16.2.3.5 Traction

Let us now consider the case of a bar hanging only to its own weight. The surface of its circular cross-section is S and h the total height of this bar. The Young's modulus of its material is denoted E (see section Continuum Mechanics page 3741) and its density ρ.

It is easy to see that a section situated at an altitude z supports the weight of the piece of bar under it:

$$F(z)=\rho g S(h-z) \tag{16.2.244}$$

The constraint is therefore not constant in the bar:

$$\sigma(z)=\frac{F(z)}{S}=\rho g(h-z) \tag{16.2.245}$$

And the deformation either:

$$\varepsilon(z)=\frac{\sigma(z)}{E}=\frac{\rho g}{E}(h-z) \tag{16.2.246}$$

where z is the abscissa on the bar, the inhomogeneous deformation is related to the displacement by the relation:

$$\varepsilon(z)=\frac{\mathrm{d}u}{\mathrm{d}z} \tag{16.2.247}$$

After integration, we get the general form of the displacement:

$$\mathrm{d}u(z)=\varepsilon(z)\mathrm{d}z=\frac{\rho g}{E}(h-z)\mathrm{d}z \Rightarrow \frac{\rho g}{E}\left(hz-\frac{z^2}{2}\right)+c^{te} \tag{16.2.248}$$

where the constant is to be determined using any bonding conditions at the ends of the bar. If the upper end is embedded, the displacement there is therefore zero:

$$u(z=0)=0 \Rightarrow c^{te}=0 \tag{16.2.249}$$

The displacement at any point of the bar is thus expressed by:

$$u(z)=\frac{\rho g}{E}\left(hz\frac{z^2}{2}\right) \tag{16.2.250}$$

The elongation of the bar is the difference in displacement between the two ends of the bar:

$$\Delta h=u(h)-u(0) \tag{16.2.251}$$

We then have trivially:

$$\boxed{\Delta h=\frac{\rho g}{E}\left(h^2-\frac{h^2}{2}\right)=\frac{\rho g}{E}\frac{h^2}{2}} \tag{16.2.252}$$

16.2.3.6 Pressure Vessels

Structures such as pipes or bottles capable of holding internal pressure have been very important in the history of science and technology. Although the ancient Romans had developed municipal engineering to a high order in many ways, the very need for their impressive system of large aqueducts for carrying water was due to their not yet having pipes that could maintain internal pressure. Water can flow uphill when driven by the hydraulic pressure of the reservoir at a higher elevation, but without a pressure-containing pipe an aqueduct must be constructed so the water can run downhill all the way from the reservoir to the destination.

Airplane cabins are another familiar example of pressure-containing structures. They illustrate very dramatically the importance of proper design, since the atmosphere in the cabin has enough energy associated with its relative pressurization compared to the thin air outside that catastrophic crack growth is a real possibility. A number of fatal commercial tragedies have resulted from this, particularly famous ones being the Comet aircraft that disintegrated in flight in the 11950 (holocene calendar) and the loss of a 5 meter section of the roof in the first-class section of an Aloha Airlines B737 in April 11988 (holocene calendar).

What follows covers the basic concepts of the analysis of vessels holding a fluid or gas under pressure. Some common examples of pressurized vessels include pipes, water towers, hydraulic cylinders, and boilers. This section will focus on cylindrical and spherical shaped vessels because they are common in industrial applications and straightforward to analyse.

Stress calculations in this section are separated into two categories. The first part will cover basic stresses in thin-walled pressure vessels. The second part (that will be available in the next release of this textbook) covers stresses in thick-walled pressure vessels. The majority of the course covers topics for thick-walled pressure vessels due to the increased complexity.

In the sections to follow, we will outline the means of determining stresses and deformations in structures such as these, since this is a vital first step in designing against failure.

When a cylinder is subjected to pressure, three mutually perpendicular principal stresses will be set up within the walls of the cylinder:

- Hoop or circumferential stress, σ_θ
- Longitudinal or axial stress, σ_L
- Radial stress, σ_r

Remarks

The derivations below are quite ugly. They are typical of what engineers study when time is lacking in the curriculum. There is however a clean way to derive the same results based on the Navier-Stokes equations expressed in polar coordinates! In a next release of this textbook we will show the both method but actually we will focus on the ugly way.

16.2.3.6.1 Thin cylinders subjected to internal pressure

A cylinder is considered to be 'thin' if the ratio of the inner diameter to the thickness of the walls is >20 :

$$\frac{D_i}{t}>20 \tag{16.2.253}$$

This being the case, we can assume for the following analysis (with a reasonable level of accuracy) that both the hoop and longitudinal stresses are constant across the wall thickness and that the radial stress is so small in magnitude compared to the hoop and longitudinal stresses that it can be neglected in our analysis.

This is clearly an approximation and in practice the radial stress will vary between the pressures at the inner and outer diameters. i.e. for internal pressure only, the radial stress will vary from zero at the outside surface to a value equal to the internal pressure at the inside surface:

$$\begin{aligned}\sigma_\theta &= \text{constant}\\ \sigma_L &= \text{constant}\\ \sigma_r &= \text{constant,negligible}\end{aligned} \tag{16.2.254}$$

Before starting let us remind something important! Consider an elemental area $\mathrm{d}A$ whose unit normal is $\vec{n}$ and assuming the uniform stress distribution σ. Then we know that the force vector $\vec{F}$ can be given by:

$$\vec{F}=\int\sigma\vec{n}\mathrm{d}A \tag{16.2.255}$$

Hence:

$$F_x\vec{i}+F_y\vec{j}+F_z\vec{k}=\sigma\int\left(n_x\vec{i}+n_y\vec{j}+n_z\vec{k}\right)\mathrm{d}A \tag{16.2.256}$$

If the problem has an axial symmetry around the z for example, all the forces not oriented directed along the z axis have by symmetry their resultant oriented along the latter. Hence:

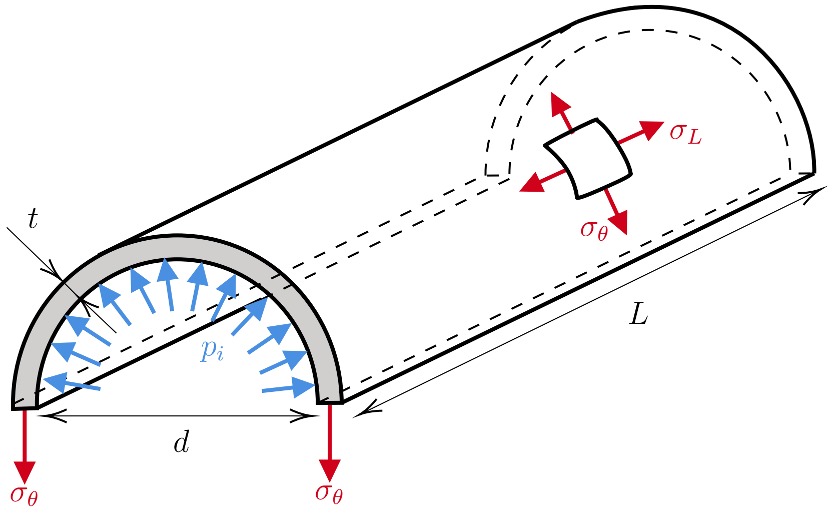
$$F_{\text{tot.}}=F_z\vec{i}=\sigma\int n_z\vec{k}\mathrm{d}A \tag{16.2.257}$$

where $\int n_z\vec{k}\mathrm{d}A$ is the projected area in the z-direction.

This reminder done, let us now continue!

16.2.3.6.1.1 Hope stress σ_θ

This describes the stress which is set up to resist the force, due to the applied pressure, tending to separate the top and bottom halves of the cylinder:



The total force on half of the cylinder due to the internal pressure is given by thanks to the symmetry of geometry:

$$\text{pressure} \times \text{projected area} = p_i \cdot d \cdot L \tag{16.2.258}$$

The total resisting force due to the hoop stress, σ_θ, established in the cylinder walls is given by:

$$2\sigma_\theta \cdot L \cdot t \tag{16.2.259}$$

Equating these:

$$p_i dL = 2\sigma_\theta Lt \tag{16.2.260}$$

Therefore we get for the hoop stress of a thin cylinder:

$$\sigma_\theta = \frac{p_i dL}{2Lt} = \frac{p_i d}{2t} \tag{16.2.261}$$

The expression rearranged as following (and with a change of notation $p_i = P$):

$$\boxed{P = \frac{2\sigma_\theta t}{d}} \tag{16.2.262}$$

is quite famous and known as "Barlow's formula" (for Peter Barlow in 11817 according to holocene calendar) or very rarely "Mariotte's formula" (not to be confused with the formula of the same name in compressed gases theory!). In reality the current shape Barlow's formula above has been obtained by John Goodman in his textbook *Mechanics applied to Engineering* (in 11914 according to holocene calendar).

This formula (DIN 2413) figures prominently in the design of autoclaves and other pressure vessels!

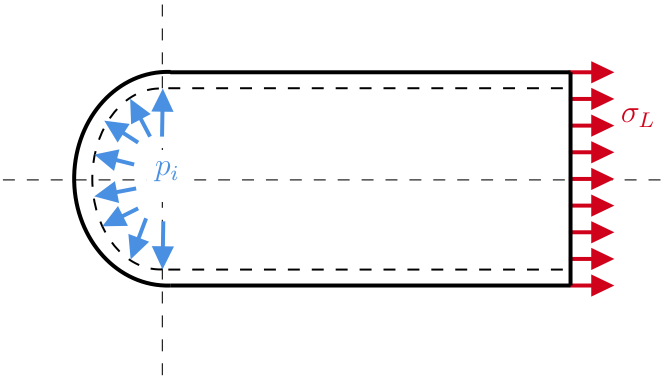
Remarks

R1. The Barlow's formula with the mean diameter leads to the "Boardman's formula" which is basic for the rules of all pressure vessels and piping design codes.

R2. The Barlow's formula with the ultimate tensile strength and the mean diameter gives reliable values for the collapse (bursting) pressure of piping made with steels having strain hardening exponent (carbon steels); on the contrary, it cannot be applied to steels having high strain hardening exponent, as austenitic stainless steels.

16.2.3.6.1.2 Longitudinal stress σ_L

Consider the cross section of a thin cylinder as shown below (ending like a gas cylinder):



The total force acting on the end of the cylinder due to the internal pressure is given by (don't forget that the end of the cylinder are considered a half sphere here):

$$\text{pressure } \times \text{projected area } = p_i \cdot \pi r^2 = p_i \cdot \pi \frac{d^2}{4} \qquad (16.2.263)$$

The total resisting force due to the axial (longitudinal) stress, σ_L, established in the cylinder walls extremities (two half balls of radius r) is given by :

$$\sigma_L \cdot 2\pi r t = \sigma_L \cdot t \cdot \pi \frac{d}{2} \qquad (16.2.264)$$

Equating these:

$$p_i \pi \frac{d^2}{4} = \sigma_L t \pi \frac{d}{2} \qquad (16.2.265)$$

Therefore we get for the longitudinal (axial) stress of a thin cylinder:

$$\sigma_L = \frac{p_i d}{2t} \qquad (16.2.266)$$

Surprisingly the result for a cylinder that ends with a flat disc rather than a half sphere is the same as the project area is equal.

Notice that:

$$\sigma_L \leq \sigma_\theta \qquad (16.2.267)$$

VEL Mate
GAS.de

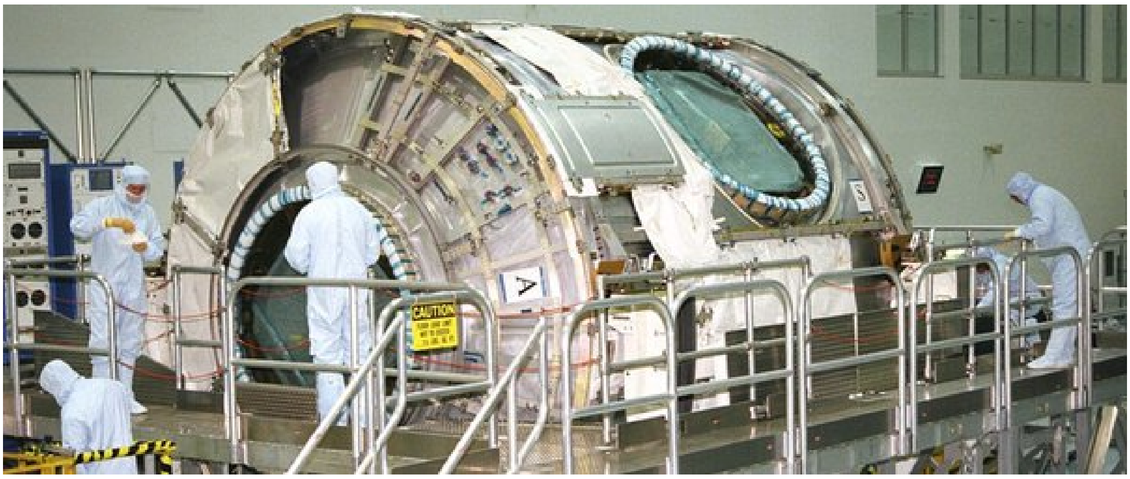
✍**Example:**

Consider the typical International Space Station (ISS) module cylinder of 13.7 meters long (ending with flat discs), with a 1.9 meter internal diameter with walls 4 millimetres thick (all values are real and taken from NASA website) is subjected to an internal pressure of 1 atmosphere (i.e. $101.3\cdot 10^3\,[\mathrm{N}\cdot\mathrm{m}^{-2}]$). We have therefore:

$$\sigma_\theta=\frac{p_i d}{2t}=\frac{(101.3\cdot 10^3)\cdot 1.9}{2\cdot 4\cdot 10^{-3}}=24.1\,[\mathrm{MN}\cdot\mathrm{m}^{-2}]$$

and:

$$\sigma_L=\frac{p_i d}{4t}=\frac{(101.3\cdot 10^3)\cdot 1.9}{2\cdot 4\cdot 10^{-3}}=12.03\,[\mathrm{MN}\cdot\mathrm{m}^{-2}]$$

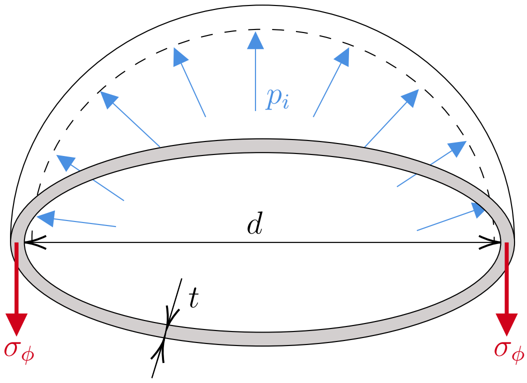


Most ISS modules are made of 2219 aluminium alloy whose tensile strength is 172 to $476\,[\mathrm{MN}\cdot\mathrm{m}^{-2}]$.

It's the difference of pressure between the outside and inside of a vessel that defines the thickness of the walls of that same vessel! In space, for the ISS, the difference is of 1 atmosphere i.e. $101.3\cdot 10^3\,[\mathrm{N}\cdot\mathrm{m}^{-2}]$), however for submarines the difference in deep ocean can be of 1104 atmospheres, that's why for submarines the walls are much thicker!

16.2.3.6.2 Thin sphere subjected to internal pressure

Deriving stresses in the walls of a spherical container is very similar to cylindrical containers. Consider the half section of the spherical container shown in in the figure below:



Consider now a simple spherical vessel of radius r and wall thickness tb, such as a round balloon. An internal pressure p_I induces equal biaxial tangential tensile stresses in the walls, which can be denoted using spherical $r\theta\phi$ coordinates as σ_θ and σ_ϕ.

The container will have an internal pressure p_i. For this case, the resultant force is the pressure times the area, which is a circular area. For a sphere inside diameter d or inside radius r, the total force on half the sphere is given by:

$$\text{pressure} \times \text{projected area} = p_i \frac{\pi d^2}{4} = p_i \pi r^2 \tag{16.2.268}$$

which is balanced by the force obtained by multiplying the wall stress times its area, i.e.:

$$\sigma_\phi(2\pi r t) \tag{16.2.269}$$

Equating these:

$$p_i\left(\pi r^2\right) = \sigma_\phi(2\pi r t) \tag{16.2.270}$$

Hence:

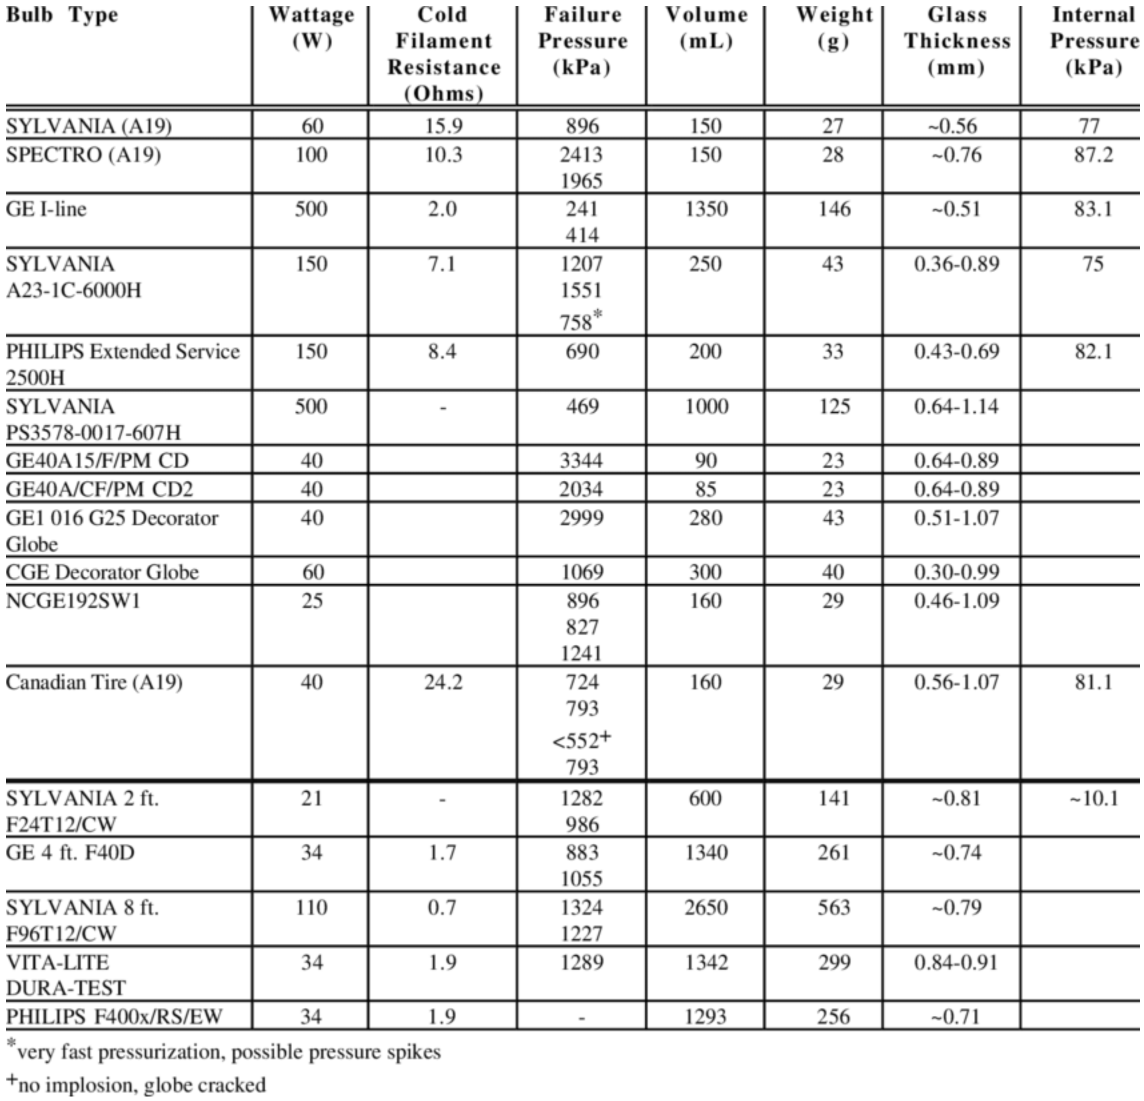
$$\sigma_\phi = \frac{p_i r}{2t} = \frac{p_i d}{4t} \tag{16.2.271}$$

Note that this is a statically determined result, with no dependence on the material properties. Further, the stresses in any two orthogonal circumferential directions are the same; i.e. $\sigma_\phi = \sigma_\theta$.

Therefore, a spherical pressure vessel can carry twice the internal pressure of a cylinder in comparison to the hoop stress.

LIQUIFIED HYDROGEN
FLAMMABLE GAS

It's a myth that all domestic light bulbs have their internal volume that is made of vacuum. The interior of an incandescent light bulb about depends a lot on the type of glass - or glass coated with polymers - the bulb is made of and varies since their creation between 1 [atm] made of inert gas like Argon and good vacuum. When the light is switched and the inert gas is heated up by the incandescent filament, it's easy to compute using the law of perfect gas that the internal pressure of the bulb will increase! For example we have the table below for light bulbs that were manufactured and the end of the 120th century[9] (holocene calendar):



Bulb Type	Wattage (W)	Cold Filament Resistance (Ohms)	Failure Pressure (kPa)	Volume (mL)	Weight (g)	Glass Thickness (mm)	Internal Pressure (kPa)

16.2.3.7 Centrifugal expansion of a rotating ring

Centrifugal expansion of a rotating ring is a fascinating interplay between rotational motion and material elasticity and a very common type of structure and case in many objects of everyday life. When a ring spins about its axis, each infinitesimal segment experiences a centrifugal force directed outward. This force stretches the ring, increasing its radius slightly - an effect governed by the ring's density, angular velocity, and Young's modulus.

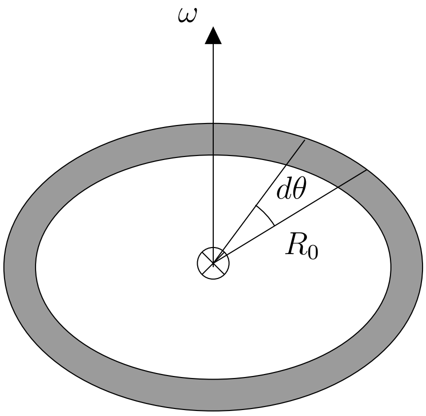

Figure 16.93: Simplified schema of a rotating ring

Let's take a look at an interesting physics problem and this problem is about a ring of density ρ made of some elastic material with Young modulus E that's what the gray ellipse shape above is a ring and we are rotating this ring about an axis perpendicular to its own plane and through the center of the ring right and so this arrow here in this diagram labelled ω that's the angular velocity vector of the ring it's just going around anti-clockwise about that axis now we also know that it has a radius of R_0.

The question is basically by how much does that radius expand when we start doing this rotation. The reason we would expect it to expand is because an object that is rotating moving in a circle experiences a fictitious centrifugal force which tries to push it outwards and so each individual bit of that ring is kind of being pushed outwards by this centrifugal force and so if it's an elastic material it can actually stretch and so we'd expect the whole thing to expand to some extent.

First let us remind that Young's modulus is defined by (see section Continuum Mechanics page 3741):

$$E=\frac{\sigma}{\varepsilon} \tag{16.2.272}$$

Now let us write the new radius when the ring is rotating as:

$$R=R_0+\Delta R=R_0\left(1+\frac{\Delta R}{R_0}\right) \tag{16.2.273}$$

Now let us write:

$$\mathrm{d}m=\rho\mathrm{d}V=\rho R\mathrm{d}\theta A \tag{16.2.274}$$

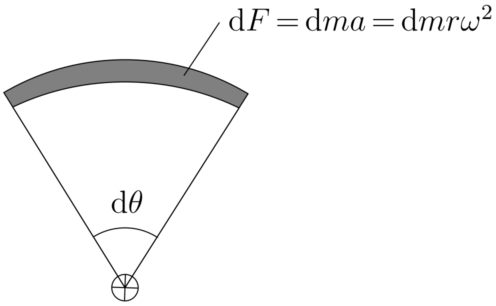
where A is the cross-sectional area of the ring.

Hence:

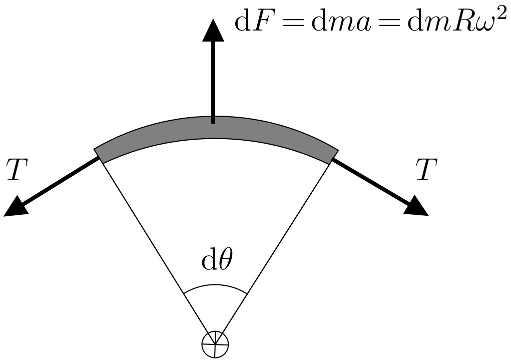
$$\frac{\mathrm{d}m}{\mathrm{d}\theta} = \rho R A \tag{16.2.275}$$

So the next thing we would like to do is start looking at the forces acting on a little element. So let's draw out a diagram that's going to help us see more clearly and more quantitatively what forces are acting on it:

When the ring rotates an element of mass is submitted to the centrifugal force:



So that the ring doesn't blow up there must be an equilibrium with other forces. These forces are the tension forces that we will denote by T and represented in the figure below:



And therefore we can write:

$$R\omega^2 \mathrm{d}m = 2T\sin\left(\frac{\mathrm{d}\theta}{2}\right) \cong 2T\frac{\mathrm{d}\theta}{2} \tag{16.2.276}$$

Hence:

$$T \cong R\omega^2 \frac{\mathrm{d}m}{\mathrm{d}\theta} = R^2\omega^2 A\rho \tag{16.2.277}$$

Remember that the Young's modulus was the stress divided by the strain and the stress is the force acting per unit cross-sectional area right and so the stress is in fact just you know the force that is acting um along the length of the ring is just this tension force and so the stress is just going to be the tension divided by the cross sectional area um and from this expression up here that's just going to be:

$$\sigma = \frac{T}{A} \cong \rho R^2 \omega^2 \tag{16.2.278}$$

What about the strain ? We can actually figure out the strain fairly easily as well because remember we said that was the fractional increase in the length of the ring in other words it's circumferential length and so um basically the the change in circumference is going to be:

$$\varepsilon=\frac{2\pi R-2\pi R_0}{2\pi R_0}=\frac{\Delta R}{R_0} \tag{16.2.279}$$

And as:

$$\sigma=E\varepsilon \tag{16.2.280}$$

We therefore have:

$$\rho R^2\omega^2\cong\frac{E\Delta R}{R_0} \tag{16.2.281}$$

Hence after rearranging:

$$\Delta R\cong\frac{\rho R^2R_0\omega^2}{E} \tag{16.2.282}$$

As we have:

$$R=R_0\left(1+\frac{\Delta R}{R_0}\right) \tag{16.2.283}$$

Therefore:

$$\Delta R\cong\frac{\rho R_0^3\omega^2}{E}\left(1+\frac{\Delta R}{R_0}\right)^2 \tag{16.2.284}$$

Let us take the case of small deformations:

$$\frac{\Delta R}{R_0}\ll 1 \tag{16.2.285}$$

So finally:

$$\boxed{\Delta R\cong\frac{\rho R_0^3\omega^2}{E}} \tag{16.2.286}$$

16.3. Electrical Engineering

We will see in this section the study - under its mathematical aspect of sure - of general electronic circuits, chips, and electronic machinery, transmitter / receivers that the engineer must know formalize, analyse, understand, build and simulate after his studies. For this reason we have chosen in this textbook to focus - as always - on mathematical case of practical (useful!) applications in the every days life, mentioning the potential pitfalls and dangers of the electronic assembly when necessary!

We will deal here first with analogic electronics, then power electronics (electrotechnic), digital electronics and of the physics of semiconductor to understand the foundations of some components.

Electrical engineering is therefore a hierarchy of models. This is the only way to approach the design of complex systems. In principle, the operation of many devices can certainly always be reduced to the application of Maxwell's equations (see section Electrodynamics page 4095) or Schrödinger equation (see section Wave Quantum Physics page 4758) for more complicated case, however it is humanly impossible to understand the design of some systems by staying at this theoretical level.

It is therefore customary in the industry to perform the analysis in six stages:

L0. **Solid State Physics:** This model is essential for the analysis of electric and magnetic properties of matter. It is based on the laws of quantum physics and essentially leads to the description of energy bands and to the calculation of their degree of occupation. This model explains for example the fundamental properties of semiconductors.

L1. **Electromagnetism:** This model is essential for the analysis of devices working at microwave frequencies and the electromagnetic devices. It is based on Maxwell's relations and uses the mathematical theory of partial differential equations. This model don't allows anymore to analyse the influence of an atom as the studied objects are at a macroscopic level, described by their dimensions, their permittivity, their conductivity, etc.

L2. **Circuit Theory:** This model is essential for the analysis of electronic devices in the very common case where the dimensions of the device are well below the wavelength of the phenomenon studied. This model is based on Kirchhoff's lemma and the definition of a half-dozen of discrete elements, resistance, capacitance, inductance, etc. There is one more geometries in such a model but only a topologic (structural) approach. One can calculate the current and voltage, scalar quantities, and the fields have most of time meaning anymore at this scale. Mathematical techniques are those of ordinary differential equations, Laplace transformations, complex computation and matrices, etc.

L3. **Block Diagrams:** At this level, we do not take into account currents or voltages, and we don't care about the geometry (topology) of the system. This is constituted by the block connections doing functions/works characterized by the relations between output and input variables.

L4. **Systems:** At this level, we schematize as a functional block a set of blocks of level 3. A computer is such an interconnection of various logical systems each performing a particular function.

L5. **Software:** From this level, the engineer don't add any more additional devices, don't combines them anymore into larger systems, but program the machine. The theoretical methods then are usually closer to the linguistic than to mathematics.

The reader must not forget that we have proved in the section of Electrokinetics (page 4231) that even in a strong industrial electric field, the drift velocity is negligible compared to the thermal velocity (only a few millimetres per seconds)!

As the thermal velocity depends only a little bit of the electric field, it turns out that in practice the electron velocity is independent of the electric field. In other words, establishing a current, even intense, has only a negligible effect on the speed of electrons!

It is therefore not the electrons that carry the energy, neither mobile electrons push each other trough a circuit, contrary to a falsely held belief, due to bad analogies (which are always bad equivalences as we already know...!) - typically the analogy of electrons that behaves like water flow in cables - as taught in the non-graduate degrees of the school education system!!!!

Before we start, here are some typical voltage scales:

Magnitude $[\text{V}]$	**Description**
$500 \cdot 10^{-9}$	Change in nerve cell potential caused by opening a single acetylcholine receptor channel
$1.2 \cdot 10^{-3}$	Potential created at ambient temperatures from K Type Thermocouple
$75 \cdot 10^{-3}$	Nerve cell resting potential
$320 \cdot 10^{-3}$	Typical voltage reference level in consumer audio electronics
$500 \cdot 10^{-3}$	Typical MOSFET threshold voltage for modern processes
$700 \cdot 10^{-3}$	Forward voltage drop of normal silicon diodes
$900 \cdot 10^{-3}$	Typical positive supply voltage of a low voltage CMOS digital integrated circuit or a Lemon battery cell (made with copper and zinc electrodes
0-3	Magnitudes of standard reduction potentials in chemistry
1.5	Alkaline battery AAAA, AAA, AA, C or D battery
3.3	One of the most common low voltage CMOS digital circuit supply voltages
5	USB power, used for example to charge a cell phone or a digital camera.[18] Also one of the most common digital circuit supply voltages for both TTL and CMOS technologies
12	Typical car battery
100-240	Domestic wall socket voltage
600	Electric eel sends this voltage in an average attack
630	London Underground railway tracks
2450	Electric chair execution in Nebraska
$3\text{-}10 \cdot 10^{3}$	Electric fence
$3 \cdot 10^{3}$	Voltage required to generate a 1 $[\text{mm}]$ electric arc in standard air
$3\text{-}35 \cdot 10^{3}$	Accelerating voltage for a typical television cathode ray tube
$4.16\text{-}34.5 \cdot 10^{3}$	Typical voltages in North America for distribution of power from distribution substations to end users
$15 \cdot 10^{3}$	Train 15 $[\text{kV}]$ AC railway electrification overhead lines, $16^2/_3$ $[\text{Hz}]$
$25 \cdot 10^{3}$	European high-speed train overhead power lines
$69\text{-}230 \cdot 10^{3}$	Range used in North American power high-voltage transmission substations
$345\text{-}800 \cdot 10^{3}$	Range used in EHV (Electrical High Voltage) power transmission system
$3 \cdot 10^{6}$	Used by the ultra-high voltage electron microscope at Osaka University
$25.5 \cdot 10^{6}$	The largest man-made DC voltage – produced in a Van de Graaff generator at Oak Ridge National Laboratory
$100 \cdot 10^{6}$	The potential difference between the ends of a typical lightning bolt
$7 \cdot 10^{15}$	Theoretical voltage around a particular energetic highly magnetized rotating neutron star

$1.05 \cdot 10^{27}$	Planck voltage

Table 16.7: Some common voltage scales

and here are some typical current values:

Magnitude $[\mathrm{A}]$	**Description**
$1.602 \cdot 10^{-19}$	One electron per second
$10 \cdot 10^{-6}$	Minimum current necessary to cause death (by ventricular fibrillation when applied directly across the human heart)
$700 \cdot 10^{-6}$	Typical portable hearing aid
$1\text{-}5 \cdot 10^{-3}$	Cathode ray tube electron gun beam current
$10 \cdot 10^{-3}$	Through the hand to foot may cause a person to freeze and be unable to let go
$20 \cdot 10^{-3}$	Common light-emitting diode (constant current); also deadly limit for skin contact (at 120–230 $[\mathrm{V}]$)
$250\text{-}450 \cdot 10^{-3}$	230 $[\mathrm{V}]$ AC Tungsten incandescent light bulb (60–100 $[\mathrm{W}]$)
1	Typical iPhone charger (5 $[\mathrm{W}]$)
9	230 $[\mathrm{V}]$ AC, toaster, kettle (2 $[\mathrm{kW}]$)
10 or 20	230 $[\mathrm{V}]$ AC, Europe common domestic circuit breaker rating
10 or 20	Typical 12 $[\mathrm{V}]$ motor vehicle starter motor (typically 1-2 $[\mathrm{kW}]$)
80 or 375	TIG welding arc
166	400 $[\mathrm{V}]$ low voltage secondary side distribution transformer with primary 12 $[\mathrm{kV}]$; 200 $[\mathrm{kVA}]$ (up to 1000 $[\mathrm{kVA}]$ also common)
$2 \cdot 10^{3}$	10.5 $[\mathrm{kV}]$ secondary side from an electrical substation with primary 115 $[\mathrm{kV}]$; 63 $[\mathrm{MVA}]$
$30 \cdot 10^{3}$	Typical lightning strike
$100 \cdot 10^{3}$	Low range of Birkeland current that creates Earth's aurorae
$180 \cdot 10^{3}$	Typical current used in electric arc furnace for ferroalloys
$5 \cdot 10^{6}$	Flux tube between Jupiter and Io (moon)
$26 \cdot 10^{6}$	Sandia National Laboratories, Z machine approximate firing current

Table 16.8: Some common current scales

16.3.1 Elementary primitive electrical symbols

This section will help you become familiar with the language and some methods of calculation used by engineers of the industry for the first 4 levels. However and strictly speaking, any training in this area should be completed by practical laboratory work!

Sadly still in 12016 (holocene calendar) there are several national and international standards for graphical symbols in circuit diagrams, in particular:

- IEC 60617 (also known as British Standard BS 3939).
- ANSI standard Y32.2 (also known as IEEE Std 315).
- IEEE Std 91/91a: graphic symbols for logic functions (used in digital electronics). It is referenced in ANSI Y32.2/IEEE Std 315. Australian Standard AS 1102.

We have tried to respect at best in diagrams the norm NF EN 60617 for electrical components symbols. As they are very numerous, we propose below a list only of the components used or mentioned so far in this textbook. This table will therefore evolve over time!

16.3.2 Alternative current VS Direct current

The reader will notice that throughout this section, we will mainly work with alternating current. It seems important to explain the origin of this trend of the contemporary industrial world for the alternating current before going further.

In fact, the origin of this trend is relatively simple:

When power plants came into being, especially in remote areas of urban centers, it was necessary to transport electric power over long distances. But the cables that carry the electricity have some resistance and this posed a major problem.

Indeed, an average city can largely need a power of about 10 [MW]. If this quantity had to be transported under a modest voltage of about 100 [V], as we have $P=UI$ (see section Electrokinetics page 4253), the current had to be enormous: $100,000$ [A]!

But the Joule effect in the copper of 1 [cm] diameter has a linear resistance of $R\cong 0.4\,[\Omega\cdot\text{km}^{-1}]$. With a current of $100,000$ [A], the energy loss per Joule effect would be about (neglecting the potential drop):

$$P=RI^2=4000\,[\text{MW}\cdot\text{km}] \tag{16.3.1}$$

we see quite quick the problem if we not have any supra-conductors...

At the price of $0.1\,[\$\cdot\text{kW}\cdot\text{h}]$, this represents a cost (loss) of about:

$$C=0.4\cdot 10^6\,[\$\cdot\text{kW}\cdot\text{h}] \tag{16.3.2}$$

humm ...!

There were no other economic choices than to lower the current. Clearly, if the voltage reached 10^5 [V], the same power could be carried efficiently by 100 [A]. Thus, by raising the voltage by a factor of $1,000$, we can reduce the current by a factor of $1,000$ as well, and thus the Joule loss by a factor 10^6.

As there was already a simple device for raising and lowering the AC voltage (transformers) without any comparable device for DC voltage (at least at the time), the race was won by the adepts of alternating current.

It should also be added as a second interest that some linear electrical components (see below) do not have much interest in DC ... we will come back to it!

Let's see a simple assembly to generate single-phase alternating current:

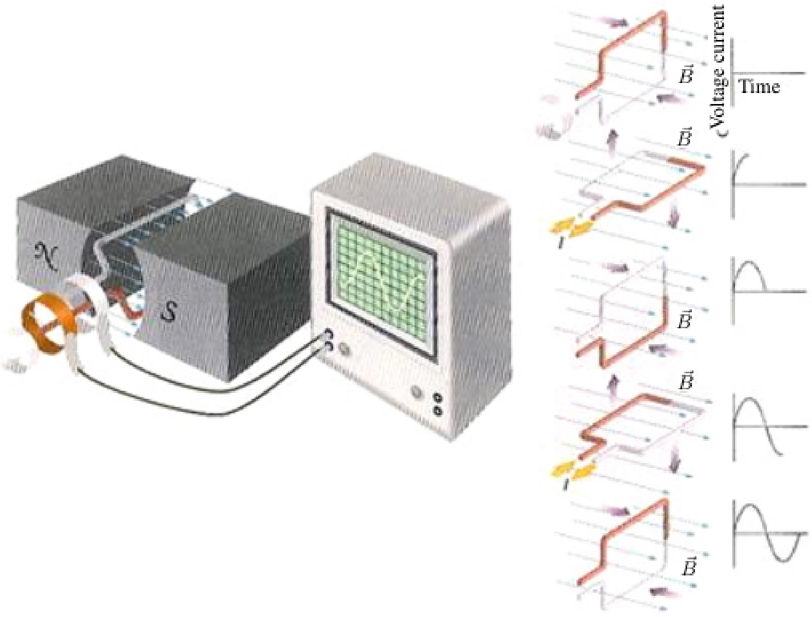

Figure 16.95: **Schematic diagram of an alternating current generator**

The voltage (respectively the current) is determined by the Faraday law proved in the section Electrokinetics (see page 4259):

$$e=-\frac{\mathrm{d}\Phi}{\mathrm{d}t} \tag{16.3.3}$$

Which therefore gives the induced electromotive force (or voltage in the case of a generator without resistance...).

We obviously have in the situation above if the magnet is permanent and the length of the square turn is L:

$$e=-\frac{\mathrm{d}\Phi}{\mathrm{d}t}=-\frac{\vec{B}\circ\mathrm{d}S}{\mathrm{d}t}=-BL^2\frac{\mathrm{d}\cos(\theta)}{\mathrm{d}t}=-BS\frac{\mathrm{d}\cos(\omega t)}{\mathrm{d}t}=BS\omega\sin(\omega t) \tag{16.3.4}$$

We already see that in order to obtain a given electromotive force it will be preferable to play with the frequency of rotation rather than with the surface or the intensity of the magnetic field... Or to increase the number of turns by a mounting allowing to arrive at the following relation (we noted the different way you can find this result in the literature):

$$\boxed{e=NBS\omega\sin(\omega t)=NB(RL)\omega\sin(\omega t)=N\Phi\omega\sin(\omega t)=N\Phi\omega_0\sin(\omega_0 t)=N\Phi\omega(t)} \tag{16.3.5}$$

where R is the radius of the armature and L the length of the conductor in the slot (in most undergraduate classes $R=L$). Depending on the number of poles and the total number of conductors, engineers denote the latter relation sometimes in the following way:

$$e=k\phi\omega(t) \tag{16.3.6}$$

where k is named the "machine constant" (...).

It should be pointed out for the sceptics that there is conservation of energy in this system! Indeed, the energy needed to turn the coil will be that used in part by the system (and that is why dams run turbines with water and nuclear power plants with steam and wind turbines with wind...).

Figure 16.96: **Example of nuclear plant (author: Thomas Soell)**

Obviously the opposite case as an alternating current injected into the coil will cause it to rotate in the magnetic field. So in a situation, we have an electric generator and in the opposite case an electric motor.

It is possible with similar equipment to produce a nearly reliable DC voltage in the following manner named "dynamo" (see the more detailed study of that apparatus further below at page 8447):

$\frac{\pi}{\omega}$
$\frac{3\pi}{2\omega}$
$\frac{2\pi}{\omega}$
t

Figure 16.97: **Example of direct current generator (dynamo)**

The simple generator given first with some horseshoe magnets producing the magnetic field was widely used at the beginning of the era of electrical technology but at high voltages (several [kV]) and high internal currents too (more that 50 [A]). Metal brushes and slip rings produced sparks and deteriorated relatively quickly. Currently, this rotating armature machine is no longer widely used.

To avoid the difficulties associated with voltages exceeding about 600 [V], we now turn electromagnets around a stationary armature. The current supplying the rotating electromagnets (which may also be permanent magnets) is relatively low and does not pose any problem to the operation of the rings and brushes. This configuration is then referred to as an "alternator".

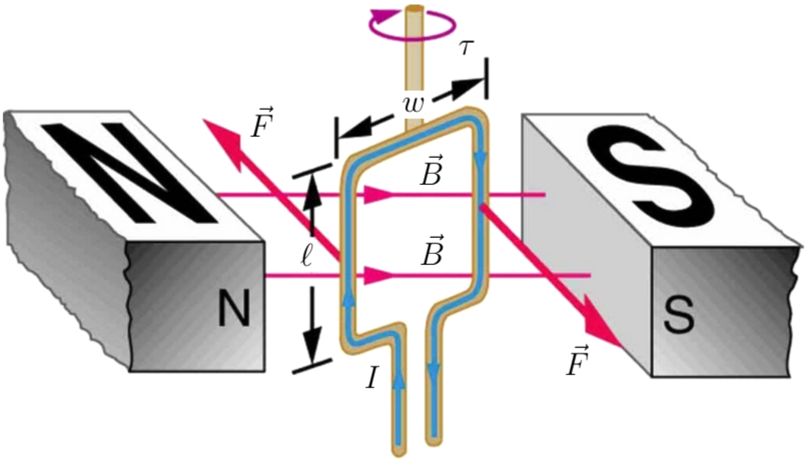
With linear electrical components it is also possible to straighten the tension (we will see this much further). Then we fall back on a dynamo again!

Figure 16.98: **An anti-electricity cartoon from 11900s (holocene calendar)**

16.3.2.1 DC generator (dynamo)

Motors are the most common application of magnetic force on current-carrying wires. Motors have loops of wire in a magnetic field. When current is passed through the loops, the magnetic field exerts torque on the loops, which rotates a shaft. Electrical energy is converted to mechanical work in the process.

As depicted in the below figure where a current-carrying loop of wire attached to a vertically rotating shaft feels magnetic forces that produce a clockwise torque as viewed from above:



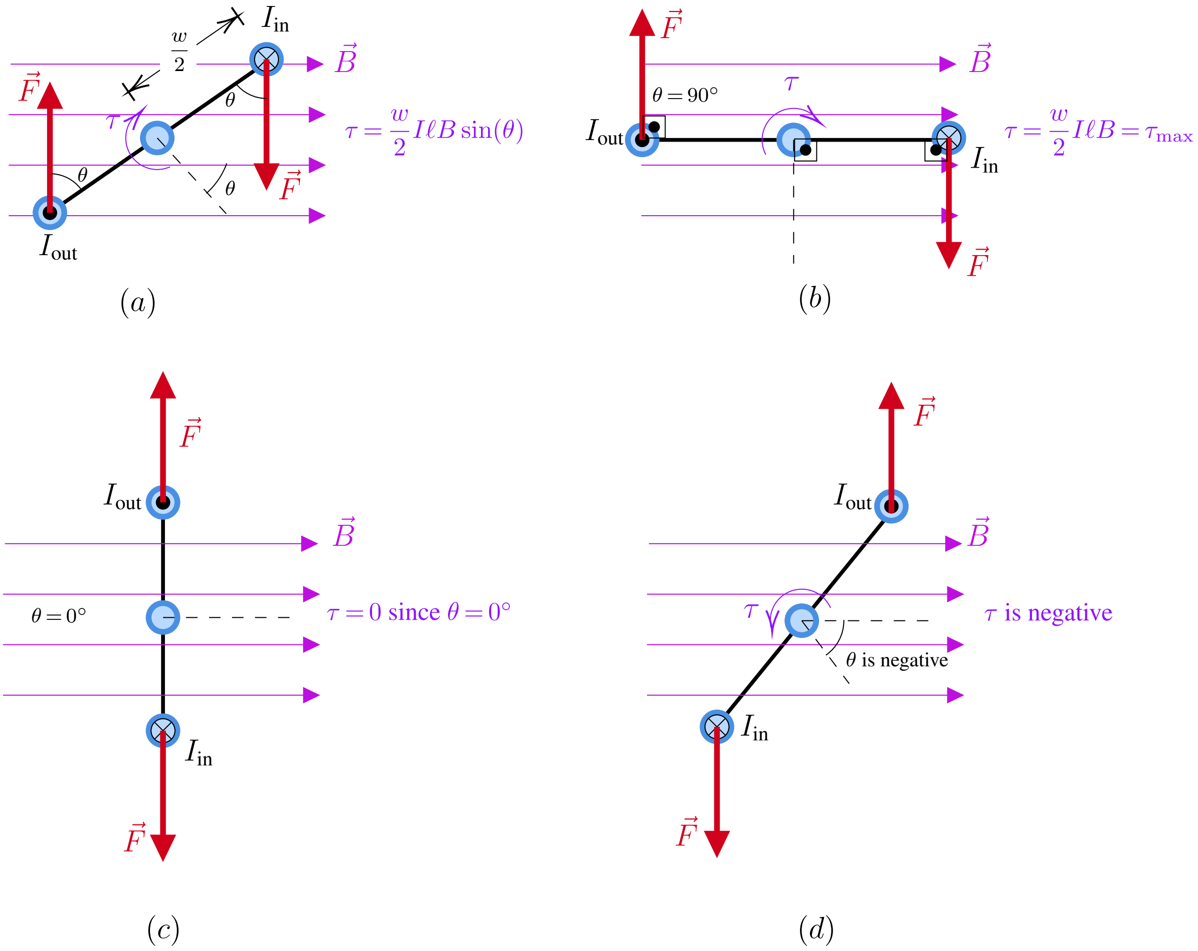
Let us examine the force on each segment of the loop in the figure above to find the torques produced about the axis of the vertical shaft (this will lead to a useful equation for the torque on the loop.).

We take the magnetic field to be uniform over the rectangular loop, which has width w and height ℓ. First, we note that the forces on the top and bottom segments are vertical and, therefore, parallel to the shaft, producing no torque according the Laplace's force law (see section Magnetostics page 4063):

$$\vec{F}=I\vec{l}\times\vec{B} \tag{16.3.7}$$

Those vertical forces are equal in magnitude and opposite in direction, so that they also produce no net force on the loop.

The figure below shows views of the loop from above:



I_{in}
$\frac{w}{2}$
$\vec{B}$
$\vec{F}$
τ
θ
$\tau = \frac{w}{2} I\ell B \sin(\theta)$
I_{out}
(a)

$\vec{B}$
τ
τ is negative
θ is negative
I_{in}
$\vec{F}$
(d)

Figure 16.99: **(a) The equation for torque is derived using this view. Note that the perpendicular to the loop makes an angle θ with the field that is the same as the angle between $w/2$ and $\vec{F}$. (b) The maximum torque occurs when θ is a right angle and $\sin(\theta) = 1$. (c) Zero (minimum) torque occurs when θ is zero and $\sin(\theta) = 0$. (d) The torque reverses once the loop rotates past $\theta = 0$.**

Torque is we know defined as:

$$\tau = \vec{r} \times \vec{F} = rF\sin(\theta) \tag{16.3.8}$$

where F is the force, r is the distance from the pivot that the force is applied, and θ is the angle between $\vec{r}$ and $\vec{F}$. As seen in the top left illustration above! Right rand rule gives the forces on the sides to be equal in magnitude and opposite in direction, so that the net force is again zero. However, each force produces a clockwise torque. Since $r = w/2$, the torque on each vertical segment is:

$$\tau = \frac{w}{2} F\sin(\theta) \tag{16.3.9}$$

and the two add to give a total torque.

Now, each vertical segment has a length ℓ that is perpendicular to B, so that the force on each is $F = I\ell B$. Entering F into the expression for torque yields:

$$\tau = rF\sin(\theta) = wI\ell B\sin(\theta) \tag{16.3.10}$$

If we have a multiple loop of N turns, we get N times the torque of one loop. Finally, note that the surface of the loop is $S = w\ell$; the expression for the torque becomes:

$$\boxed{\tau = NISB\sin(\theta)} \tag{16.3.11}$$

This is the "torque on a current-carrying loop" in a uniform magnetic field. This equation can be shown to be valid for a loop of any shape. The loop carries a current I, has N turns, each of surface S, and the perpendicular to the loop makes an angle θ with the field $\vec{B}$. The net force on the loop is zero.

✍**Example:**

Let us find the maximum torque on a 100-turn square loop of a wire of 10 [cm] on a side that carries 15 [A] (small Neodym magnets have a typical field of 1.4 [T]) of current in a 2 [T] field.

We know that the torque on the loop can be found using $\tau = NISB\sin(\theta)$. Obviously the maximum torque occurs when $\theta = 90°$ and $\sin(\theta) = 1$.

For $\sin(\theta) = 1$ the maximum torque is:

$$\tau_{\text{max}} = NISB \tag{16.3.12}$$

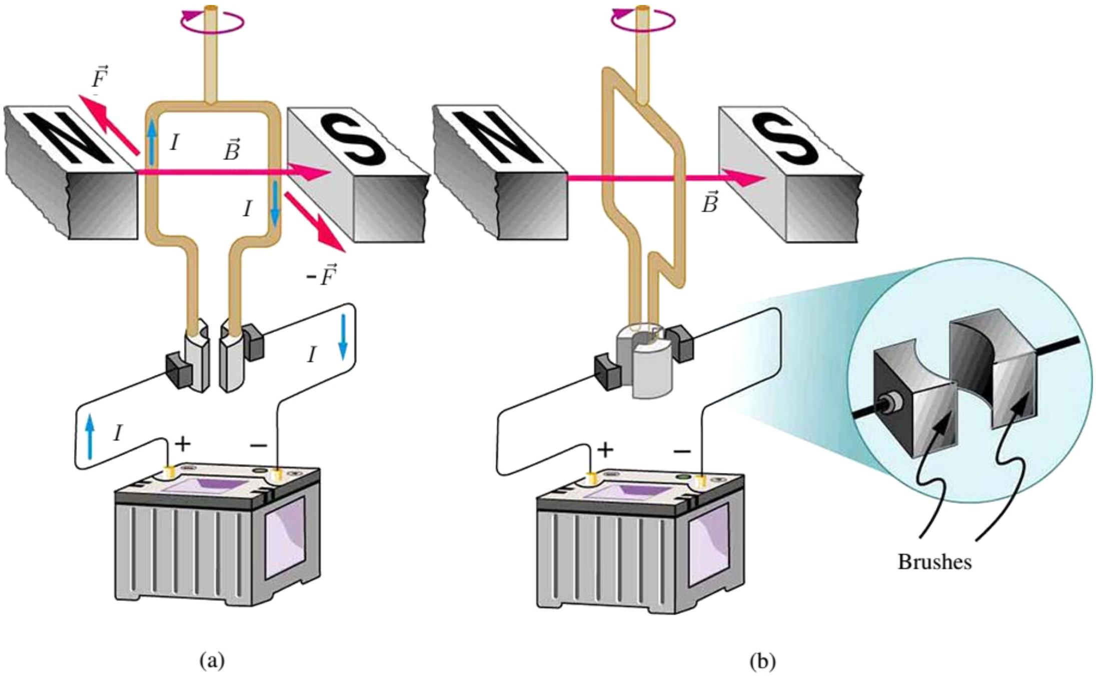
Entering known values yields:

$$\tau_{\text{max}} = 100 \cdot 15 \cdot 0.1 \cdot 2 = 30\,[\text{N} \cdot \text{m}] \tag{16.3.13}$$

This torque is large enough to be useful in a small motor.

Notice that the Re 460 Swiss locomotive has a current of 593 [A] ($2,180$ [V]) but obviously the architecture of such an engine is almost completely different from the above one!

The torque found in the preceding example is the maximum. As the coil rotates, the torque decreases to zero at $\theta = 0$. The torque then reverses its direction once the coil rotates past $\theta = 0$ (see (d) in the figure above) This means that, unless we do something, the coil will oscillate back and forth about equilibrium at $\theta = 0$. To get the coil to continue rotating in the same direction, we can reverse the current as it passes through $\theta = 0$ with automatic switches named "brushes"as illustrated below:



16.3.2.2 Average power

We have defined in the section Electrokinetics (see page 4253) that Joule power was given in constant supply for a conductor by:

$$P=UI=RI^2 \tag{16.3.14}$$

In alternating regime system and at low frequency (in order to consider the resistance as constant) we have in the purely resistive case:

$$p(t)=Ri^2(t) \tag{16.3.15}$$

It then comes (see section Statistics page 569) for the mean value of a periodic signal of period T:

$$\bar{p}=\frac{1}{T}\int_{t_0}^{t_0+T} u(t)i(t)\mathrm{d}t=R\left(\frac{1}{T}\int_{t_0}^{t_0+T} i^2(t)\mathrm{d}t\right) \tag{16.3.16}$$

The term in brackets can therefore be compared to the value that would have a direct current producing the same Joule power. Therefore:

$$\bar{p}=RI^2=R\left(\frac{1}{T}\int_{t_0}^{t_0+T} i^2(t)\mathrm{d}t\right) \tag{16.3.17}$$

We name this equivalent current the "effective current value" or "current root mean square" (abbreviated "RMS current") and we denote it by:

$$I_{\text{eff}}=\sqrt{\frac{1}{T}\int_{t_0}^{t_0+T} i^2(t)\mathrm{d}t} \tag{16.3.18}$$

The RMS values being what the multimeters measure. For the sinusoidal regimes, we then have:

$$I_{\text{eff}}=\sqrt{\frac{1}{T}\int_{t_0}^{t_0+T}i^2(t)\mathrm{d}t}=\sqrt{\frac{1}{2\pi}\int_0^{2\pi}i^2(\theta)\mathrm{d}\theta}=\sqrt{\frac{1}{2\pi}I_0^2\int_0^{2\pi}\cos^2(\theta)\mathrm{d}\theta}=\sqrt{\frac{1}{2\pi}I_0^2\pi}=\frac{I_0}{\sqrt{2}} \tag{16.3.19}$$

Therefore we have in this special case:

$$p=u(t)i(t)=u(t)\frac{I_0}{\sqrt{2}} \tag{16.3.20}$$

And using the same method, wishing to calculate the average voltage, we get in sinusoidal regime:

$$U_{\text{eff}}=\frac{U_0}{\sqrt{2}} \tag{16.3.21}$$

Therefore for a voltage and current having the same phase, we can write:

$$\bar{p}=U_{\text{eff}}I_{\text{eff}}=\frac{U_0}{\sqrt{2}}\frac{I_0}{\sqrt{2}}=\frac{U_0I_0}{2} \tag{16.3.22}$$

Strictly speaking, we must generalize this last relation for situations where the current and the voltage are out of phase with an angle (or time) φ.

Remark

Unfortunately, many electronic books or even research articles have defined a power that has no physical meaning and that is named "RMS power" and measures "RMS watts" defined by analogy by:

$$P_{\text{eff}}=\sqrt{\frac{1}{T}\int_t^{t+T}p^2(t)\mathrm{d}t} \tag{16.3.23}$$

Even though this term is used by advertisers and some editors, it has no place in good technical publications. It often appears to give a semblance of technical expertise...

Let us consider now another approach of the Power this time from the instantaneous point of view in a more general than purely resistive case. In a more general case, we have the right to write the voltage and the current in the sinusoidal steady state with cosines in the following form (which implicitly also takes into account the phase shift of current and voltage):

$$\begin{aligned}u(t)&=U_0\cos(\omega t+\alpha)\\ i(t)&=I_0\cos(\omega t+\beta)\end{aligned} \tag{16.3.24}$$

We then have using the remarkable trigonometric relations (see section Trigonometry page 2519):

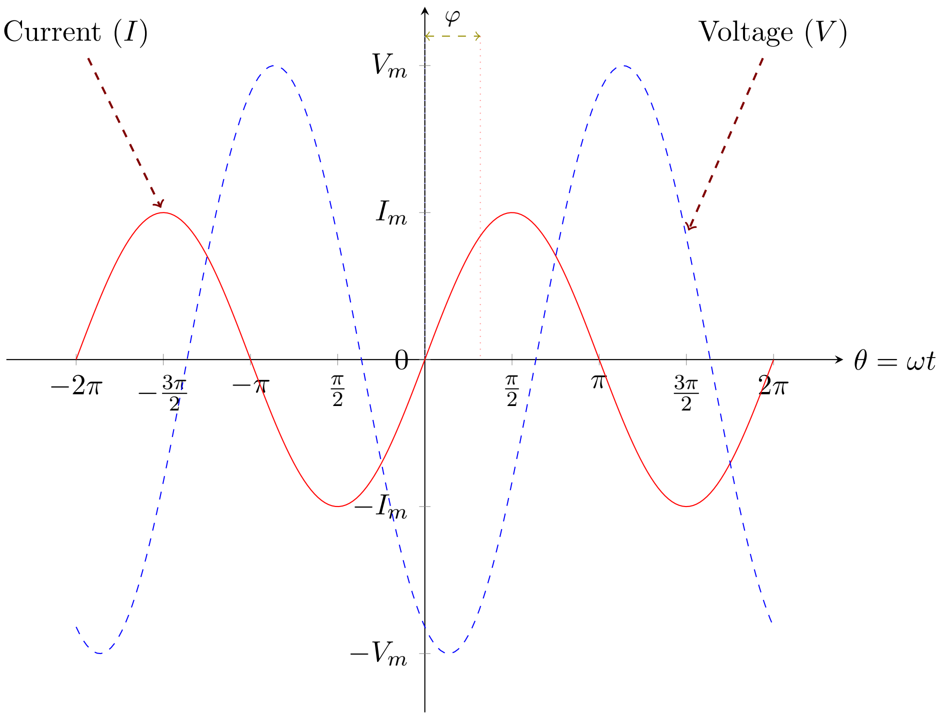
$$\begin{aligned}p(t)&=u(t)i(t)=I_0U_0\cos(\omega t+\alpha)\cos(\omega t+\beta)\\ &=U_0I_0\left(\frac{\cos(\alpha-\beta)+\cos(2\omega t+\alpha+\beta)}{2}\right)=\frac{U_0I_0}{2}\cos(\varphi)+\frac{U_0I_0}{2}\cos(2\omega t+\alpha+\beta)\\ &=U_{\text{eff}}I_{\text{eff}}\cos(\varphi)+U_{\text{eff}}I_{\text{eff}}\cos(2\omega t+\alpha+\beta)\end{aligned} \tag{16.3.25}$$

where we are free to put:

$$\varphi = \alpha - \beta \tag{16.3.26}$$

such that this term φ is positive or null (we can always choose to subtract one of the two terms to the other in order to have a strictly positive or zero φ value without changing the developments and conclusions that follow below) and where we used the results obtained previously:

$$U_{\text{eff}} = \frac{U_0}{\sqrt{2}} \qquad I_{\text{eff}} = \frac{I_0}{\sqrt{2}} \tag{16.3.27}$$



Therefore, in the expression:

$$p(t) = U_{\text{eff}} I_{\text{eff}} \cos(\varphi) + U_{\text{eff}} I_{\text{eff}} \cos(2\omega t + \alpha + \beta) \tag{16.3.28}$$

the instantaneous power thus comprises a constant component (first term) and a pulsed component with a frequency double that of the current and the voltage.

By using:

$$\varphi = \alpha - \beta \Rightarrow \beta = \alpha - \varphi \tag{16.3.29}$$

as well as the following remarkable trigonometric relations (see section Trigonometry page 2519):

$$\cos(2\omega t + \alpha + \beta) = \cos(2\omega t + 2\alpha - \varphi) = \cos(\varphi)\cos(2\omega t + 2\alpha) + \sin(\varphi)\sin(2\omega t + 2\alpha) \tag{16.3.30}$$

We then have:

$$\begin{aligned} p(t) &= U_{\text{eff}} I_{\text{eff}} \cos(\varphi) + U_{\text{eff}} I_{\text{eff}} \left[\cos(\varphi)\cos(2\omega t + 2\alpha) + \sin(\varphi)\sin(2\omega t + 2\alpha)\right] \\ &= U_{\text{eff}} I_{\text{eff}} \cos(\varphi)\left[1 + \cos(2\omega t + 2\alpha)\right] + U_{\text{eff}} I_{\text{eff}} \sin(\varphi)\sin(2\omega t + 2\alpha) \end{aligned} \tag{16.3.31}$$

Denoted:

$$\boxed{p(t)=U_{\text{eff}}I_{\text{eff}}\cos(\varphi)\left[1+\cos(2\omega t+2\alpha)\right]+U_{\text{eff}}I_{\text{eff}}\sin(\varphi)\sin(2\omega t+2\alpha)} \tag{16.3.32}$$

This last relation highlights that the instantaneous power can always be reduced in a permanent sinusoidal regime as the sum of two terms where:

- The first term is a pulsed component, always positive (by construction), which oscillates around the mean value $U_{\text{eff}}I_{\text{eff}}\cos(\varphi)$ and which translates a unidirectional energy exchange between a source and a load.
- The second term is an alternating component that varies sinusoidally with an amplitude $U_{\text{eff}}I_{\text{eff}}\sin(\varphi)$ and a zero average value. It is therefore alternately positive and negative and translates an oscillatory exchange of energy between a source and a charge.

When $\varphi=0$ (perfect purely resistive load), we then have:

$$\cos(\varphi)=1 \qquad \sin(\varphi)=0 \tag{16.3.33}$$

The mean value $U_{\text{eff}}I_{\text{eff}}\cos(\varphi)$ is then maximum and equal to $U_{\text{eff}}I_{\text{eff}}$, while the second term (the alternative component) is zero.

On the other hand, when $\varphi=\pm\dfrac{\pi}{2}$ (purely reactive load as an ideal inductance or capacity), then:

$$\cos(\varphi)=0 \qquad \sin(\varphi)=\pm 1 \tag{16.3.34}$$

and in this case the instantaneous power is reduced to the only alternative component. From this arises the following definitions:

Definitions (#16.3.728):

D1. We name "active power" the term:

$$\boxed{P=U_{\text{eff}}I_{\text{eff}}\cos(\varphi)=U_{\text{rms}}I_{\text{rms}}\cos(\varphi)} \tag{16.3.35}$$

and this quantity is measurable by a wattmeter and which corresponds to a real supply of energy convertible to work or heat and which is therefore maximum in the case of a purely resistive (ideal) load and zero in the case of a purely reactive (ideal) charge.

D2. We name "reactive power" the term:

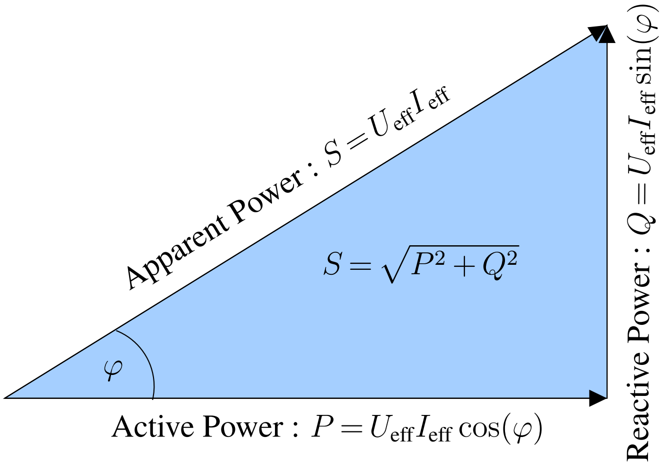
$$\boxed{Q=U_{\text{eff}}I_{\text{eff}}\sin(\varphi)=U_{\text{rms}}I_{\text{rms}}\sin(\varphi)} \tag{16.3.36}$$

which is not measurable by a wattmeter since equal to zero as it is alternative.

D3. We name "apparent power" the product $U_{\text{eff}}I_{\text{eff}}$ that is in faced denoted most of time as:

$$\boxed{S=\sqrt{P^2+Q^2}=U_{\text{eff}}I_{\text{eff}}} \tag{16.3.37}$$

hence the famous "power triangle":



Apparent Power : $S = U_{\text{eff}} I_{\text{eff}}$
$S = \sqrt{P^2 + Q^2}$
φ
Active Power : $P = U_{\text{eff}} I_{\text{eff}} \cos(\varphi)$
Reactive Power : $Q = U_{\text{eff}} I_{\text{eff}} \sin(\varphi)$

Figure 16.100: Electric Power triangle

Which is in appearance a power but does not necessarily provide work, hence its name ... Traditionally it is the apparent power that is indicated on large industrial installations. It can be recognized because the units are often indicated in volts-amps [VA] rather than in watts [W] (because this is not totally a power)!

16.3.3 Transformers

A static electric transformer is an electrical machine which makes it possible to modify the voltage and current intensity values delivered by an alternative electrical power source into a voltage and current system of different values but with the same frequency and the same shape.

Since the invention of the first constant potential transformer in 11885 (holocene calendar), transformers have become essential for the transmission, distribution, and utilization of alternating current electrical energy. A wide range of transformer designs is encountered in electronic and electric power applications. Transformers range in size from RF transformers less than a cubic centimetre in volume to units interconnecting the power grid weighing hundreds of tons for Nuclear Plant.

Let us recall that we have proved in the section of Electrokinetics that (see page 4263):

$$e = -N\frac{\mathrm{d}\Phi}{\mathrm{d}t} = -L\frac{\mathrm{d}i}{\mathrm{d}t} \qquad (16.3.38)$$

If we can in one way or another to pass the flow of a first solenoid, then named "primary winding", having:

$$e_1 = -N_1\frac{\mathrm{d}\Phi}{\mathrm{d}t} = -L_1\frac{\mathrm{d}i}{\mathrm{d}t} \qquad (16.3.39)$$

to a second solenoid, then named "secondary winding", without any loss (or at least a negligible loss) such as:

$$e_2 = -N_2\frac{\mathrm{d}\Phi}{\mathrm{d}t} = -L_2\frac{\mathrm{d}i}{\mathrm{d}t} \qquad (16.3.40)$$

Then it comes by term-by-term identification:

$$\frac{e_1}{e_2}=\frac{N_1}{N_2} \tag{16.3.41}$$

And if the internal resistances are negligible the induced electromotive force is then equal to the voltage at the terminals, then it comes:

$$\frac{U_1}{U_2}=\frac{N_1}{N_2} \tag{16.3.42}$$

And if all the energy of the magnetic field is transmitted in the secondary winding (without loss) by the conservation of energy, we have:

$$P_1=P_2\Leftrightarrow U_1I_1=U_2I_2 \tag{16.3.43}$$

from where:

$$\boxed{\frac{U_1}{U_2}=\frac{I_2}{I_1}=\frac{N_1}{N_2}} \tag{16.3.44}$$

Thus, the ratio of the number of primary turns to the number of secondary turns totally determines the transformation ratio of the transformer which can then be used as a voltage transformation station by raising or lowering it as a function of the number of turns of the secondary winding. It should also be noted that a transformer which increases the voltage simultaneously decreases the current and vice versa.

A typical historical and pedagogical instrument to do this is the single-phase transformer with a ferromagnetic core:

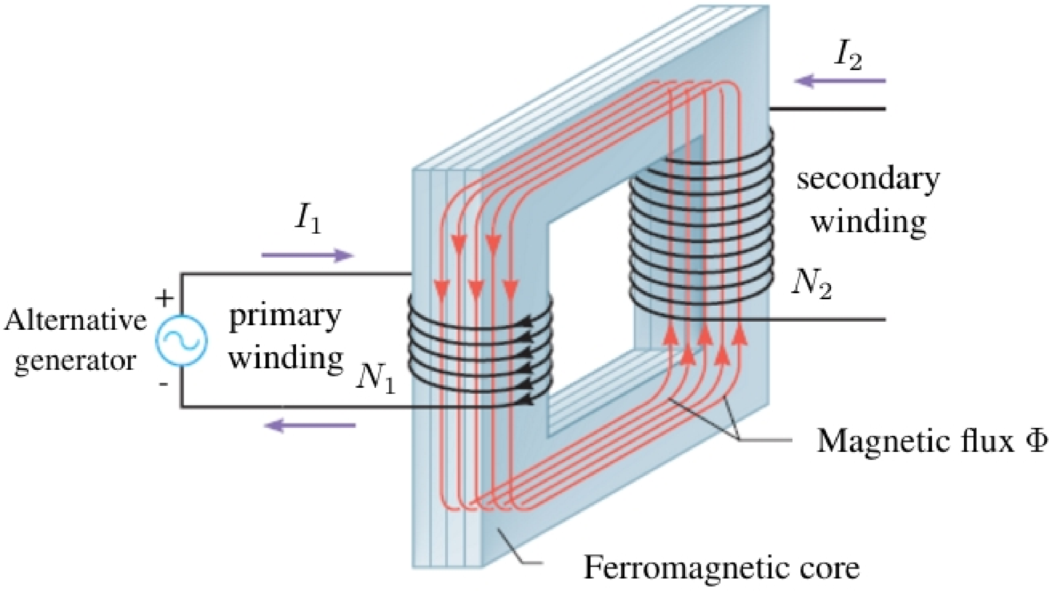


Figure 16.101: **Typical example of a single-phase transformer with a ferromagnetic core**

In practice, monophasic transformers have windings that are concentric to minimize flux leakage. An insulation is inserted between the primary circuit and the secondary:

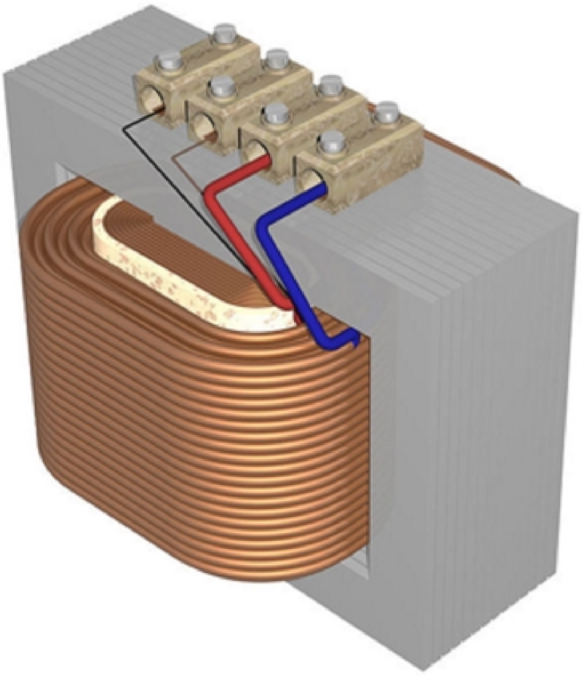

Figure 16.102: **Concentric monophasic transformer type (source: Wikipedia)**

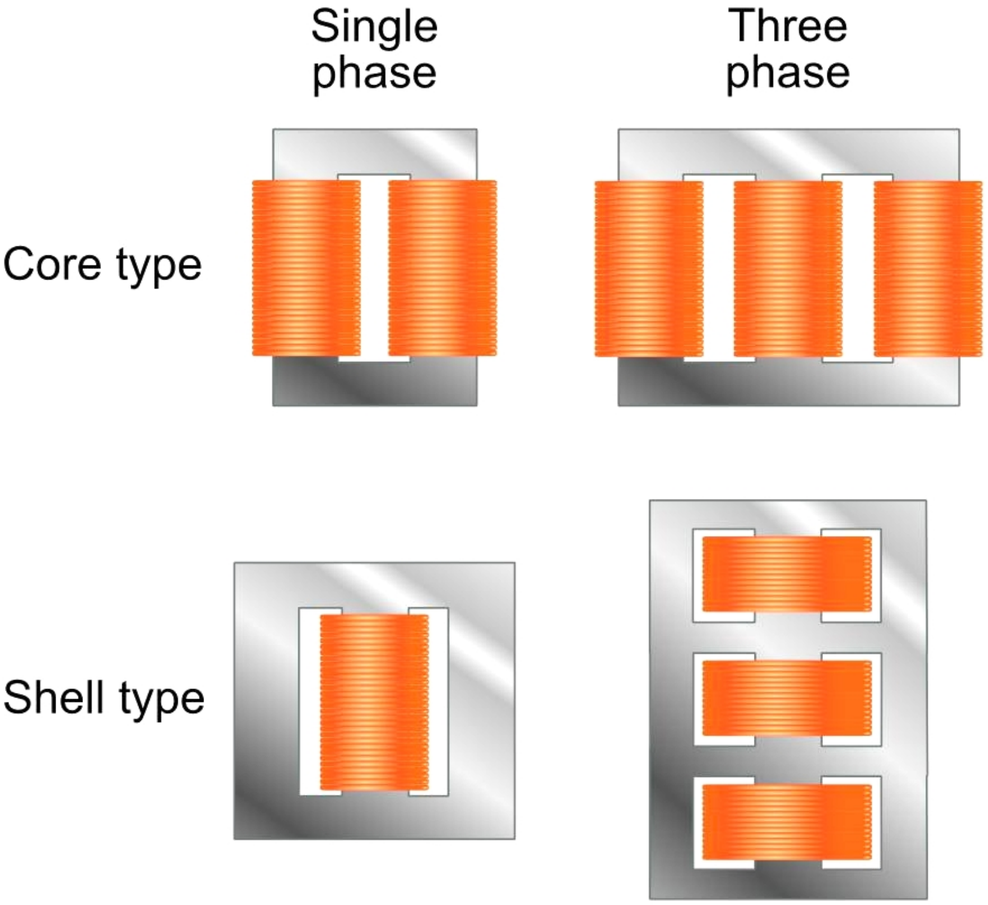
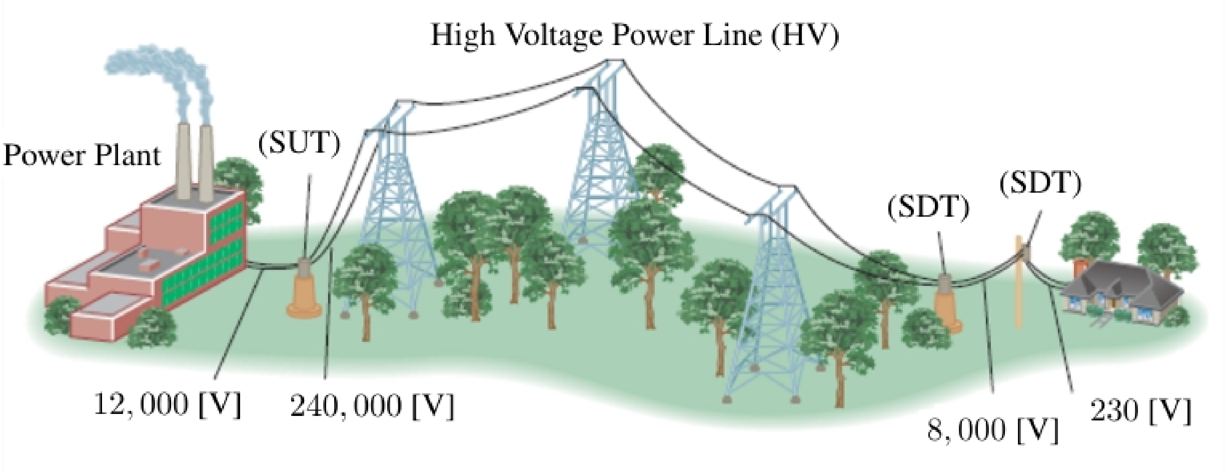
Closed-core transformers are constructed in "core form" or "shell form". When windings surround the core, the transformer is core form; when windings are surrounded by the core, the transformer is shell form. Shell form design may be more prevalent than core form design for distribution transformer applications due to the relative ease in stacking the core around winding coils. Core form design tends to, as a general rule, be more economical, and therefore more prevalent, than shell form design for high voltage power transformer applications at the lower end of their voltage and power rating ranges (less than or equal to, nominally, 230 [kV] or 75 [MVA]). At higher voltage and power ratings, shell form transformers tend to be more prevalent. Shell form design tends to be preferred for extra-high voltage and higher [MVA] applications because, though more labor-intensive to manufacture, shell form transformers are characterized as having inherently better kVA-to-weight ratio, better short-circuit strength characteristics and higher immunity to transit damage:



Single phase
Three phase
Core type
Shell type

Figure 16.103: **Schematic representation of various transformers (source: Wikipedia, author: Spinningspark)**

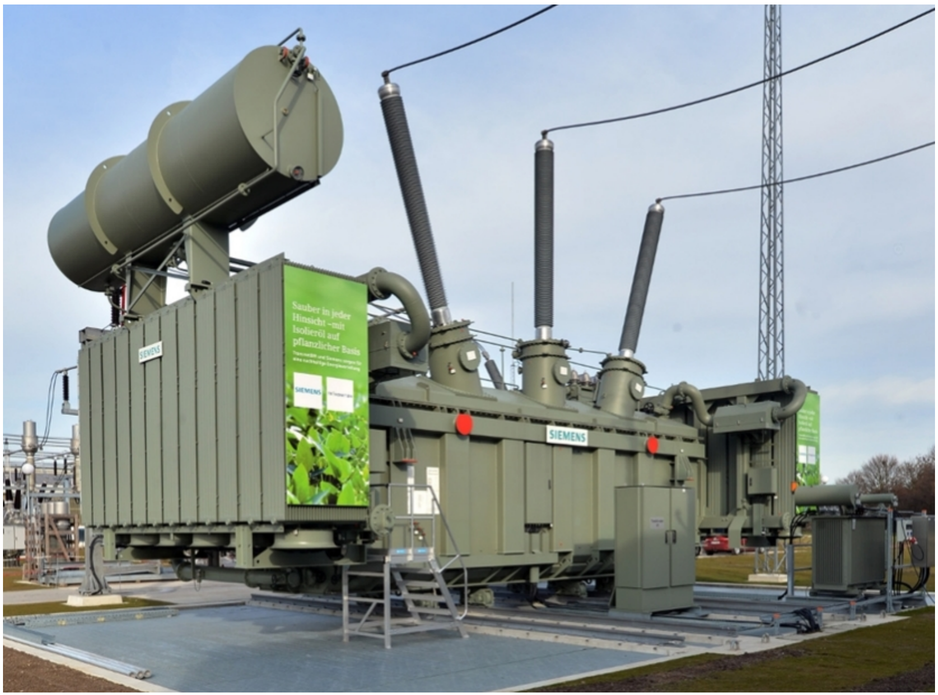
Transformers by their ability to increase voltage and reduce current (saving by Joule loss as we have already mentioned) play an important role in the transmission of electricity from domestic infrastructures (low voltage: LV, medium voltage: MV, high voltage HV). Thus we find the step-up transformers (SUT) and step-down transformers (STD) in everyday life:



High Voltage Power Line (HV)
Power Plant
(SUT)
(SDT)
(SDT)
12, 000 [V]
240, 000 [V]
8, 000 [V]
230 [V]

Figure 16.104: **Typical civilian voltage transformation cascade installation in Switzerland**

Here is an example of the largest triphasic step-up transformer (SUT) in the world in 12014 (according to holocene calendar):



Sauber in jeder Hinsicht –mit Isolieröl auf pflanzlicher Basis
SIEMENS
SIEMENS

Figure 16.105: **Largest plant-oil-based transformer in the World in 12014 (source: TransnetBW GmbH)**

And a primary triphasic step-down transformer with a slice cut:

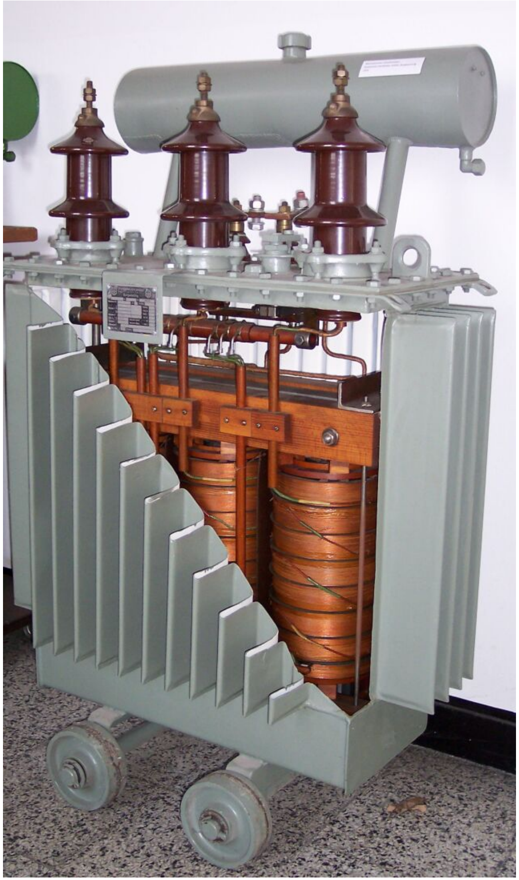


Figure 16.106: **Cutaway view of liquid-immersed construction transformer. The conservator (reservoir) at top provides liquid-to-atmosphere isolation as coolant level and temperature changes. The walls and fins provide required heat dissipation balance (source: Wikipedia)**

And a typical USA pole-mounted distribution step-down transformer with center-tapped secondary winding used to provide split-phase power for residential and light commercial service:

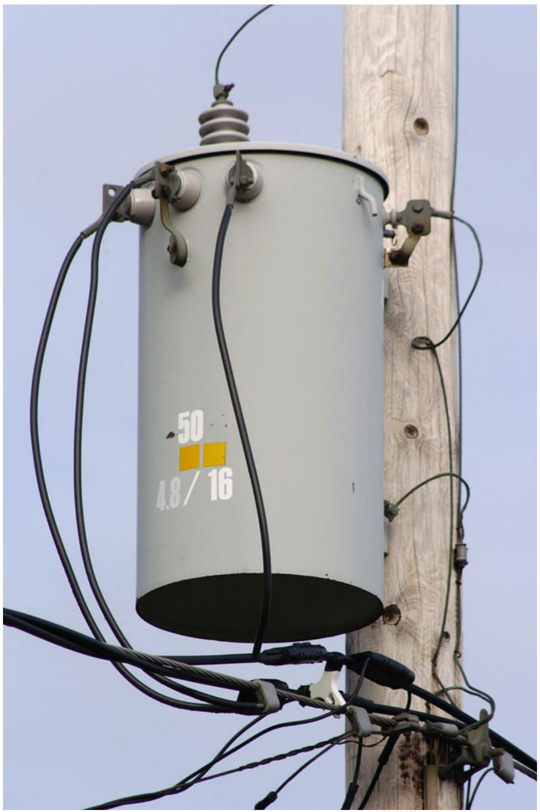

Figure 16.107: **Typical pole-mounted distribution transformer in USA with center-tapped secondary winding (source: Wikipedia)**

And finally typical small size domestic transformers for computer, TV, Hi-Fi, etc. :

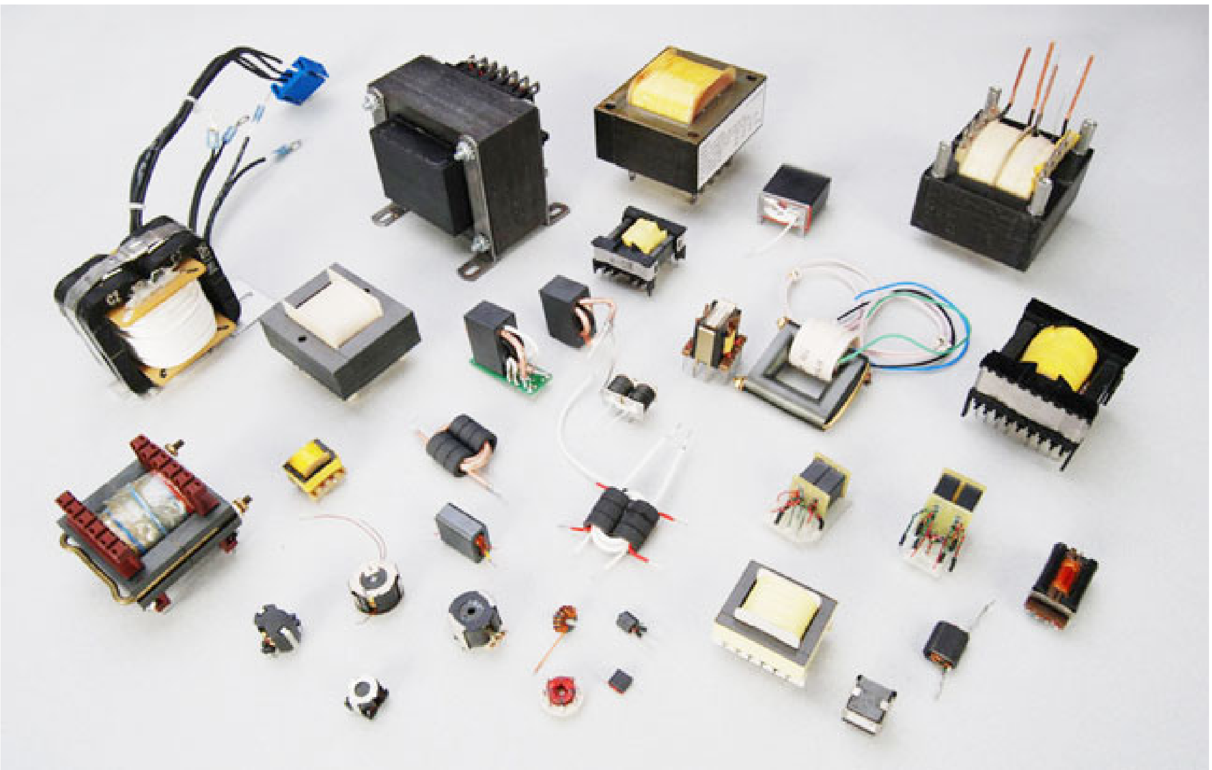

Figure 16.108: Small domestic size transformers (source: Mohawk Electro Techniques Inc.)

16.3.3.1 Transformer universal EMF equation

If the flux in the core is purely sinusoidal, the relationship for either winding between its RMS voltage e_{eff} of the winding, and the supply frequency f, number of turns N, core cross-sectional area S and peak magnetic flux density B_{peak} is given by the universal EMF equation that we will prove now!

The derivation of EMF equation of the transformer is shown below. First remember that we have:

$$e=-N\frac{\mathrm{d}\Phi}{\mathrm{d}t} \tag{16.3.45}$$

Explicitly:

$$e=-N\frac{\mathrm{d}\hat{\Phi}\sin(\omega t)}{\mathrm{d}t}=-N\omega\hat{\Phi}\cos(\omega t)=-N\omega\hat{\Phi}\sin\left(\omega t-\frac{\pi}{2}\right) \tag{16.3.46}$$

So we see again that the induced EMF lags flux by 90°.

The maximum value of EMF is obviously equal to:

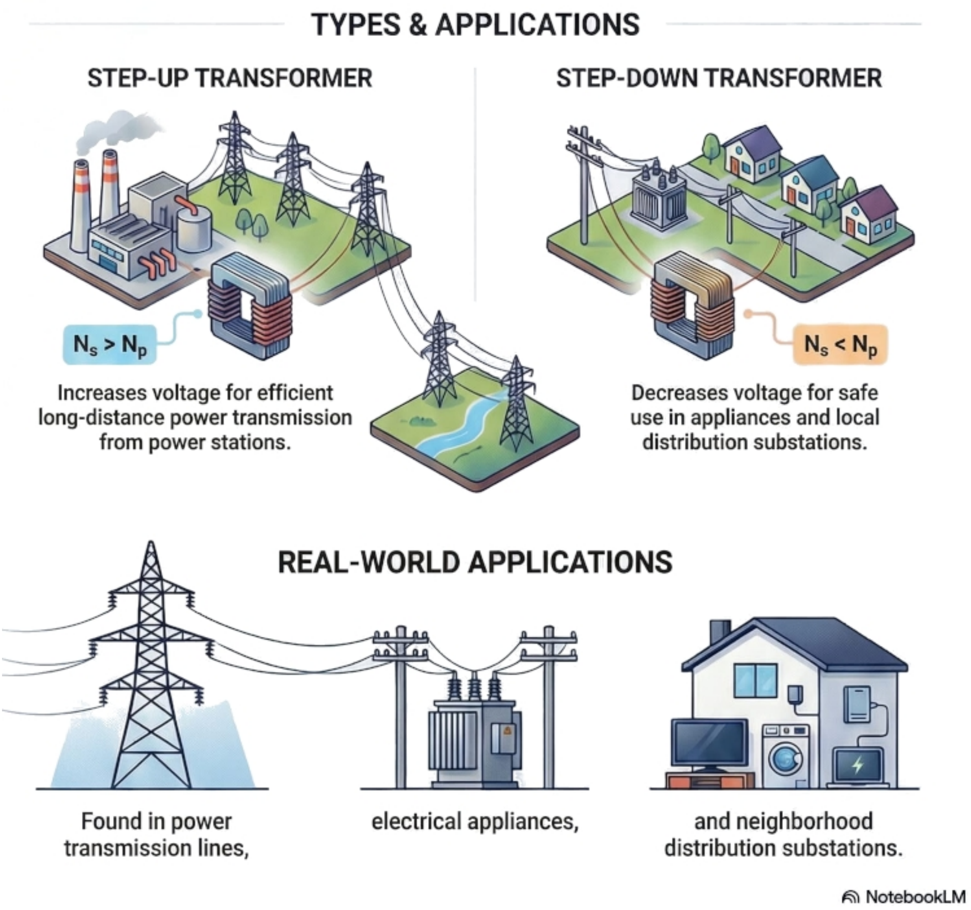
$$e_{\max}=N\omega\hat{\Phi}=N2\pi f\hat{\Phi} \tag{16.3.47}$$

The root mean square RMS value is therefore:

$$e_{\text{eff}}=\frac{e_{\max}}{\sqrt{2}}=\frac{N2\pi f\hat{\Phi}}{\sqrt{2}}=\sqrt{2}\pi fN\hat{\Phi}\cong 4.44fN\hat{\Phi} \tag{16.3.48}$$

As $\Phi = B_{\text{peak}} \cdot S$ we get finally the "transformer universal EMF equation":

$$\boxed{e_{\text{eff}} \cong 4.44 f N S B_{\text{peak}}} \tag{16.3.49}$$



TYPES & APPLICATIONS
STEP-UP TRANSFORMER
STEP-DOWN TRANSFORMER
N_s > N_p
Increases voltage for efficient long-distance power transmission from power stations.
N_s < N_p
Decreases voltage for safe use in appliances and local distribution substations.
REAL-WORLD APPLICATIONS
Found in power transmission lines,
electrical appliances,
and neighborhood distribution substations.
NotebookLM

16.3.4 Steady State Linear Circuits

We will see here circuits composed of simple elements such as resistance, capacitance and impedance. These circuits, whose representative equation is a linear differential equation, are named "linear circuits". Moreover, they are an excellent example to see the cumbersome developments using classical mathematical tools as opposed to other more flexible and powerful techniques (representation by phasors and Laplace transforms).

Before we start, the reader must keep in mind something quite important! As we have already mentioned it, it's not the electrons that carry the energy, neither they push each other (the water flow analogy being a wrong equivalence as every analogy in Science). If we consider the naive circuit below with a battery and a lamp:

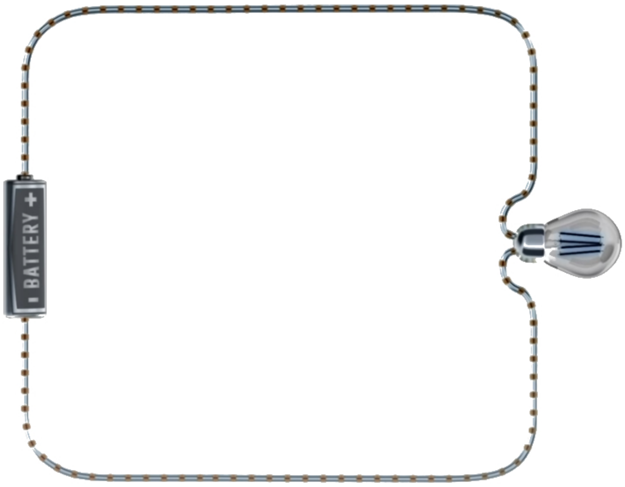


Figure 16.109: **Naive battery lamp circuit (source: Veritasium)**

The energy is in fact transported by the Poynting vector (see section Electrodynamics page 4156) of the electromagnetic field as the circuit behaves like a dipole antenna:

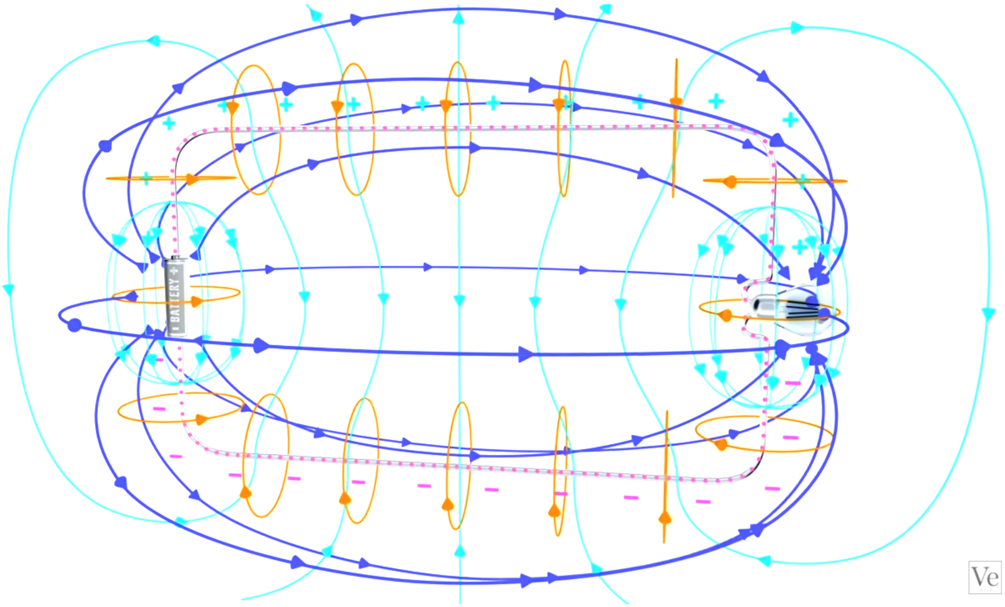

Figure 16.110: **Naive circuit behaves like an antenna (source: Veritasium)**

To have a look at how energy gets into a light globe we consider the related case of a segment of wire that is nice and straight instead of being coiled up tightly. We need to look at the electric and magnetic fields just inside the surface of the wire. As we have already seen, the electric field $\vec{E}$ inside the wire points along the axis of the wire and, just inside the surface, the lines of $\vec{E}$ lie along the surface and parallel to it. The lines of the magnetic field $\vec{B}$ form closed loops around the wire. The diagram shows some of these lines just inside the surface of the wire. Now the energy density vector $\vec{S}$ must be perpendicular to the lines of both $\vec{E}$ and $\vec{B}$ so it must be every where perpendicular to the wire's surface.

Using the right-hand rule for the vector product stated above, we can conclude that energy is flowing into the wire at every point on its curved surface.

To calculate the value of the power transfer, just multiply the value of the Poynting vector by the surface area. Since the electric and magnetic fields are right angles to each other, the magnitude of the energy flux density is just:

$$\vec{S} = \frac{1}{\mu}\vec{E}\times\vec{B} = \frac{1}{\mu}EB \tag{16.3.50}$$

The power input is the product of the power per area, S, and the curved exterior surface area of the cylinder of radius r and length d, A :

$$P = SA = \frac{1}{\mu}EB2\pi rd \tag{16.3.51}$$

Now we can find values for the fields in terms of the potential difference and current. The magnitude of the electric field is the potential difference between the ends of the segment of wire divided by the length of the wire:

$$E = \frac{U}{d} \tag{16.3.52}$$

and the magnetic field produced by the current at the surface of the wire is given by the well-known formula:

$$B = \frac{\mu I}{2\pi r} \tag{16.3.53}$$

Substituting these two expressions for the fields gives the familiar formula for the power dissipation:

$$P = UI \tag{16.3.54}$$

So the field model for energy transfer gives the right answer for energy dissipation in a resistive wire.

As an extension to the derivation above, we could look at what happens just outside the wire. Since the axial component of the electric field is the same just outside as it is inside and the magnetic field is practically the same, we can conclude that the energy flux derived above still works out as expected. But ... now there is also a radial component of the electric field as well. If that radial component is not zero then, together with the magnetic field, it contributes to a component of the Poynting vector that is parallel to the wire - but only outside the wire. That means that energy may also be travelling along beside the wire (and getting in somewhere else).

A similar mathematical argument can be used to find the rate at which energy is extracted from the battery by the electromagnetic field. Just model the battery as a cylindrical object and the whole argument is the same except for one thing: in the battery the current goes from low potential to high potential, against the electric field, so the direction in which the magnetic field loops around the battery is reversed. That's the only difference in the argument, but it reverses the direction of the Poynting vector at the surface. So energy comes out of the cylinder instead of going in. Conservation of energy rules!

The point is to reveal something that's most of time hidden by the way that we think about and teach electric circuits. We use voltage and current and lumped elements because they're more convenient than working with Maxwell equation. But we should never forget that the main actors are actually the fields. They are what carry the energy!

Hence as we have just seen Maxwell's equations combined with Poynting's theorem give us a model where electricity is energy carried along with the electromagnetic field (energy is stored in the field, not into kinetic energy of the electron in this model).

However we also know that the Drude model (see section Elektronkinetics page 4226) was created using kinetic gas theory and Boltzmann statistics. In this theory, electricity is carried by movement of "free electrons" that are accelerated by electric field and then "bounce" along the way. We are able to get "drift velocity":

$$v=\frac{qE}{m}\tau \tag{16.3.55}$$

of the electron this way and this velocity is quite small in the order of a meter per hour!

The theory combining the concepts of quantum mechanics and Fermi-Dirac statistics, resulting in Sommerfeld model that is still used in solid-state physics. Drift velocity is replaced with Fermi velocity (see section Elektronkinetics page 4305):

$$v_F=\sqrt{\frac{2E_{c,F}}{m_e}} \tag{16.3.56}$$

and electrons that have Fermi energy will take part in electric conductivity. With the quasi-particle model, semi conductors are explained pretty well and it's a very useful way to do it because even a single small grain of sand contains so many electrons that solving the exact Schrödinger partial differential equation would be practically impossible. Sometimes the real dynamics can be replaced by a quasi-particle model, which is based on the overall result of the interactions of a complex system. The Fermi velocity for copper is in the order of $1\cdot 10^6$ $[\text{m}\cdot\text{s}^{-1}]$.

Element	**Fermi Energy** [eV]	**Fermi Temperature** $\times 10^4$ [K]	**Fermi Velocity** $\times 10^6$ $[\text{m} \cdot \text{s}^{-1}]$

Table 16.9: **Fermi Energies, Fermi Temperatures, and Fermi Velocities (source: N. W. Ashcroft and N. D. Mermin)**

And we have a third speed, the group velocity speed given by (see section Electromagnetism page 4272):

$$v_g = \sqrt{\frac{8\omega}{\mu\sigma}} \tag{16.3.57}$$

For copper the latter is of order of six meters per second as we have calculated it in the section of Electromagnetism.

The three models for the speed above are useful, correct and consistent with each other! That's why its sometimes confusing for some people!

16.3.4.1 RC series circuit

Any circuit having a capacitor also have a resistance, if only that of the connection wires. Such RC (Resistance-Capacitor) series circuits are very common and sometimes of great importance (pacemaker for example). Indeed, when we close a circuit which contains only resistors (purely resistive circuit), the current rises to its nominal value in an extremely short time, so that we can consider that the current and the voltage are constant with an excellent approximation a short time after the circuit was closed (at least in common civil applications...). Thus, the permanent regime is established after a very brief transitional regime. On the contrary, in a series RC circuit, voltage and current take a long time to reach their nominal values. This dependence over time has multiple applications and allows to produce a whole range of signals that can be modulated over time as required.

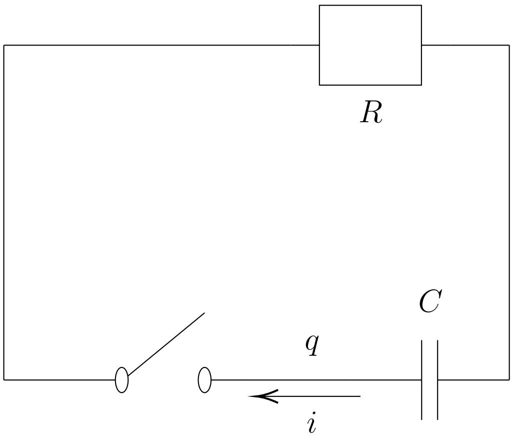

Figure 16.111: **RC serie circuit**

The study of such a circuit is also important in science as quite many mechanical (like damped oscillating mass) or economic systems (price dynamic to events) reacts like an RC circuit.

16.3.4.1.1 RC series step response

We assume that initially the capacitor is charged and that no current flows (open switch):

$$q(t=0)=q_0 \quad \text{and} \quad i(t=0)=0 \tag{16.3.58}$$

When we close the switch the electrons go away from the capacitor C. We then have at the terminals of the resistor:

$$u_R=R\cdot i=R\frac{\mathrm{d}q}{\mathrm{d}t} \tag{16.3.59}$$

At the terminals of the capacitor:

$$u_C=\frac{1}{C}q \tag{16.3.60}$$

The equation of the circuit is then:

$$R\frac{\mathrm{d}q}{\mathrm{d}t}+\frac{1}{C}q=0 \tag{16.3.61}$$

Therefore:

$$\frac{1}{q}\mathrm{d}q=-\frac{1}{RC}\mathrm{d}t \tag{16.3.62}$$

Trivial differential equation (but we can detail on readers request) whose solution is with the initial conditions:

$$\ln\left(\frac{Q}{Q_0}\right)=-\frac{t}{RC} \tag{16.3.63}$$

Therefore:

$$q=Q_0e^{-t/RC} \tag{16.3.64}$$

The current then has the following form:

$$i=-\frac{Q_0}{RC}e^{-t/RC} \tag{16.3.65}$$

It is therefore a system in which the current decreases exponentially and this even faster than the RC factor named the "time constant" is small. We see this kind of system when the light inside a car turns off slowly after closing the doors.

So in the end we have the two following two relations for the discharge:

$$\begin{aligned}i&=-\frac{Q_0}{RC}e^{-t/RC}\\ u_C&=\frac{Q_0}{C}e^{-t/RC}\end{aligned} \tag{16.3.66}$$

When this regime is placed under a constant voltage equation, then we have an equation of the form:

$$R\frac{\mathrm{d}q}{\mathrm{d}t}+\frac{1}{C}q=U_0 \tag{16.3.67}$$

An obvious special solution is then:

$$q=Q_0=CU_0 \tag{16.3.68}$$

We then have the general solution:

$$q=-Q_0e^{-t/RC}+CU_0 \tag{16.3.69}$$

either for the current:

$$i=\frac{\mathrm{d}q}{\mathrm{d}t}=\frac{Q_0}{RC}e^{-t/RC} \tag{16.3.70}$$

And for the voltage at the terminals of the capacitor:

$$u_C=\frac{1}{C}q=-\frac{Q_0}{C}e^{-t/RC}+U_0=-U_0e^{-t/RC}+U_0=U_0(1-e^{-t/RC}) \tag{16.3.71}$$

Which therefore represents the voltage at the terminals of the capacitor during charging. So in the end we have the two following two relations for the charge:

$$\begin{gathered} i=\frac{Q_0}{RC}e^{-t/RC} \\ u_C=U_0(1-e^{-t/RC}) \end{gathered} \tag{16.3.72}$$

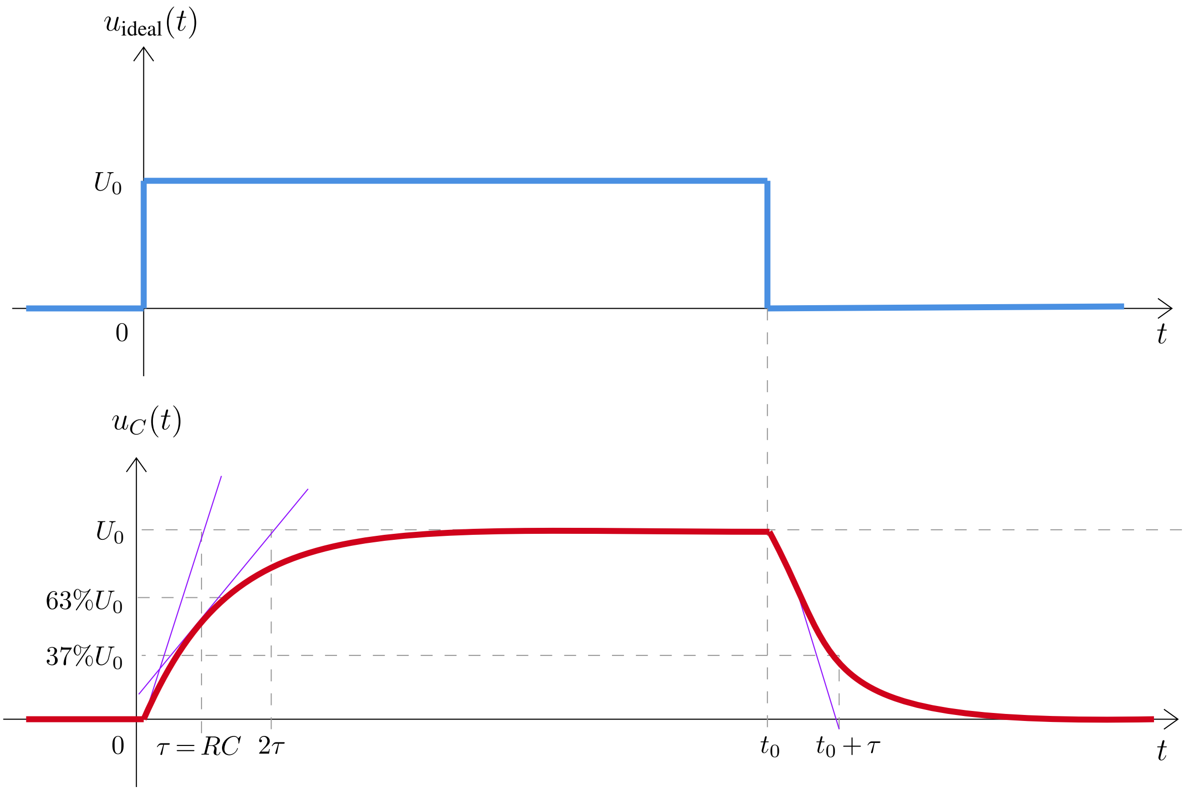

Figure 16.112: **Charging and discharging of the capacitor when opening / closing the switch**

Let us now study the energetic aspect of this circuit that is important in engineering, since power consumption or loss of power is a major selling factor in some applications!

For this purpose let us take up the relation:

$$R\frac{\mathrm{d}q}{\mathrm{d}t}+\frac{1}{C}q=R\frac{\mathrm{d}q}{\mathrm{d}t}+u_C=U_0 \tag{16.3.73}$$

And let us multiply by i:

$$Ri^2+u_Ci=U_0i \tag{16.3.74}$$

What we write:

$$p_R+p_C=p_G \tag{16.3.75}$$

As:

$$u_C=\frac{1}{C}q\Rightarrow\frac{\mathrm{d}u_C}{\mathrm{d}t}=\frac{1}{C}\frac{\mathrm{d}q}{\mathrm{d}t}=\frac{1}{C}i\Rightarrow i=C\frac{\mathrm{d}u_C}{\mathrm{d}t} \tag{16.3.76}$$

Where we see that as soon as the transient charge or discharge is completed, the voltage at the terminals of the capacitor being zero then the current is also zero.

We have then:

$$U_0 i = Ri^2 + u_0 C\frac{\mathrm{d}u_C}{\mathrm{d}t} = Ri^2 + \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{1}{2}Cu_C^2\right) \tag{16.3.77}$$

where the first term is the power supplied by the generator to the circuit, the second term is the Joule effect term and the third is the power stored in the capacitor.

The energy supplied by the generator is stored in the capacitor and dissipated by the resistance by Joule effect.

What is the most important is to make an energetic balance study over the whole duration of charge of the capacitor to indicate the power dissipated in the sales characteristics sheet (it is better for must buyer than putting equations in it...). To do this, it suffices to integrate the preceding relation from 0 to infinity to obtain the energy dissipated.

The first term to the left of the equality gives:

$$\begin{aligned}\int\limits_0^{+\infty} U_0 i\mathrm{d}t &= U_0\int\limits_0^{+\infty} i\mathrm{d}t = U_0\int\limits_0^{+\infty} C\frac{\mathrm{d}u_C}{\mathrm{d}t} = U_0 C\int\limits_0^{+\infty}\mathrm{d}u_C\\ &= U_0 C\left(u_0(+\infty) - u_0(0)\right) = U_0 C(U_0 - 0) = CU_0^2\end{aligned} \tag{16.3.78}$$

The second term is integrated using $i(t)$:

$$\begin{aligned}\int\limits_0^{+\infty} Ri^2\mathrm{d}t &= \int\limits_0^{+\infty} R\left(\frac{Q_0}{RC}e^{-t/RC}\right)^2\mathrm{d}t = \int\limits_0^{+\infty} R\left(\frac{1}{R^2}\left(\frac{Q_0}{C}\right)^2 e^{-2t/RC}\right)\mathrm{d}t = \frac{U_0^2}{R}\int\limits_0^{+\infty} e^{-2t/RC}\mathrm{d}t\\ &= \frac{U_0^2}{R}\left(-\frac{RC}{2}e^{-2t/RC}\right)\Bigg|_0^{+\infty} = -\frac{U_0^2 C}{2}(0-1) = \frac{1}{2}U_0^2 C\end{aligned} \tag{16.3.79}$$

The third term integrates immediately since we already have the primitive:

$$\int\limits_0^{+\infty}\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{1}{2}Cu_C^2\right)\mathrm{d}t = \int\limits_0^{+\infty}\mathrm{d}\left(\frac{1}{2}Cu_C^2\right) = \frac{1}{2}CU_0 \tag{16.3.80}$$

Finally, we get:

$$CU_0^2 = \frac{1}{2}U_0^2 C + \frac{1}{2}U_0^2 C \tag{16.3.81}$$

Thus, for long durations, half of the energy supplied by the generator is dissipated by the Joule effect and the other stored in the capacitor.

16.3.4.1.2 RC series linear response

Let us study now the answer of the circuit to a linear increase (or decrease by symmetry) of the RC series circuit.

In our circuit above, the loop equation remains:

$$u_S = u_R + u_C \tag{16.3.82}$$

where u_S is the dynamic voltage of the source.

Explicitly:

$$u_S = iR + \frac{1}{C}\int i \mathrm{d}t \tag{16.3.83}$$

Differentiating:

$$\frac{\mathrm{d}u_S}{\mathrm{d}t} = R\frac{\mathrm{d}i}{\mathrm{d}t} + \frac{i}{C} \tag{16.3.84}$$

Rearranging:

$$\frac{\mathrm{d}i}{\mathrm{d}t} + \frac{i}{RC} = \frac{1}{R}\frac{\mathrm{d}u_S}{\mathrm{d}t} \tag{16.3.85}$$

Noting that $\tau = RC$:

$$\frac{\mathrm{d}i}{\mathrm{d}t} + \frac{i}{\tau} = \frac{1}{R}\frac{\mathrm{d}u_S}{\mathrm{d}t} \tag{16.3.86}$$

In your special case, u_S is a ramp, thus: $u_S = Kt$, where K is the slope of the ramp. Hence:

$$\frac{\mathrm{d}u_S}{\mathrm{d}t} = K \tag{16.3.87}$$

and the equation to be solved by the integrating factor method (see section Differential and Integral Calculus page 1615) is:

$$\frac{\mathrm{d}i}{\mathrm{d}t} + \frac{i}{\tau} = \frac{K}{R} \tag{16.3.88}$$

The integrating factor is:

$$\mathrm{IF} = e^{\int \frac{1}{\tau}\mathrm{d}t} = e^{\frac{t}{\tau}} \tag{16.3.89}$$

Therefore:

$$ie^{\frac{t}{\tau}} = \int \frac{K}{R}e^{\frac{t}{\tau}}\mathrm{d}t + c^{te} \tag{16.3.90}$$

Hence:

$$ie^{\frac{t}{\tau}} = KCe^{\frac{t}{\tau}} + c^{te} \tag{16.3.91}$$

Rearranging:

$$i = KC + c^{te} e^{-\frac{t}{\tau}} \tag{16.3.92}$$

Assuming initial conditions are zero (linear increasing tension source from zero), $c^{te} = -KC$, hence:

$$i = KC\left(1 - e^{-\frac{t}{\tau}}\right) \tag{16.3.93}$$

As for a capacitor:

$$i = C\frac{\mathrm{d}u_C}{\mathrm{d}t} \Rightarrow u_C = \frac{1}{C}\int i\mathrm{d}t + c^{te} \tag{16.3.94}$$

Hence:

$$u_C = \frac{1}{C}\int KC\left(1 - e^{-\frac{t}{\tau}}\right)\mathrm{d}t + c^{te} = K\left(t + \tau e^{-\frac{t}{\tau}}\right) + c^{te} \tag{16.3.95}$$

The constant has to be determined by the initial conditions. In our case, as u_C is zero at $t = 0$ then:

$$u_C = K\left(t - \tau + \tau e^{-\frac{t}{\tau}}\right) \tag{16.3.96}$$

The same reasoning for a linear decrease of the voltage leads to:

$$u_C = K\left(t - \tau e^{-\frac{t}{\tau}}\right) \tag{16.3.97}$$

16.3.4.2 RL series circuit

Let us consider now the following circuit:

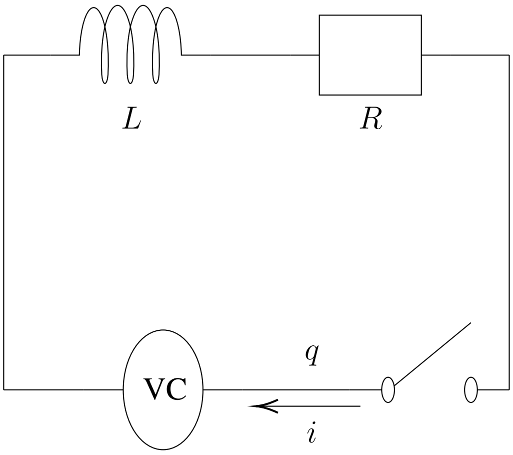

Figure 16.113: **RL circuit serie**

When we close the switch, we then have at the terminals of the resistor:

$$u_R = R \cdot i \tag{16.3.98}$$

and at the terminals of the inductance:

$$u_L = L\frac{\mathrm{d}i}{\mathrm{d}t} \tag{16.3.99}$$

and U_0 at the terminals of the DC voltage generator.

The equation of the circuit is then:

$$L\frac{\mathrm{d}i}{\mathrm{d}t} + Ri = U_0 \tag{16.3.100}$$

Therefore:

$$\frac{L}{\mathrm{d}t} = \frac{U_0 - Ri}{\mathrm{d}i} \tag{16.3.101}$$

By reversing:

$$\frac{1}{L}\mathrm{d}t = \frac{1}{U_0 - Ri}\mathrm{d}i \tag{16.3.102}$$

Let us do a change of variable:

$$U_0 - Ri = x \Rightarrow \frac{\mathrm{d}x}{\mathrm{d}i} = -R \tag{16.3.103}$$

Then:

$$\int\limits_0^t \frac{1}{L}\mathrm{d}t = \frac{1}{R}\int\limits_{U_0}^{U_0-RI} \frac{1}{x}\mathrm{d}x \tag{16.3.104}$$

It then comes after integration:

$$\frac{1}{L}t = -\frac{1}{R}\ln(x)\Big|_{U_0}^{U_0-RI} = -\frac{1}{R}\left[\ln(U_0 - Ri) - \ln(U_0)\right] = -\frac{1}{R}\ln\left(\frac{U_0 - Ri}{U_0}\right) \tag{16.3.105}$$

Let us multiply the two members by $-R$, then let us take the exponential of the two members:

$$-\frac{R}{L}t = \ln\left(\frac{U_0 - Ri}{U_0}\right) \tag{16.3.106}$$

and:

$$\frac{U_0 - Ri}{U_0} = e^{-\frac{R}{L}t} \tag{16.3.107}$$

Then:

$$i = \frac{U_0}{R}\left(1 - e^{-\frac{R}{L}t}\right) = \frac{U_0}{R}\left(1 - e^{-t/\tau}\right) \tag{16.3.108}$$

Where we have the time constant defined by:

$$\tau = \frac{L}{R} \tag{16.3.109}$$

Thus, when the switch is closed, the current increases exponentially with an asymptote at the value U_0/R. Thus, unlike the RC circuit, the current tends to a non-zero fixed value when t tends to infinity!

We therefore have:

$$u_L(t)=L\frac{\mathrm{d}}{\mathrm{d}t}\frac{U_0}{R}\left(1-e^{t/\tau}\right)=\frac{LU_0}{R}\frac{\mathrm{d}}{\mathrm{d}t}\left(1-e^{t/\tau}\right)=\frac{LU_0}{R}\frac{\mathrm{d}}{\mathrm{d}t}\left(-e^{-\frac{R}{L}t}\right)=U_0e^{-\frac{R}{L}t} \tag{16.3.110}$$

So in the end we have the two relations:

$$\boxed{\begin{aligned}&i=\frac{U_0}{R}\left(1-e^{-t/\tau}\right)\\&u_L=U_0e^{-\frac{R}{L}t}\end{aligned}} \tag{16.3.111}$$

Let us now study the energy aspect that is important in engineering, since power consumption or loss of power is a major selling factor in some applications! As for the RC circuit, we will directly make a energetic balance study of the entire duration of the transient regime to signal the power dissipated in the sales characteristics (it passes better than to put equations in it...):

$$L\frac{\mathrm{d}i}{\mathrm{d}t}+Ri=U_0 \tag{16.3.112}$$

Let us multiply the terms of the differential equation by $i(t)$:

$$L\frac{\mathrm{d}i}{\mathrm{d}t}i+Ri^2=\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\left(Li^2\right)+Ri^2=U_0i \tag{16.3.113}$$

What we will write:

$$p_L(t)+p_R(t)=p_G(t) \tag{16.3.114}$$

To calculate the dissipated energy, we proceed in the same way as for the series RC circuit. We have after integration:

$$\frac{1}{2}L\left(i^2(+\infty)-i^2(0)\right)+\int_0^{+\infty}Ri^2\mathrm{d}t=\int_0^{+\infty}U_0i\mathrm{d}t \tag{16.3.115}$$

Therefore:

$$\begin{aligned}&\frac{1}{2}Li^2+R\int_0^{+\infty}\left(\frac{U_0}{R}\left(1-e^{-t/\tau}\right)\right)^2\mathrm{d}t=U_0\int_0^{+\infty}\left(\frac{U_0}{R}\left(1-e^{-t/\tau}\right)\right)\mathrm{d}t\\&\frac{1}{2}Li^2+\frac{U_0^2}{R}\int_0^{+\infty}\left(1-e^{-\frac{R}{L}t}\right)^2\mathrm{d}t=\frac{U_0^2}{R}\int_0^{+\infty}\left(1-e^{-\frac{R}{L}t}\right)\mathrm{d}t\end{aligned} \tag{16.3.116}$$

Unlike the case of the RC circuit, we can not integrate above with the given terminals because of the "$1-$" which is in front of the exponential because it causes the consumed power to reach the infinite, which is logical, unlike the RC circuit which ends up blocking itself after the capacitor has been charged (the current i tending towards zero very quickly).

Thus, we only integrate up to a sufficiently large limit time with respect to the values of the passive elements (two or three τ), or we are interested purely in terms of the instantaneous value of the power. We have then:

$$\begin{aligned}
p_G(t) &= U_0\cdot i = U_0\cdot\frac{U_0}{R}\left(1-e^{-t/\tau}\right)=\frac{U_0^2}{R}\left(1-e^{-t/\tau}\right)\\
p_R(t) &= R\cdot i^2 = R\cdot\frac{U_0^2}{R^2}\left(1-e^{-t/\tau}\right)^2=\frac{U_0^2}{R}\left(1-e^{-t/\tau}\right)^2\\
p_L(t) &= u_L(t)\cdot i = U_0 e^{-\frac{R}{L}t}\frac{U_0}{R}\left(1-e^{-t/\tau}\right)=\frac{U_0^2}{R}e^{-t/\tau}\left(1-e^{-t/\tau}\right)
\end{aligned} \tag{16.3.117}$$

And therefore at the end of the transitional regime when $t\rightarrow+\infty$:

$$\begin{aligned}
p_G(t) &= \frac{U_0^2}{R}\\
p_R(t) &= \frac{U_0^2}{R}\\
p_L(t) &= 0
\end{aligned} \tag{16.3.118}$$

Therefore, in a steady state, the resistance is the only energy dissipative element in the circuit and it is sufficient to multiply the power dissipated by the desired time interval in order to have an estimate of the energy dissipated.

16.3.4.3 Source-Free serial RLC circuit

An electrical wire (an antenna for example) is not a perfect conductor. In reality it can be assimilated to a resistance, a capacitance and an internal inductance in series. If we take the case, for example, of the generators, we often consider only the internal resistance as non-negligible, and this obviously reduces the nominal voltage of the generator by a factor to a first approximation proportional to the current flowing through it.

To study the behaviour of such an element often named "RLC circuit", we first represent it in the following form:

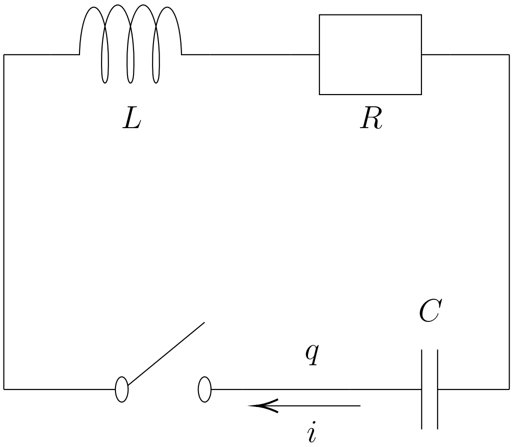

Figure 16.114: **RLC serie circuit**

We assume that initially the capacitor is charged and that no current flows (open switch):

$$q(t=0)=q_0 \quad \text{and} \quad i(t=0)=0 \tag{16.3.119}$$

When we close the switch the electrons go away from the capacitor C. We then have at the terminals of the resistor:

$$u_R=Ri=R\frac{\mathrm{d}q}{\mathrm{d}t} \tag{16.3.120}$$

and at the terminals of the condensator:

$$u_C=\frac{1}{C}q \tag{16.3.121}$$

and at the terminal of the inductance:

$$u_L=L\frac{\mathrm{d}i}{\mathrm{d}t}=L\frac{\mathrm{d}^2q}{\mathrm{d}t} \tag{16.3.122}$$

The sum of the potential differences of the circuit is equal to the initial difference of potential, hence:

$$L\frac{\mathrm{d}^2q}{\mathrm{d}t}+R\frac{\mathrm{d}q}{\mathrm{d}t}+\frac{1}{C}q=0 \tag{16.3.123}$$

Or written differently:

$$\boxed{LC\frac{\mathrm{d}^2q}{\mathrm{d}t}+RC\frac{\mathrm{d}q}{\mathrm{d}t}+q=0} \tag{16.3.124}$$

It is a second-order linear differential equation very well known in physics (we find it identically in other domains with just different constants). To solve it, we must look for the roots of the associated characteristic equation (see section Differential and Integral Calculus page 1608):

$$LCx^2+RCx+1=0 \tag{16.3.125}$$

The latter has for discriminant:

$$\Delta=R^2C^2-4LC \tag{16.3.126}$$

The resistance value for which this discriminant is zero is named the "critical resistance":

$$R_C=2\sqrt{\frac{L}{C}} \tag{16.3.127}$$

We can also write the discriminant in the following form:

$$\Delta=C^2\left(R^2-4\frac{L}{C}\right)=C^2\left(R^2-R_C^2\right) \tag{16.3.128}$$

The solutions of the differential equation are different according to the number and type of the roots of the characteristic equation.

16.3.4.3.1 Critically damped response ($R^4=4L/C$)

This is the case where $R=R_C$. The characteristic equation then admits a real double root since:

$$\Delta=C^2\left(R^2-4\frac{L}{C}\right)=C^2\left(R^2-R_C^2\right)=0 \tag{16.3.129}$$

We then have (so the roots are negative, real and equal as stated just earlier):

$$x_{1,2}=\frac{-RC\pm\sqrt{\Delta}}{2LC}=\frac{-R_C}{2L}=-\frac{1}{\sqrt{LC}}=-\frac{1}{\tau}=K \tag{16.3.130}$$

with:

$$\tau=\sqrt{LC} \tag{16.3.131}$$

The differential equation then admits a solution of the following type when the discriminant is zero (see section Differential and Integral Calculus page 1609):

$$q=(C_1t+C_2)\,e^{-\frac{t}{\sqrt{LC}}} \tag{16.3.132}$$

by omitting the delay.

Which gives for the intensity:

$$i=\frac{\mathrm{d}q}{\mathrm{d}t}=\left(C_1-C_1\frac{t}{\sqrt{LC}}-\frac{C_2}{\sqrt{LC}}\right)e^{-\frac{t}{\sqrt{LC}}} \tag{16.3.133}$$

The constants are defined by the initial conditions:

$$\begin{cases} q(t=0)=C_2=q_0 \\ i(t=0)=\left(C_1-\dfrac{C_2}{\sqrt{LC}}\right)=0\Rightarrow C_1=\dfrac{C_2}{\sqrt{LC}}=\dfrac{q_0}{\sqrt{LC}} \end{cases} \tag{16.3.134}$$

We thus obtain for the global solution:

$$q=q_0\left(1+\frac{t}{\tau}\right)e^{-t/\tau} \tag{16.3.135}$$

So in the end, we have the relations:

$$\boxed{\begin{aligned} q&=q_0\left(1+\frac{t}{\tau}\right)e^{-t/\tau} \\ i&=\frac{\mathrm{d}q}{\mathrm{d}t}=-\frac{q_0t}{\tau^2}e^{-t/\tau} \\ u_C&=\frac{q}{C}=\frac{q_0}{C}\left(1+\frac{t}{\tau}\right)e^{-t/\tau} \\ u_L&=L\frac{\mathrm{d}i}{\mathrm{d}t}=q_0L\left(\frac{t}{\tau^3}-\frac{1}{\tau^2}\right)e^{-t/\tau} \end{aligned}} \tag{16.3.136}$$

The following figures illustrate the trend of the time evolution of the discharge of the capacitor and of the current through the inductance. The intensity is maximum for $t=\tau$ in the inductance (we highlighted in red the current plot because it's the most commonly showed in textbooks):

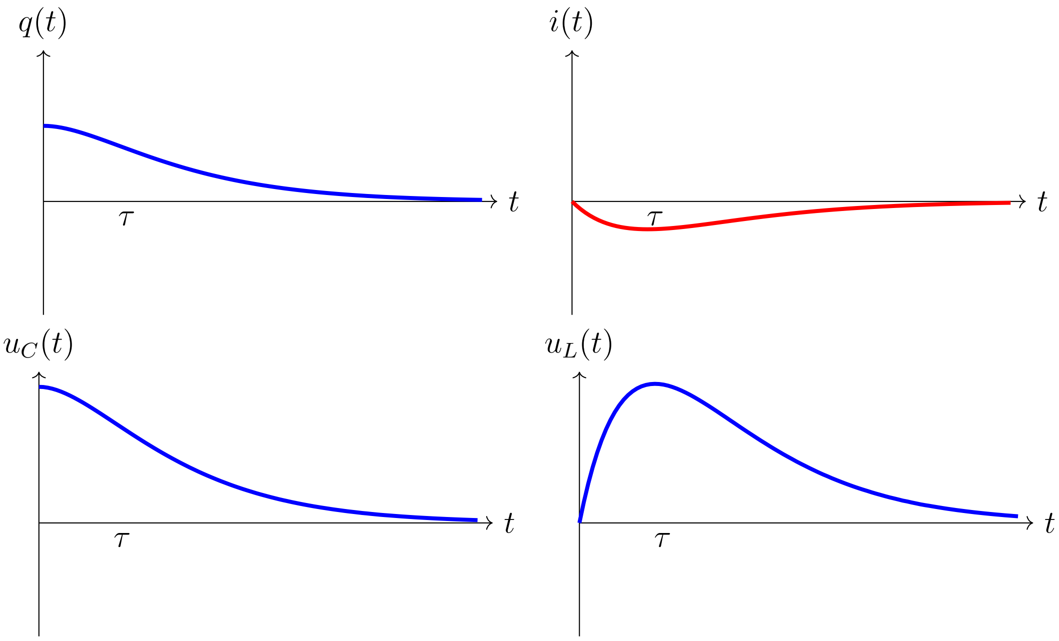

Figure 16.115: Behaviour of the charge, current and voltage in the circuit during the discharge of the capacitor in a critically damped serial RLC circuit

16.3.4.3.2 Overdamped (hypercritic) response ($R^2>4L/C$)

This is the case where $R>R_C$. The characteristic equation then admits two distinct real roots:

$$\Delta=C^2\left(R^2-4\frac{L}{C}\right)>0 \tag{16.3.137}$$

Therefore:

$$\begin{aligned}K_{1,2}&=\frac{-RC\pm\sqrt{C^2\left(R^2-4\frac{L}{C}\right)}}{2LC}=\frac{-RC\pm C\sqrt{R^2-4\frac{L}{C}}}{2LC}=\frac{-R\pm\sqrt{R^2-4\frac{L}{C}}}{2L}\\&=\frac{-R\pm\sqrt{R^2-R_C^2}}{2L}\end{aligned} \tag{16.3.138}$$

The two roots are of the same sign, because by using the Vieta relations (see section Calculus page 1383) we have:

$$K_1K_2=\frac{1}{LC}>0 \tag{16.3.139}$$

The two roots are therefore necessarily negative (real, distinct and negative)! We denote their absolute values:

$$|K_{1,2}|=\frac{R\pm\sqrt{(R^2-R_C^2)}}{2L} \tag{16.3.140}$$

that therefore satisfy:

$$K_1K_2 = \frac{1}{LC} = \frac{1}{\tau^2} \tag{16.3.141}$$

We have seen in the section of Differential and Integral Calculus (page 1609) that at this moment the solution (without phase shift) is of the form:

$$q = Ae^{K_1t} + Be^{K_2t} \tag{16.3.142}$$

Which gives for intensity:

$$i = AK_1e^{K_1t} + BK_2e^{K_2t} \tag{16.3.143}$$

The constants A and B are defined by the initial conditions:

$$\begin{cases} q(t=0) = A + B = q_0 \\ i(t=0) = K_1A + K_2B = 0 \end{cases} \tag{16.3.144}$$

Which gives us:

$$\begin{gathered} A - \frac{K_1}{K_2}A = q_0 \Rightarrow A\left(1 - \frac{K_1}{K_2}\right) = q_0 \Rightarrow A = \frac{K_2q_0}{K_2 - K_1} \\ -\frac{K_2}{K_1}B + B = q_0 \Rightarrow B\left(1 - \frac{K_2}{K_1}\right) = q_0 \Rightarrow B = \frac{K_1q_0}{K_1 - K_2} \end{gathered} \tag{16.3.145}$$

Either in conventional form:

$$A = -\frac{K_2q_0}{K_1 - K_2} \qquad B = \frac{K_1q_0}{K_1 - K_2} \tag{16.3.146}$$

Therefore:

$$q = \frac{q_0}{K_1 - K_2}\left(K_1e^{K_2t} - K_2e^{K_1t}\right) \tag{16.3.147}$$

Hence the set of relations:

$$\boxed{\begin{aligned} q &= \frac{q_0}{K_1 - K_2}\left(K_1e^{K_2t} - K_2e^{K_1t}\right) \\ i &= \frac{\mathrm{d}q}{\mathrm{d}t} = \frac{K_1K_2q_0}{K_1 - K_2}\left(e^{K_2t} - e^{K_1t}\right) \\ u_C &= \frac{q}{C} = \frac{q_0}{C(K_1 - K_2)}\left(K_1e^{K_2t} - K_2e^{K_1t}\right) \\ u_L &= L\frac{\mathrm{d}i}{\mathrm{d}t} = \frac{LK_1K_2q_0}{(K_1 - K_2)}\left(K_2e^{K_2t} - K_1e^{K_1t}\right) \end{aligned}} \tag{16.3.148}$$

The following figures (we highlighted in red the current plot because it's the most commonly showed in textbooks) illustrate the temporal evolution of these functions (remember that the roots are negative!):

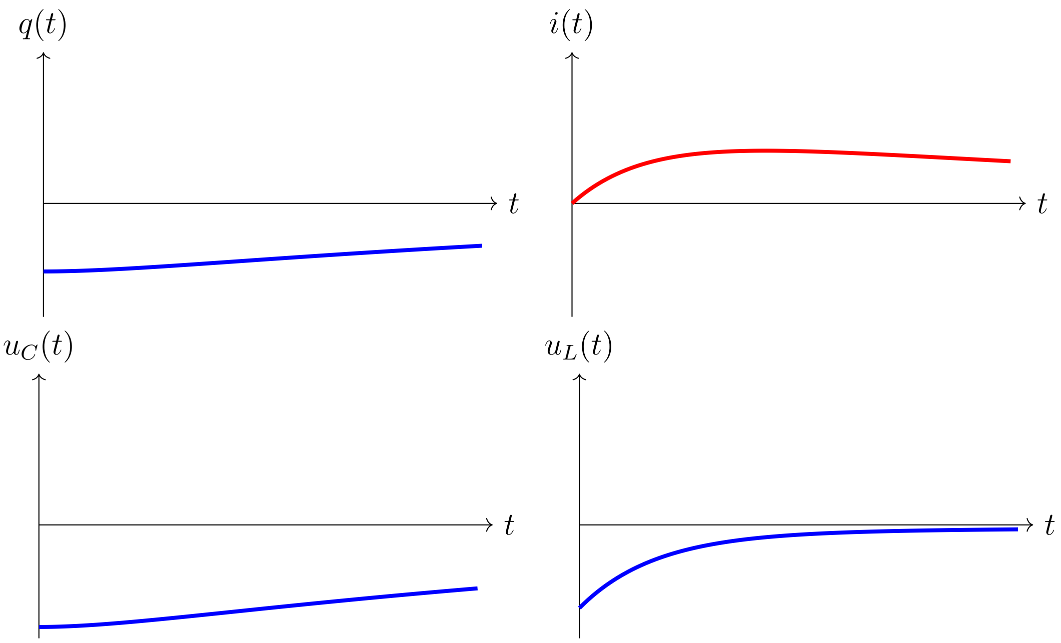

Figure 16.116: **Behaviour of the charge, current and voltage in the circuit during the discharge of the capacitor in a overdamped serial RLC circuit**

16.3.4.3.3 Underdamped (decaying oscillation) response ($R^2 < 4L/C$)

This is the case where $R < R_C$. The characteristic equation then admits two conjugate complex roots:

$$K_{1,2}=\frac{-R\pm\sqrt{R^2-R_C^2}}{2L}=\frac{-R\pm\sqrt{-\left(R_C^2-R^2\right)}}{2L}=\frac{-R\pm\sqrt{\mathrm{i}^2\left(R_C^2-R^2\right)}}{2L}=\frac{-R\pm\mathrm{i}\sqrt{R_C^2-R^2}}{2L} \tag{16.3.149}$$

Which are assimilated to the resistance of the circuit. We name it "complex impedance".

We will see that contrary to the intuition of that time they were invented (as often in pure mathematics) complex roots have a real physical meaning.

Let us denote for this α and ω the absolute values of the real and imaginary parts of these roots:

$$K_{1,2}=-\alpha\pm\mathrm{i}\omega \tag{16.3.150}$$

with:

$$\alpha=K_{1,2}=\frac{R}{2L} \tag{16.3.151}$$

and:

$$\omega=\frac{\sqrt{R_C^2-R^2}}{2L}=\sqrt{\frac{R_C^2}{4L}-\frac{R^2}{4L}}=\sqrt{\frac{1}{LC}-\alpha^2}=\sqrt{\frac{1}{\tau^2}-\alpha^2} \tag{16.3.152}$$

We have seen in the section of Differential and Integral Calculus that the solution of the differential equation is then written (see page 1610):

$$q=Ae^{K_1t}+Be^{K_2t}=e^{\alpha x}\left(A'\cos(\omega t)+B'\cos(\omega t)\right)=C'e^{-\alpha t}\cos(\omega t-\phi) \tag{16.3.153}$$

What gives us for the intensity:

$$\begin{aligned}i&=\frac{\mathrm{d}}{\mathrm{d}t}C'e^{-\alpha t}\cos(\omega t-\phi)=-\alpha C'e^{-\alpha t}\cos(\omega t-\phi)-C'e^{-\alpha t}\sin(\omega t-\phi)\\&=-C'e^{-\alpha t}\left[\alpha\cos(\omega t-\phi)+\omega\sin(\omega t-\phi)\right]\end{aligned}\tag{16.3.154}$$

The constants C' and ϕ are determined by the initial conditions:

$$\begin{aligned}q(t=0)&=C'\cos(\phi)=q_0\\i(t=0)&=-C'\left[\alpha\cos(-\phi)+\omega\sin(-\phi)\right]=0\end{aligned}\tag{16.3.155}$$

Which gives us:

$$C'=\frac{q_0}{\cos(\phi)}\qquad\text{and}\qquad\tan(-\phi)=\frac{\alpha}{\omega}\tag{16.3.156}$$

Therefore:

$$C'=\frac{q_0}{\cos(\phi)}\qquad\text{and}\qquad\tan(\phi)=\frac{\sin(\phi)}{\cos(\phi)}=-\frac{\alpha}{\omega}\tag{16.3.157}$$

Thus by reporting in the expressions of the charge q and of the current i:

$$q=\frac{q_0}{\cos(\phi)}e^{-\alpha t}\cos(\omega t-\phi)\tag{16.3.158}$$

and:

$$\begin{aligned}i&=-\frac{q_0}{\cos(\phi)}e^{-\alpha t}\left[\alpha\cos(\omega t-\phi)+\omega\sin(\omega t-\phi)\right]\\&=-\frac{q_0}{\cos(\phi)}e^{-\alpha t}\sqrt{\alpha^2+\omega^2}\left[\frac{\alpha}{\sqrt{\alpha^2+\omega^2}}\cos(\omega t-\phi)+\frac{\omega}{\sqrt{\alpha^2+\omega^2}}\sin(\omega t-\phi)\right]\end{aligned}\tag{16.3.159}$$

Let us try to simplify this last equality a little. First we have proved just before:

$$\alpha^2=\omega^2\tan^2(\phi)\tag{16.3.160}$$

Therefore:

$$\begin{aligned}\sqrt{\alpha^2+\omega^2}&=\sqrt{\omega^2\tan^2(\phi)+\omega^2}=\omega\sqrt{\tan^2(\phi)+1}=\omega\sqrt{\frac{\sin^2(\phi)}{\cos^2(\phi)}+1}\\&=\frac{\omega}{\cos\phi}\sqrt{\sin^2(\phi)+\cos^2(\phi)}=\frac{\omega}{\cos(\phi)}\end{aligned}\tag{16.3.161}$$

Which gives:

$$\begin{aligned}i&=-\frac{q_0}{\cos(\phi)}e^{-\alpha t}\left[\alpha\cos(\omega t-\phi)+\omega\sin(\omega t-\phi)\right]\\&=-\frac{\omega q_0}{\cos^2(\phi)}e^{-\alpha t}\left[\frac{\alpha}{\sqrt{\alpha^2+\omega^2}}\cos(\omega t-\phi)+\frac{\omega}{\sqrt{\alpha^2+\omega^2}}\sin(\omega t-\phi)\right]\end{aligned}\tag{16.3.162}$$

But, we also have:

$$\omega\frac{1}{\sqrt{\alpha^2+\omega^2}}=\omega\frac{\cos(\phi)}{\omega}=\cos(\phi)\tag{16.3.163}$$

and:

$$\alpha\frac{1}{\sqrt{\alpha^2+\omega^2}}=\alpha\frac{\cos(\phi)}{\omega}=\cos(\phi)\frac{\alpha}{\omega}=-\cos(\phi)\frac{\sin(\phi)}{\cos(\phi)}=-\sin(\phi) \tag{16.3.164}$$

We then have:

$$\begin{aligned}i&=-\frac{\omega q_0}{\cos^2(\phi)}e^{-\alpha t}\left[-\sin(\phi)\cos(\omega t-\phi)+\cos(\phi)\sin(\omega t-\phi)\right]\\&=\frac{\omega q_0}{\cos^2(\phi)}e^{-\alpha t}\left[\sin(\phi)\cos(\omega t-\phi)-\cos(\phi)\sin(\omega t-\phi)\right]\\&=\frac{\omega q_0}{\cos^2(\phi)}e^{-\alpha t}\sin(-\omega t)=-\frac{\omega q_0}{\cos^2(\phi)}e^{-\alpha t}\sin(\omega t)\end{aligned} \tag{16.3.165}$$

We have in the end the following set of relations:

$$\boxed{\begin{aligned}q&=\frac{q_0}{\cos(\phi)}e^{-\frac{R}{2L}t}\cos(\omega t-\phi)\\i&=\frac{\mathrm{d}q}{\mathrm{d}t}=-\frac{\omega q_0}{\cos^2(\phi)}e^{-\frac{R}{2L}t}\sin(\omega t)\\u_C&=\frac{q}{C}=\frac{q_0}{C\cos(\phi)}e^{-\frac{R}{2L}t}\cos(\omega t-\phi)\\u_L&=L\frac{\mathrm{d}i}{\mathrm{d}t}=-\frac{1}{2}\frac{\omega q_0e^{\left(-\frac{R}{2L}t\right)}(-R\sin(\omega t)+2\omega\cos(\omega t)L)}{\cos(\phi)^2L}\end{aligned}} \tag{16.3.166}$$

So a plot of the current i in the inductance and q of the capacitance will give:

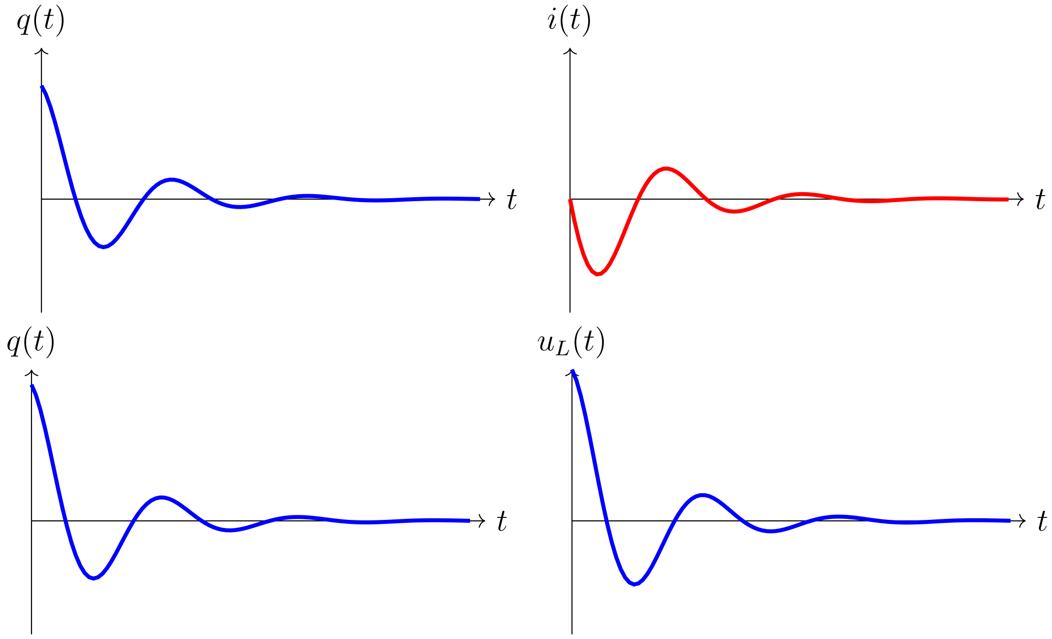

Figure 16.117: Behaviour of the charge, current and voltage in the circuit during the discharge of the capacitor in a underdamped serial RLC circuit

where:

$$\alpha=\frac{R}{2L} \tag{16.3.167}$$

is the "amortization factor" (some engineers defined instead $\gamma = R/L$ as the "damping factor"). If we wish to have beautiful oscillations smoothly and slowly damped, it is advantageous to have this term as small as possible and therefore have a small value of R.

When R is zero we then have:

$$i(t) = -\omega q_0 \sin(\omega t) \tag{16.3.168}$$

with therefore:

$$\omega = \frac{\sqrt{R_C^2 - R^2}}{2L} = \frac{R_C}{2L} = \frac{2\sqrt{\dfrac{L}{C}}}{2L} = \sqrt{\frac{1}{LC}} = \frac{1}{\sqrt{LC}} \tag{16.3.169}$$

which we name the "resonance pulsation" or "natural frequency". Either a period of:

$$T = \frac{2\pi}{\omega} = \frac{2\pi}{\sqrt{\dfrac{1}{LC}}} = 2\pi\sqrt{LC} \tag{16.3.170}$$

It is then necessary to play with C or L to obtain the desired period in the case where the resistance is zero. Note also that this particular situation is named a "harmonic oscillator".

Finally, from the results obtained, we thus have the generalization of the RC, RL or LC series circuits without source.

Now, suppose that in the circuit we were placing a continuous supply in series in the circuit. We have then:

$$L\frac{\mathrm{d}^2 q}{\mathrm{d}t^2} + R\frac{\mathrm{d}q}{\mathrm{d}t} + \frac{1}{C}q = U_0 \tag{16.3.171}$$

The linear differential equation with constant coefficients now has a second member (constant in this case). We then immediately find a special solution which it is then sufficient to add to all the solutions which we have obtained previously.

A special solution is therefore:

$$q = c^{te} \tag{16.3.172}$$

Hence:

$$L\frac{\mathrm{d}^2 q}{\mathrm{d}t^2} + R\frac{\mathrm{d}q}{\mathrm{d}t} + \frac{1}{C}q = L\cdot 0 + R\cdot 0 + \frac{1}{C}q = \frac{1}{C}q = U_0 \tag{16.3.173}$$

Therefore:

$$q = \frac{U_0}{C} \tag{16.3.174}$$

This special solution, which is to be added to the preceding solutions, has no influence on the equations of the current (its derivative being zero). On the other hand, it shifts the plot of $q(t)$ upwards. This is the effect of adding a constant voltage source (such as a simple battery).

So for summary to compare the three configurations (for the current only because its the most common plot in other textbooks):

$$\begin{aligned} i_c &= \frac{\mathrm{d}q}{\mathrm{d}t} = -\frac{q_0 t}{\tau^2} e^{-t/\tau} \\ i_o &= \frac{\mathrm{d}q}{\mathrm{d}t} = \frac{K_1 K_2 q_0}{K_1 - K_2} \left(e^{K_2 t} - e^{K_1 t}\right) \\ i_u &= \frac{\mathrm{d}q}{\mathrm{d}t} = -\frac{\omega q_0}{\cos^2(\phi)} e^{-\frac{R}{2L}t} \sin(\omega t) \end{aligned} \tag{16.3.175}$$

where again i_u, i_o, and i_c refer to underdamped, overdamped, and critically-damped cases (in many textbooks the reader can find variations of the graph below because some authors take different values of R, C, L and some even take the absolute value of i_c, i_o for pedagogical reasons).

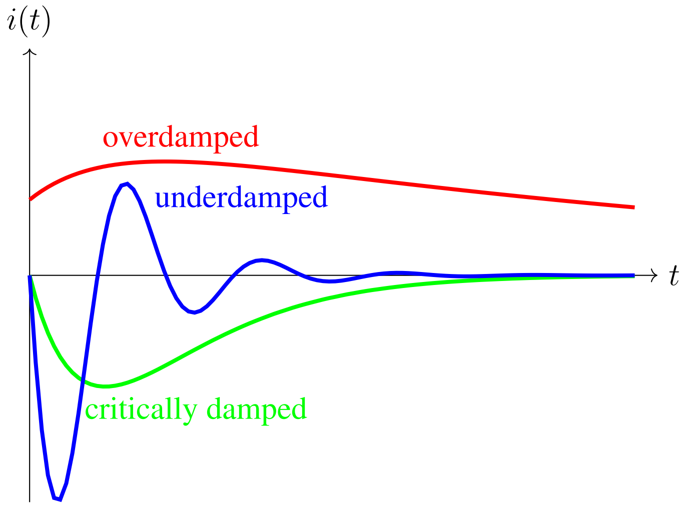

Figure 16.118: **Serial RLC without source typical modes of current**

Using the following definitions:

$$\begin{aligned} \omega_0 &= \frac{1}{\sqrt{LC}}, \qquad \gamma = \frac{R}{L} \\ \omega_1 &= \sqrt{\omega_0^2 - \gamma^2/4}, \qquad \alpha = \sqrt{\gamma^2/4 - \omega_0^2} \end{aligned} \tag{16.3.176}$$

and the physicist trick (variable change) seen in the section of Differential and Integral Calculus (page 1609), the three above relations can be found in some textbooks as following:

$$i = \begin{cases} i_u = -q_0 e^{-\gamma t/2} \left(\frac{\gamma^2 + 4\omega_1^2}{4\omega_1}\right) \sin\left(\omega_1 t\right), & \omega_0 > \gamma/2 \\ i_o = -\alpha q_0 \left(1 - \frac{\gamma^2}{4\alpha^2}\right) e^{-\gamma t/2} \sinh(\alpha t) & \omega_0 < \gamma/2 \\ i_c = -\frac{\gamma^2}{4} q_0 t e^{-\gamma t/2} & \omega_0 = \gamma/2 \end{cases} \tag{16.3.177}$$

Remark

It seems that the first practical use for RLC circuits was in the 11890s (holocene calendar) in spark-gap radio transmitters to allow the receiver to be tuned to the transmitter.

There are many other case of the RLC circuit that are studied in by electrical engineers during their curriculum like:

- Source-free serial RLC (see above)
- Source-free parallel RLC
- Alternate source serial RLC
- Alternate source parallel RLC
- Step response serial RLC
- Step response parallel RLC
- ...

The RLC is an important subject especially because of it's mechanical analogue that is a particle in simple harmonic motion as illustrated below:

Table 16.10: **Mechanical analogue of RLC circuit**

16.3.4.4 Telegrapher's Equations

These "Telegrapher's equations" are a pair of coupled, linear partial differential equations that describes an electrical signal travelling along a transmission cable. First derived in the horse and buggy days of the telegraph (hence the name), it is still useful for describing long distance power lines and cable TV systems.

The model demonstrates that the electromagnetic waves can be reflected on the wire, and that wave patterns can form along the line.

The above model did not include any internal resistance of the wires comprising the transmission lines, nor did it include the leakage of current out of the wire to the outside environment (collectively named "ground"). Leakage occurs due to a combination of factors: conductance G through the wire's insulation and capacitive coupling C between wire and ground. We want the conductance (which is measured in units that are the inverse of resistance) between the wire and the ground as low as possible – and we want this coupling C to be fairly small as well.

The telegrapher's equations, like all other equations describing electrical phenomena, result from Maxwell's equations. In a more practical approach, one assumes that the conductors are composed of an infinite series of two-port elementary components, each representing an infinitesimally short segment of the transmission line:

- The distributed resistance R of the conductors is represented by a series resistor (expressed in ohms per unit length). In practical conductors, at higher frequencies, R increases approximately proportional to the square root of frequency due to skin effect.
- The distributed inductance L (due to the magnetic field around the wires, self-inductance, etc.) is represented by a series inductor (henries per unit length).
- The capacitance C between the two conductors is represented by a shunt capacitor C (farads per unit length).
- The conductance G of the dielectric material separating the two conductors is represented

by a shunt resistor between the signal wire and the return wire (siemens per unit length). This resistor in the model has a resistance of $1/G$ ohms. G accounts for both bulk conductivity of the dielectric and dielectric loss. If the dielectric is an ideal vacuum, then $G=0$.

Notice that the traditional notation in the context of the Telegrapher equation may be misleading. Indeed, instead of writing R, L, C and G as in the figure below, we should instead write ρ_R, ρ_L, ρ_C and ρ_G.

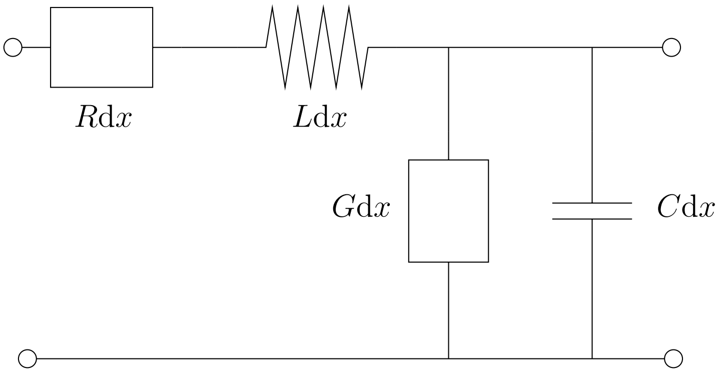

Figure 16.120: **Telegrapher scheme**

Consider a piece of wire being modelled as an electrical circuit element (see Figure above) consisting of an infinitesimal piece of (telegraph) wire of resistance $R\mathrm{d}x$ and inductance $L\mathrm{d}x$, while it is connected to a ground with conductance $(G\mathrm{d}x)^{-1}$ and capacitance $C\mathrm{d}x$.

Let $i(x,t)$ and $u(x,t)$ denote the current and voltage across the piece of wire at position x at time t.

The change in voltage across the piece of wire is given by:

$$u(x+\mathrm{d}x,t)-u(x,t)=-i(x,t)R\mathrm{d}x-\frac{\partial i}{\partial t}(x,t)L\mathrm{d}x \tag{16.3.178}$$

and the amount of current that disappears via the ground is:

$$i(x+\mathrm{d}x,t)-i(x,t)=-i(x,t)G\mathrm{d}x-\frac{\partial v}{\partial t}(x,t)C\mathrm{d}x \tag{16.3.179}$$

Dividing by $\mathrm{d}x$ gives the pair of coupled linear partial differential equations we were speaking about at the beginning:

$$\begin{aligned}\frac{\partial u}{\partial x}&=-Ri-L\frac{\partial i}{\partial t}\\ \frac{\partial i}{\partial x}&=-Gu-C\frac{\partial v}{\partial t}\end{aligned} \tag{16.3.180}$$

To combine these two relations, let us derivate partially once again each of them as following:

$$\begin{aligned}\frac{\partial^2 u}{\partial x^2}&=-R\frac{\partial i}{\partial x}-L\frac{\partial^2 i}{\partial x\partial t}\\ \frac{\partial^2 i}{\partial x\partial t}&=-G\frac{\partial v}{\partial t}-C\frac{\partial^2 v}{\partial t^2}\end{aligned} \tag{16.3.181}$$

If the term $\frac{\partial^2 i}{\partial x \partial t}$ is now substituted, we get:

$$\frac{\partial^2 u}{\partial x^2} = -R\frac{\partial i}{\partial x} - L\left(-G\frac{\partial u}{\partial t} - C\frac{\partial^2 e}{\partial t^2}\right) \tag{16.3.182}$$

and if $\frac{\partial i}{\partial x}$ is finally substituted the result is:

$$\frac{\partial^2 u}{\partial x^2} = LC\frac{\partial^2 u}{\partial t^2} + (RC+GL)\frac{\partial u}{\partial t} + (GR)u \tag{16.3.183}$$

Doing the same in the opposite way results in:

$$\frac{\partial^2 i}{\partial x^2} = LC\frac{\partial^2 i}{\partial t^2} + (RC+GL)\frac{\partial i}{\partial t} + (GR)i \tag{16.3.184}$$

The both relations:

$$\boxed{\begin{aligned}\frac{\partial^2 u}{\partial x^2} &= LC\frac{\partial^2 u}{\partial t^2} + (RC+GL)\frac{\partial u}{\partial t} + (GR)u\\ \frac{\partial^2 i}{\partial x^2} &= LC\frac{\partial^2 i}{\partial t^2} + (RC+GL)\frac{\partial i}{\partial t} + (GR)i\end{aligned}} \tag{16.3.185}$$

are named the Telegrapher's equations". As we can see, except for the dependent variable (i, u) the relations are identical.

If we define $c := 1/\sqrt{LC}, a := c^2(LG+RC), b := c^2RG$, then the Telegrapher equation in u becomes:

$$\frac{\partial^2 u}{\partial t^2} + a\frac{\partial u}{\partial t} + bu = c^2\frac{\partial^2 v}{\partial x^2} \tag{16.3.186}$$

For reasons we will explain below the $a\frac{\partial v}{\partial t}$ term is named the "dissipation term", and the and the bu term is the "dispersion term".

Of course, if $a = b = 0$, we are back to the vibrating string, i.e. wave equation, with its right and left moving wave solution representation.

In many situations we can neglect resistive losses. We then put $R = 0$ and $G = 0$. The equations are therefore reduced to (Alembert equations type, i.e. wave equation):

$$\begin{aligned}\frac{\partial^2 u}{\partial x^2} &= LC\frac{\partial^2 u}{\partial t^2}\\ \frac{\partial^2 i}{\partial x^2} &= LC\frac{\partial^2 i}{\partial t^2}\end{aligned} \tag{16.3.187}$$

we know very well how we may interpret the equation. It's the one of a wave, right and left moving wave solution at the speed:

$$\boxed{v = \frac{1}{\sqrt{LC}}} \tag{16.3.188}$$

This is the propagation speed of waves travelling through the transmission line. For transmission lines made of parallel perfect conductors with vacuum between them, this speed is equal to the speed of light c.

If we consider:

$$u(x,t)=U_0\cos(\omega t-kx)=U_0\cos\left(\omega t-\omega\frac{x}{c}\right) \tag{16.3.189}$$

Then we have obviously:

$$\frac{\partial u(x,t)}{\partial x}=U_0\frac{\omega}{c}\sin\left(\omega t-\omega\frac{x}{c}\right) \tag{16.3.190}$$

But for the telegrapher line, if $R=G=0$ we have just proved above that:

$$\frac{\partial u}{\partial x}=-L\frac{\partial i}{\partial t} \tag{16.3.191}$$

Therefore:

$$\frac{\partial i}{\partial t}=-\frac{U_0\omega}{Lc}\sin\left(\omega t-\omega\frac{x}{c}\right) \tag{16.3.192}$$

Hence:

$$i(x,t)=\frac{U_0}{Lc}\cos\left(\omega t-\omega\frac{x}{c}\right) \tag{16.3.193}$$

Therefore the characteristic impedance of the telegrapher line with $R=G=0$ is given:

$$Z_c=\frac{u(x,t)}{i(x,t)}=Lc=\sqrt{\frac{L}{C}} \tag{16.3.194}$$

Now let us recall that we have proved that for a coaxial capacitor (see section Electrostatics page 3997) that the coaxial capacity per unit length was given by:

$$C=2\pi\varepsilon\frac{1}{\ln\left(\dfrac{R_2}{R_1}\right)} \tag{16.3.195}$$

and similarly for a coaxial inductance (see section Electrostatics page 4266):

$$L=\frac{\mu}{2\pi}\ln\left(\frac{R_2}{R_1}\right) \tag{16.3.196}$$

Therefore:

$$Z_c=\sqrt{\frac{L}{C}}=\frac{1}{2\pi}\sqrt{\frac{\mu}{\varepsilon}}\ln\left(\frac{R_2}{R_1}\right) \tag{16.3.197}$$

And also notice that with $L=G=0$ we get for the potential equation[10]:

$$\frac{\partial^2 u}{\partial x^2}=RC\frac{\partial u}{\partial t} \tag{16.3.198}$$

We recognize here the heat equation (see section Thermodynamics page 3684)!

---

[10] At the slow signalling speeds of a human-operated telegraph key (a dozen or so words per minute), inductive effects were negligible in the Atlantic Cable, and conductance was pretty small, too (that is, the leakage resistance between the conductors was very large)

16.3.4.4.1 Thomson's law of squares of transmission lines (latency metallic cables)

The "Thomson's law of squares of transmission lines" is a theorem concerning transmission lines. It states that the current injected into the line by a step in voltage reaches a maximum at a time proportional to the square of the distance down the line. The theorem is due to William Thomson, the future Lord Kelvin. The law had some importance in connection with submarine telegraph cables.

The law of squares was proposed by William Thomson in 11854 (holocene calendar) at Glasgow University. He had some input from George Gabriel Stokes. Thomson and Stokes were interested in investigating the feasibility of the proposed transatlantic telegraph cable.

Thomson get through a quite awful way to the result we have just presented earlier above:

$$\frac{\partial^2 u}{\partial x^2}=RC\frac{\partial u}{\partial t} \tag{16.3.199}$$

and after he derived the propagation time law in a quite awful and old way.

Let us do a modern derivation of its result using Laplace transform (see section Analysis page 2336). Notice that the entire development below is inspired from the excellent book: *Transients for Electrical Engineers* [409].

We start by taking the unilateral Laplace transform (see section Analysis page 2358) of:

$$\frac{\partial^2 u}{\partial x^2}=LC\frac{\partial^2 u}{\partial t^2}+(RC+GL)\frac{\partial u}{\partial t}+(GR)u \tag{16.3.200}$$

That we will denote as following:

$$\mathcal{UL}\left(u(x,t)\right)=\int\limits_{0+}^{+\infty}v(x,t)e^{-st}\mathrm{d}t=U(x,s) \tag{16.3.201}$$

using the property of time derivation of the unilateral Laplace transformed proved in the section dedicated to it (see section Analysis page 2359), we also have:

$$\begin{aligned}\mathcal{UL}\left(\frac{\partial u}{\partial t}\right)&=sU(x,s)-u(x,0+)\\ \mathcal{UL}\left(\frac{\partial^2 u}{\partial t^2}\right)&=s^2U(x,s)-su(x,0+)-\left.\frac{\mathrm{d}u(x,t)}{\mathrm{d}t}\right|_{t=0+}\\ \mathcal{UL}\left(\frac{\partial^2 u}{\partial x^2}\right)&=\frac{\partial^2}{\partial x^2}[\mathcal{UL}\left(u(x,t)\right)]=\frac{\partial^2}{\partial x^2}U(x,s)=\frac{\mathrm{d}^2}{\mathrm{d}x^2}U(x,s)\end{aligned} \tag{16.3.202}$$

The difference between the last two lines - note which variable the derivatives are with respect to - should be carefully understood. Thus:

$$\frac{\partial^2 u}{\partial x^2}=LC\frac{\partial^2 u}{\partial t^2}+(RC+GL)\frac{\partial u}{\partial t}+(GR)u \tag{16.3.203}$$

Becomes:

$$\begin{aligned}\frac{\mathrm{d}^2U(x,s)}{\mathrm{d}x^2}=&LC\left[s^2U(x,s)-su(x,0+)-\left.\frac{\mathrm{d}u(x,t)}{\mathrm{d}t}\right|_{t=0+}\right]\\ &+(RC+LG)[sU(x,s)-u(x,0+)]+RGU(x,s)\end{aligned} \tag{16.3.204}$$

or, after a bit of rearranging:

$$\begin{aligned}\frac{\mathrm{d}^2U(x,s)}{\mathrm{d}x^2}-(Ls+R)(Cs+G)U(x,s)=-L\left[Gu(x,0+)+C\frac{\mathrm{d}u(x,t)}{\mathrm{d}t}\bigg|_{t=0+}\right]\\ -C[Ls+R]v(x,0+)\end{aligned} \tag{16.3.205}$$

At this point, there is a subtle technical issue that needs to be addressed before continuing. The value of:

$$\frac{\mathrm{d}v(x,t)}{\mathrm{d}t}\bigg|_{t=0+} \tag{16.3.206}$$

the initial rate of change of the voltage with respect to time, at an arbitrary location along the line, is usually not obvious. We can side-step this problem if we work instead with the initial rate of change with respect to x of the current, that is, with:

$$\frac{\mathrm{d}i(x,t)}{\mathrm{d}x}\bigg|_{t=0+} \tag{16.3.207}$$

(as we will elaborate on this claim in just a moment) and we can get that value from:

$$-\frac{\partial i}{\partial x}=Gu+C\frac{\partial u}{\partial t} \tag{16.3.208}$$

So, evaluating that latter at $t=0+$ (note, carefully, that we are simply substituting $t=0+$ and are not Laplace transforming), we have:

$$-\frac{\mathrm{d}i(x,t)}{\mathrm{d}x}\bigg|_{t=0+}=Gu(x,0+)+C\frac{\mathrm{d}u(x,t)}{\mathrm{d}t}\bigg|_{t=0+} \tag{16.3.209}$$

and so:

$$C\frac{\mathrm{d}u(x,t)}{\mathrm{d}t}\bigg|_{t=0+}=-\frac{\mathrm{d}i(x,t)}{\mathrm{d}x}\bigg|_{t=0+}-Gu(x,0+) \tag{16.3.210}$$

Putting this into the unilateral Laplace transform that we have get, we obtain:

$$\frac{\mathrm{d}^2U(x,s)}{\mathrm{d}x^2}-\gamma^2U(x,s)=L\frac{\mathrm{d}i(x,t)}{\mathrm{d}x}\bigg|_{t=0+}-C[Ls+R]u(x,0+) \tag{16.3.211}$$

where:

$$\gamma=\sqrt{(Ls+R)(Cs+G)} \tag{16.3.212}$$

The reason the above differential (Laplace) equation is preferable is that the initial value of $\mathrm{d}i(x,t)/\mathrm{d}x$ is, as we have claimed earlier, usually more easily tractable than the initial value of $\mathrm{d}u(x,t)/\mathrm{d}t$ To see this, consider the problem of calculating $u(x,t)$ on a transmission line (in response to a given input signal $u(0,t)$), a line that we say to be "initially relaxed" (that is, there is no current or stored charge in the line at $t=0$). We can immediately say, for such a line, that:

$$u(x,0+)=0 \text{ for } x>0 \tag{16.3.213}$$

and:

$$i(x,0+)=0 \text{ for } x>0 \tag{16.3.214}$$

As time increases from $t = 0+$, we obviously expect the cable current at a given location to change from zero. But suppose we keep time constant, and look at the cable current as we change x. As long as $x > 0$ we are not at the beginning of the cable then as we move along the cable with increasing x we will continue to see $i = 0$ until some time $t > 0+$. Thus, we can definitely say:

$$\left.\frac{\mathrm{d}i(x,t)}{\mathrm{d}x}\right|_{t=0+} = 0 \text{ for } x > 0 \tag{16.3.215}$$

Next, consider the case of the cable voltage $u(x,t)$. As time increases from $t = 0+$ we again obviously expect the cable voltage at a given point to change from zero. Suppose now that we keep x constant (we observe a fixed point on the cable) and ask how the voltage there changes with respect to time? That is, what is:

$$\left.\frac{\mathrm{d}u(x,t)}{\mathrm{d}t}\right|_{t=0+} = 0 \tag{16.3.216}$$

Also, knowing that $u(x,0+) = 0$ for any $x > 0$ doesn't tell us anything about how the voltage changes with time. It isn't the distinction between voltage and current that is important in this consideration, but rather which variable we are differentiating with respect to (x or t). Differentiating with respect to x, and with respect to t makes a big difference.

To complete this section, we'll calculate $u(x,t)$ and $i(x,t)$ for an initially relaxed, infinitely long[11] transmission line when a unit step voltage is applied to the $x = 0$ end at $t = 0$. The general problem (for arbitrary values of $R, L, C,$ and G) was first attempted by Heaviside, using his operational calculus, but his solution seems to have been later questioned (after his death) by others. We'll work our way towards the general solution using the Laplace transform, with our first discussion dealing with the Atlantic Cable.

So from:

$$\frac{\mathrm{d}^2U(x,s)}{\mathrm{d}x^2} - \gamma^2 U(x,s) = L\left.\frac{\mathrm{d}i(x,t)}{\mathrm{d}x}\right|_{t=0+} - C[Ls+R]u(x,0+) \tag{16.3.217}$$

we start to solve the homogeneous equation:

$$\frac{\mathrm{d}^2U(x,s)}{\mathrm{d}x^2} - \gamma^2 U(x,s) = 0 \tag{16.3.218}$$

with the following initial condition: $u(0,t) = u(t)$.

This is an ordinary differential equation that is easily solved. Specifically, assume a solution of the form:

$$U(x,s) = Ke^{px} \tag{16.3.219}$$

where K and p are some constants. Then putting it back in the homogeneous equation leads to:

$$Kp^2e^{px} - \gamma^2 K = e^{px} \tag{16.3.220}$$

---

[11] To account for a finite length is not conceptually difficult, but it does add considerably to the mathematics.

therefore:

$$p=\pm\gamma \tag{16.3.221}$$

Hence (keep in mind that $\gamma\in\mathbb{R}_+^*$) :

$$U(x,s)=K_1e^{\gamma x}+K_2e^{-\gamma x} \tag{16.3.222}$$

For an infinite line we demand that $K_1=0$ as otherwise $U(x,s)$ would become unbounded as $x\rightarrow+\infty$. So:

$$U(x,s)=K_2e^{-\gamma x} \tag{16.3.223}$$

Since at $x=0$ we have $u(0,t)=u(t)$ then using the unilateral Laplace transform (see section Analysis page 2358):

$$V(0,s)=\mathcal{UL}(u(t))=\frac{1}{s}=K_2 \tag{16.3.224}$$

and so:

$$U(x,s)=\frac{1}{s}e^{-\gamma x} \tag{16.3.225}$$

For the Atlantic cable, we have $L=G=0$, which means:

$$\gamma=\sqrt{RC} \tag{16.3.226}$$

And so the above solution gives:

$$U_{\text{At.}}(x,s)=\frac{1}{s}e^{-x\sqrt{RCs}} \tag{16.3.227}$$

Using the following Unilateral Laplace transform pair (see section Analysis page 2351):

$$1-\text{erf}\left(\frac{a}{2\sqrt{t}}\right)\leftrightarrow\frac{1}{s}e^{-a\sqrt{s}} \tag{16.3.228}$$

and so with:

$$a=x\sqrt{RC} \tag{16.3.229}$$

We see then that the unit step voltage response is:

$$u(x,t)=1-\text{erf}\left(\frac{x\sqrt{RC}}{2\sqrt{t}}\right) \tag{16.3.230}$$

To find the current $i(x,t)$ on the Atlantic cable, we look back at:

$$-\frac{\partial u}{\partial x}=iR+L\frac{\partial i}{\partial t} \tag{16.3.231}$$

we set $L=0$ and then we use the Laplace transform to get:

$$-\frac{\partial U(x,s)}{\partial x}=I(x,s)R \tag{16.3.232}$$

and so:

$$I(x,s)=-\frac{1}{R}\frac{\mathrm{d}U(x,s)}{\mathrm{d}x}=-\frac{1}{R}\left(\frac{-\sqrt{RCs}e^{-x\sqrt{RCs}}}{s}\right) \tag{16.3.233}$$

or:

$$I(x,s)=\sqrt{\frac{C}{Rs}}e^{-x\sqrt{RCs}} \tag{16.3.234}$$

To get $i(x,t)$ recall this pair property (s domain derivation) of the Laplace transform (see section Analysis page 2345):

$$tx(s)\leftrightarrow -\frac{\mathrm{d}}{\mathrm{d}s}X(x) \tag{16.3.235}$$

and as (see section Analysis page 2354):

$$\frac{e^{-a^2/4t}}{\sqrt{\pi t^3}}\leftrightarrow \frac{2}{a}e^{-a\sqrt{s}} \tag{16.3.236}$$

Using the s-domain derivation property we then get:

$$t\frac{e^{-a^2/4t}}{\sqrt{\pi t^3}}\leftrightarrow -\frac{2}{a}\left(-a\frac{1}{2}s^{-1/2}\right)e^{-a\sqrt{s}} \tag{16.3.237}$$

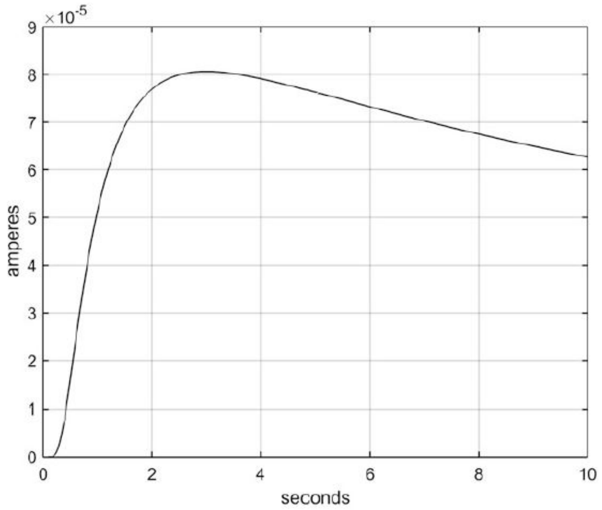
or after simplification:

$$\frac{e^{-a^2/4t}}{\sqrt{\pi t}}\leftrightarrow \frac{1}{\sqrt{s}}e^{-a\sqrt{s}} \tag{16.3.238}$$

Thus, one again setting $a=x\sqrt{RC}$, we immediately have:

$$i(x,t)=\sqrt{\frac{C}{\pi Rt}}e^{-x^2RC/4t} \tag{16.3.239}$$

The figure below shows the current $i(x,t)$ on the Atlantic cable at $x=3,704$ [km]. The values of $R=1.62\cdot 10^{-3}$ $[\Omega\cdot\mathrm{m}^{-1}]$ and $C=2.7\cdot 10^{-10}$ $[\mathrm{F}\cdot\mathrm{m}^{-1}]$ are measured for this cable and the figure shows the current for the first ten seconds after the start of the unit step input voltage at $x=0$.



There are two features in this figure of practical engineering importance.

1. First, there is a significant delay of three seconds in the occurrence of the peak current. That is, closing a telegraph key at time $t=0$ doesn't result in a maximum current response at $x=3,704$ [km] until three seconds later.

2. Second, the maximum current is a substantial current. The figure above shows that a 1 [V] step input produces a maximum current that is slightly in excess of $80\,[\mu\text{A}]$, and so if the actual sending voltage would be, say, 40 [V] (typical of the voltages used on the Atlantic copper cable), there would be a maximum current, $x=3,704$ [km] distant, three seconds later, of more than $80\,[\mu\text{A}]$, an easily detectable current in the mid-119th century (holocene calendar).

Much more interesting is the behaviour of $i(x,t)$. For any given value of x, we see from the relation above that $i(x,0)=0$ and that $i(x,=+\infty)=0$. So, for every x there must be a time $t=t_{\text{max}}$ at which $i(x,t)$ reaches an extreme value, a time that depends on the value of x. Indeed, if we differentiate:

$$i(x,t)=\sqrt{\frac{C}{\pi Rt}}e^{-x^2RC/4t} \tag{16.3.240}$$

with respect to t and set the result to zero:

$$-\frac{1}{2}\frac{e^{-x^2RC/4t}C}{\sqrt{\frac{C}{\pi Rt}}\pi Rt^2}+\frac{1}{4}\frac{\sqrt{\frac{C}{\pi Rt}}x^2RCe^{-x^2RC/4t}}{t^2}=0 \tag{16.3.241}$$

we find the "Thomson's law of squares of (metallic) transmission lines":

$$\boxed{t_{\text{max}}=\frac{1}{2}RCx^2} \tag{16.3.242}$$

Putting this back in the expression of $i(x,t)$ we get:

$$i_{\text{max}}(x,t_{\text{max}})=\frac{1}{Rx}\sqrt{\frac{2}{\pi e}} \tag{16.3.243}$$

and, if we substitute $R=1.62\cdot 10^{-3}\,[\Omega\cdot\text{m}^{-1}]$ and $x=3,704$ [km], we get $i_{\text{max}}=80.7\,[\mu\text{A}]$ at $t_{\text{max}}=3$ [s], values in excellent agreement with the above figure.

Thomson's result is quite counter-intuitive and led to some disbelieving it. The result that most telegraph engineers expected was that the delay in the peak would be directly proportional to line length. Telegraphy was in its infancy and many telegraph engineers were self taught. They tended to mistrust academics and rely instead on practical experience. Even as late as 11887 (holocene calendar), the author of a letter to *The Electrician* wished to « *...protest against the growing tendency to drag mathematics into everything.*»

Remark

A derivation not using the Laplace transform is also available at the end of the excellent book (yes the same book again...): *Transients for Electrical Engineers* **??** (as appendix).

One opponent of Thomson was of particular significance, Wildman Whitehouse, who challenged Thomson when he presented the theorem to the British Association in 11855 (holocene calendar). Both Thomson and Wildman were associated with the transatlantic telegraph cable project, Thomson as an unpaid director and scientific advisor, and Whitehouse as the Chief Electrician of the Atlantic Telegraph Company. Thomson's discovery threatened to derail the project, or at least, indicated that a much larger cable was required (a larger conductor will reduce R and a thicker insulator will reduce C). Whitehouse had no advanced mathematical education (he was a doctor by training) and did not fully understand Thomson's work. He claimed he had experimental evidence that Thomson was wrong, but his measurements were poorly conceived and Thomson refuted his claims, showing that Whitehouse's results were consistent with the law of squares.

Whitehouse believed that a thinner cable could be made to work with a high voltage induction coil. The Atlantic Telegraph Company, in a hurry to push ahead with the project, went with Whitehouse's cheaper solution rather than Thomson's. After the cable was laid, it suffered badly from retardation, an effect that had first been noticed by Latimer Clark in 11853 (holocene calendar) on the Anglo-Dutch submarine cable of the Electric Telegraph Company. Retardation causes a delay and a lengthening of telegraph pulses, the latter as if one part of the pulse has been retarded more than the other. Retardation can cause adjacent telegraph pulses to overlap making them unreadable, an effect now named "intersymbol interference". It forced telegraph operators to send more slowly to restore a space between pulses. The problem was so severe on the Atlantic cable that transmission speeds were measured in minutes per word rather than words per minute. In attempting to overcome this problem with ever higher voltage (2000 [V]), Whitehouse permanently damaged the cable insulation and made it unusable. He was dismissed shortly afterwards.

But, sure enough, by 11866 (holocene calendar), the mathematics of Thomson had resulted in the laying of two cables, each almost ten times more efficient than the previous.

Remark

There are entire books dedicated to the subject (as always...). The reader interested may read for example the following reference: *Transmission Lines and Wave Propagation* [366].

16.3.5 Linear Circuit (RLC) in Forced Regime

The objective here will be to study the behaviour of a series linear RLC circuit excited by a sinusoidal voltage generator since it is a generalization of the RL or RC circuits (it is enough to cancel L or C respectively to fall back on the solutions of a RC or RL circuit).

We then have:

$$\boxed{L\frac{\mathrm{d}^2q}{\mathrm{d}t^2}+R\frac{\mathrm{d}q}{\mathrm{d}t}+\frac{1}{C}q=U_0\sin(\omega t)} \tag{16.3.244}$$

which is a differential equation of known form and therefore important in the field of acoustics because we find it identically for the study of loudspeakers. That latter equation can often be found in the following form:

$$L\frac{\mathrm{d}i}{\mathrm{d}t}+Ri+\frac{1}{C}q=U_0\sin(\omega t) \tag{16.3.245}$$

We could very well add a phase shift to the sine on the right of the equality (phase arbitrary). This would not change the developments that follow, and let us recall that the cosine is only a sinus with a very precise phase shift!

Finally, the most important thing is that if we find a special solution to the differential equation above, then since the amplitude and the pulse can take any value at an arbitrary phase shift, then we have an infinity of special solutions. And as we have shown in our study of differential equations that the sum of special solutions is also a solution then it means that an excitation obtained with a Fourier series will also have a solution and by passing to the limit we have a Fourier transform (see section Sequences and Series page 1758)!!!

So let's move on to our study. To do this, let us derive the previous relation with respect to t:

$$L\frac{\mathrm{d}^2i}{\mathrm{d}t^2}+R\frac{\mathrm{d}i}{\mathrm{d}t}+\frac{1}{C}i=U_0\omega\cos(\omega t) \tag{16.3.246}$$

Let us then seek for a special solution of the form:

$$\begin{aligned}i&=a\cos(\omega t)+b\sin(\omega t)\\ \frac{\mathrm{d}i}{\mathrm{d}t}&=-a\omega\sin(\omega t)+b\omega\cos(\omega t)\\ \frac{\mathrm{d}^2i}{\mathrm{d}t^2}&=-a\omega^2\cos(\omega t)-b\omega^2\sin(\omega t)\end{aligned} \tag{16.3.247}$$

We notice that this proposition of solution is in every point identical to the fundamental of a Fourier series whose term a_0 is zero (which is the mean of the signal or the continuous component if it exists) as the reader can check by going back to the section of Sequences and Series where we have introduced Fourier series (see page 1727)!

Then let us inject these relationships into:

$$L\frac{\mathrm{d}^2i}{\mathrm{d}t^2}+R\frac{\mathrm{d}i}{\mathrm{d}t}+\frac{1}{C}i=U_0\omega\cos(\omega t) \tag{16.3.248}$$

By grouping the trigonometric terms of the same nature:

$$\left(-a\omega^2L+b\omega R+\frac{1}{C}a\right)\cos(\omega t)+\left(-b\omega^2L-a\omega R+\frac{1}{C}b\right)\sin(\omega t)=U_0\omega\cos(\omega t) \tag{16.3.249}$$

What is equivalent to:

$$\left(-a\omega^2L+b\omega R+\frac{1}{C}a\right)\cos(\omega t)+\left(-b\omega^2L-a\omega R+\frac{1}{C}b\right)\sin(\omega t)=U_0\omega\cos(\omega t)+0\cdot\sin(\omega t) \tag{16.3.250}$$

Hence by identifying the terms:

$$\begin{aligned}-a\omega^2L+b\omega R+\frac{1}{C}a&=U_0\omega\\-b\omega^2L-a\omega R+\frac{1}{C}b&=0\end{aligned} \tag{16.3.251}$$

We can factorize:

$$\begin{aligned}-a\left(\omega^2L-\frac{1}{C}\right)+b\omega R&=U_0\omega\\-a\omega R-b\left(\omega^2L-\frac{1}{C}\right)&=0\end{aligned} \tag{16.3.252}$$

And simplifying by ω:

$$\begin{aligned}-a\left(\omega L-\frac{1}{C\omega}\right)+bR&=U_0\\-aR-b\left(\omega L-\frac{1}{C\omega}\right)&=0\end{aligned} \tag{16.3.253}$$

and by changing the sign of the second line:

$$\begin{aligned}-a\left(\omega L-\frac{1}{C\omega}\right)+bR&=U_0\\aR+b\left(\omega L-\frac{1}{C\omega}\right)&=0\end{aligned} \tag{16.3.254}$$

It is therefore a system of two equations with two unknowns a, b which we solve by writing:

$$X=\omega L-\frac{1}{\omega C}=X_L-X_C \tag{16.3.255}$$

where we thus fall back on the "inductive reactance" and the "capacitive reactance" introduced in the section of Electrokinetics.

Which immediately gives us:

$$\begin{aligned}-aX+bR&=U_0\\aR+bX&=0\end{aligned} \tag{16.3.256}$$

hence:

$$-aX+\frac{-aR}{X}R=U_0\Rightarrow a\left(\frac{X^2+R^2}{X}\right)=-U_0\Rightarrow a=\frac{-XU_0}{X^2+R^2} \tag{16.3.257}$$

and therefore:

$$\left(\frac{-XU_0}{X^2+R^2}\right)R+bX=0\Rightarrow b=\frac{U_0R}{X^2+R^2} \tag{16.3.258}$$

We also put traditionally that (we shall see later that this expression can be assimilated to the concept of impedance by analogy with the norm of a vector):

$$Z=\sqrt{X^2+R^2} \tag{16.3.259}$$

This gives the following special solution:

$$i(t)=\frac{-XU_0}{X^2+R^2}\cos(\omega t)+\frac{U_0R}{X^2+R^2}\sin(\omega t)=\frac{U_0}{Z}\left(\frac{R}{Z}\sin(\omega t)-\frac{X}{Z}\cos(\omega t)\right) \tag{16.3.260}$$

to a given arbitrary phase value.

It is possible to find θ such as:

$$\sin(\theta)=\frac{X}{Z}\qquad\cos(\theta)=\frac{R}{Z} \tag{16.3.261}$$

Or otherwise written (thus one sees better that we browse all the possible values outside singularities):

$$\frac{\sin(\theta)}{\cos(\theta)}=\frac{X}{R} \tag{16.3.262}$$

We then have using the remarkable trigonometric relations (see section Trigonometry page 2519):

$$i(t)=\frac{U_0}{Z}\left(\cos(\theta)\sin(\omega t)-\frac{X}{Z}\sin(\theta)\cos(\omega t)\right)=\frac{U_0}{Z}\sin(\omega t-\theta) \tag{16.3.263}$$

θ is therefore the phase of the current, that is to say the advance or the delay of the current on the voltage. If $\theta=0$ then we have:

$$\sin(0)=0=\frac{X}{Z}\Rightarrow X=0\qquad\cos(0)=1=\frac{R}{Z}\Rightarrow R=Z=\sqrt{X^2+R^2}=\sqrt{0^2+R^2}=R \tag{16.3.264}$$

and then:

$$i(t)=\frac{U_0}{R}\sin(\omega t) \tag{16.3.265}$$

We then say that there is "resonance of the circuit" with therefore:

$$X=L\omega-\frac{1}{C\omega}=0\Rightarrow\omega=\frac{1}{\sqrt{LC}}=\frac{2\pi}{R} \tag{16.3.266}$$

Either when the inductive reactance is equal to the capacitive reactance.

In that latter situation we often found another expression for Z. Let us remind that it is defined by:

$$Z=\sqrt{X^2+R^2} \tag{16.3.267}$$

So in the special case where the is no phase shift between the current and voltage that latter is written:

$$Z=\sqrt{\left(L\omega-\frac{1}{C\omega}\right)^2+R^2} \tag{16.3.268}$$

That expression can been see as the module of a complex number simply given by:

$$Z=R^2+\mathrm{i}\left(L\omega-\frac{1}{C\omega}\right) \tag{16.3.269}$$

Let us prove that using the Fourier transform (see section Sequences and Series page 1758)!

Obviously the differential equation we have introduced above can be written:

$$L\frac{\mathrm{d}i(t)}{\mathrm{d}t}+Ri(t)+\frac{1}{C}\int i(t)\mathrm{d}t=u(t) \tag{16.3.270}$$

Using the Fourier transform of the derivative in time (see section Analysis page 2316):

$$\mathcal{F}\left(\frac{\mathrm{d}^n}{\mathrm{d}t^n}x(t)\right)=(\mathrm{i}\omega)^n X(\mathrm{i}\omega) \tag{16.3.271}$$

and integration in time (see section Analysis page 2316):

$$\mathcal{F}\left(\int_{-\infty}^{t} x(\tau)\mathrm{d}\tau\right)=\frac{1}{\mathrm{i}\omega}X(\mathrm{i}\omega)+\pi X(0)\delta(\omega) \tag{16.3.272}$$

we get:

$$L\mathrm{i}\omega I(\mathrm{i}\omega)+RI(\mathrm{i}\omega)+\frac{1}{C}\left(\frac{1}{\mathrm{i}\omega}I(\mathrm{i}\omega)+\pi I(0)\delta(\omega)\right)=U(\mathrm{i}\omega) \tag{16.3.273}$$

In the case of a steady state, constant harmonic frequency signal the Fourier transform $I(0)$ is equal to zero. Therefore:

$$L\mathrm{i}\omega I(\mathrm{i}\omega)+RI(\mathrm{i}\omega)+\frac{I(\mathrm{i}\omega)}{\mathrm{i}\omega C}=U(\mathrm{i}\omega) \tag{16.3.274}$$

After rearranging:

$$L\mathrm{i}\omega+R+\frac{1}{\mathrm{i}\omega C}=\frac{U(\mathrm{i}\omega)}{I(\mathrm{i}\omega)}=Z(\mathrm{i}\omega) \tag{16.3.275}$$

Therefore:

$$Z(\mathrm{i}\omega)=L\mathrm{i}\omega+R+\frac{1}{\mathrm{i}\omega C}=R+L\mathrm{i}\omega-\mathrm{i}\frac{1}{\omega C}=R+\mathrm{i}\left(L\omega+\frac{1}{C\omega}\right) \tag{16.3.276}$$

And this finish to prove our claim!

16.3.5.1 Low-pass filter

Let us consider the case where L is zero. We have then:

$$X=L\omega-\frac{1}{C\omega}=\frac{1}{C\omega} \tag{16.3.277}$$

Therefore:

$$Z=\sqrt{X^2+R^2}=\sqrt{\left(\frac{1}{C\omega}\right)^2+R^2}=\frac{1}{C\omega}\sqrt{1+C\omega R^2} \tag{16.3.278}$$

Hence:

$$i=\frac{\mathrm{d}q}{\mathrm{d}t}=\frac{C\omega}{\sqrt{1+(C\omega R)^2}}U_0\sin(\omega t-\theta) \tag{16.3.279}$$

Finally:

$$\begin{aligned}q&=\int\frac{C\omega U_0}{\sqrt{1+(C\omega R)^2}}\sin(\omega t-\theta)\mathrm{d}t=\frac{C\omega U_0}{\sqrt{1+(C\omega R)^2}}\int\sin(\omega t-\theta)\mathrm{d}t\\&=\frac{C\omega U_0}{\sqrt{1+(C\omega R)^2}}\left(-\frac{\cos(\omega t-\theta)}{\omega}\right)=-\frac{C\omega U_0}{\sqrt{1+(C\omega R)^2}}\cos(\omega t-\theta)\end{aligned} \tag{16.3.280}$$

We then have at the terminals of the capacitor:

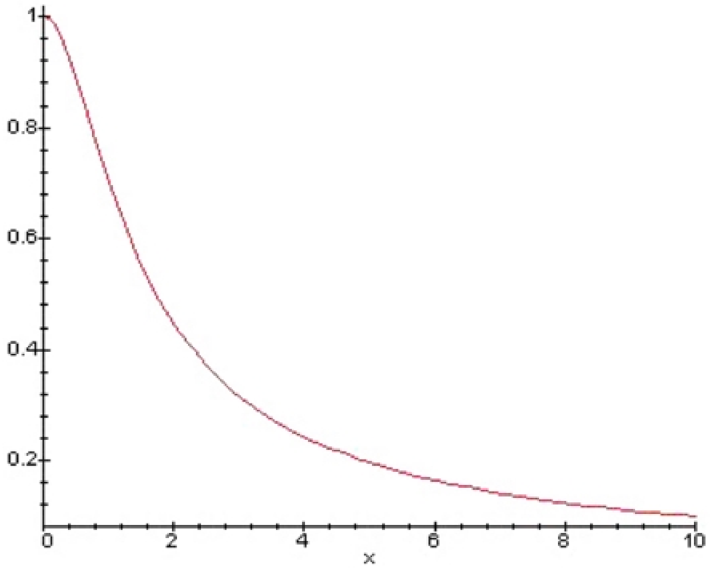
$$u_C=\frac{1}{C}q=-\frac{1}{\sqrt{1+(C\omega R)^2}}U_0\cos(\omega t-\theta) \tag{16.3.281}$$

We see then that the voltage at the terminals of the capacitor acts as what we name a "low-pass filter". That is to say that the amplitude of the voltage across the capacitor with respect to the excitation voltage of the circuit will be reduced, and this is all the more as the frequency will be high.

This type of tool is very useful for example to eliminate the high-frequency harmonics of a periodic signal obtained by Fourier series or for cleaning a high-frequency noise. Cascaded low-pass filters can also be used to perform spectrum analysers.

Here is the plot of the factor:

$$\frac{1}{\sqrt{1+(C\omega R)^2}} \tag{16.3.282}$$



We can see that at low frequencies (on the left) the amplitude is preserved (the low-pass filter therefore let pass the low frequencies). Beyond that, the signal is turned off.

The ratio:

$$\frac{u_C}{U_0}=\frac{1}{\sqrt{1+(C\omega R)^2}} \tag{16.3.283}$$

Is often expressed in decibels Db either by definition using the measure:

$$\text{dB}=20\log\left(\frac{u_C}{U_0}\right) \tag{16.3.284}$$

And is then referred to as the "transfer function" of the filter.

16.3.5.2 High-pass filter

With regard to the voltage at the terminals of the resistor, we have:

$$u_R=R\cdot i_0=\frac{RC\omega}{\sqrt{1+(C\omega R)^2}}U_0\sin(\omega t-\theta) \tag{16.3.285}$$

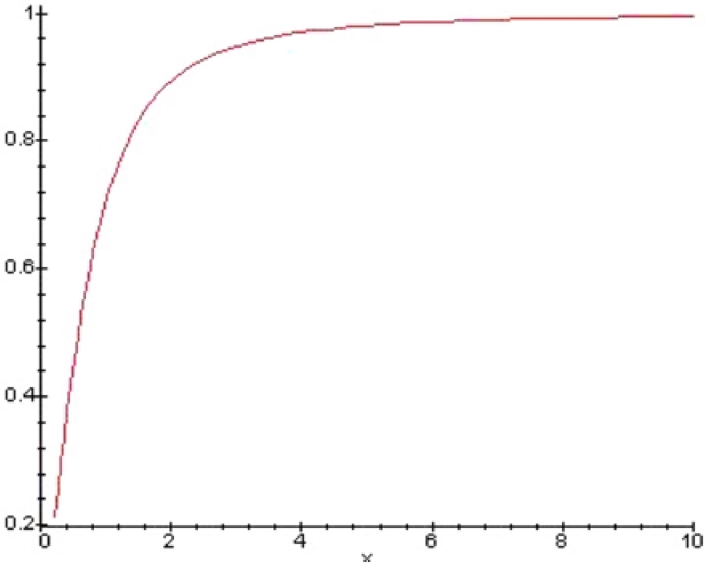
Which is traditionally modified in the following form:

$$u_R=\frac{1}{\sqrt{1+\dfrac{1}{(C\omega R)^2}}}U_0\sin(\omega t-\theta) \tag{16.3.286}$$

So we see that the voltage at the terminals of the resistor acts as what we name a "high-pass filter". That is to say that the amplitude of the voltage across the resistor with respect to the excitation voltage of the circuit will be reduced, and the more so as the frequency will be small.

Here is the plot of the factor:

$$\frac{1}{\sqrt{1+\frac{1}{(C\omega R)^2}}} \tag{16.3.287}$$



We can see that at small frequencies (on the right) the amplitude is preserved (the high-pass filter allows to pass the high frequencies). Beyond this the signal is switched off.

The ratio:

$$\frac{u_R}{U_0}=\frac{1}{\sqrt{1+\frac{1}{(C\omega R)^2}}} \tag{16.3.288}$$

Is often expressed in decibels either by definition using the measure:

$$\text{dB}=20\log\left(\frac{u_R}{U_0}\right) \tag{16.3.289}$$

and is then also referred to as the "transfer function" of the filter.

With different types of assembled filters we can thus remove (but never completely) frequency ranges. We're talking about a "band-pass filter". This is the technique used, for example, for the reception of a certain radio or television channel in a specific frequency range, or also in electronic music to attenuate low pitched or high pitched sounds. Or to separate the ADSL signal from the voice of a telephone line.

A "passive filter" is characterized by the exclusive use of linear passive components (resistors, capacitors, coupled coils or not). Therefore, their gain (power ratio between output and input) can not exceed one. They can therefore only partly attenuate signals, but not amplify them, because this would require an input of energy (which is the role of an "active filters").

16.3.5.3 Integrator and differentiator

We therefore have at the terminals of the capacitor:

$$u_C=\frac{1}{C}\int i_0\mathrm{d}t=\frac{\omega}{\sqrt{1+(C\omega R)^2}}\int U_0\sin(\omega t-\theta)\mathrm{d}t=\frac{1}{\sqrt{\dfrac{1+(C\omega R)^2}{\omega^2}}}\int U_0\sin(\omega t-\theta)\mathrm{d}t$$
$$=\frac{1}{\sqrt{\dfrac{1}{\omega^2}+(CR)^2}}\int U_0\sin(\omega t-\theta)\mathrm{d}t \tag{16.3.290}$$

Now, if $\omega\gg(RC)^{-1}$, we have:

$$u_C\cong\frac{1}{CR}\int U_0\sin(\omega t-\theta)\mathrm{d}t \tag{16.3.291}$$

If we make things so that $\theta=0$ we must have:

$$X=L\omega-\frac{1}{C\omega}=0 \tag{16.3.292}$$

Therefore:

$$L=\frac{1}{C} \tag{16.3.293}$$

Since then:

$$u_C\cong\frac{1}{CR}\int U_0\sin(\omega t)\mathrm{d}t \tag{16.3.294}$$

The circuit is then what we name logically enough ... an "integrator".

Let us now look at the resistance side:

$$u_R=R\cdot i_0 \tag{16.3.295}$$

But we have:

$$u_C=\frac{1}{C}\int i_0\mathrm{d}t\Rightarrow\frac{\mathrm{d}u_C}{\mathrm{d}t}=\frac{1}{C}i_0\Rightarrow i_0=C\frac{\mathrm{d}u_C}{\mathrm{d}t} \tag{16.3.296}$$

Therefore:

$$u_R=RC\frac{\mathrm{d}u_C}{\mathrm{d}t} \tag{16.3.297}$$

As:

$$u_C=-\frac{1}{\sqrt{1+(C\omega R)^2}}U_0\cos(\omega t-\theta) \tag{16.3.298}$$

We have then:

$$u_R=-\frac{RC}{\sqrt{1+(C\omega R)^2}}\frac{\mathrm{d}}{\mathrm{d}t}U_0\cos(\omega t-\theta)=-\frac{1}{\sqrt{\dfrac{1}{(RC)^2}+\omega^2}}\frac{\mathrm{d}}{\mathrm{d}t}U_0\cos(\omega t-\theta) \tag{16.3.299}$$

If $\omega \ll (RC)^{-1}$ then:

$$u_R = -RC\frac{\mathrm{d}}{\mathrm{d}t}U_0\cos(\omega t - \theta) \tag{16.3.300}$$

If we make things so that $\theta = \pi/2$ we must have:

$$u_R = -RC\frac{\mathrm{d}}{\mathrm{d}t}U_0\cos\left(\omega t - \frac{\pi}{2}\right) = -RC\frac{\mathrm{d}}{\mathrm{d}t}U_0\cos\left(\omega t - \frac{\pi}{2}\right) = RC\frac{\mathrm{d}}{\mathrm{d}t}U_0\sin(\omega t) \tag{16.3.301}$$

The circuit is then what we name logically enough ... a "derivator".

The utility of an integrating circuit is, for example, to transform a periodic signal into a constant (since the time average of a periodic signal having an offset will never be zero).

16.3.6 Signal Processing

Signal processing concerns the analysis, synthesis, and modification of signals, which are broadly defined as functions conveying, "information about the behaviour or attributes of some phenomenon", such as sound, images, and biological measurements. For example, signal processing techniques are used to improve signal transmission fidelity, storage efficiency, and subjective quality, and to emphasize or detect components of interest in a measured signal.

It may seems curious to the reader that we deal with signal processing in the section of Electrical Engineering as it also applies to Numerical Methods! But in my point of view, the most concerned application and tools related to signal processing is electronics as explained just in the paragraph before.

16.3.6.1 Nyquist-Shannon Theorem (Nyquist sampling theorem)

The "Nyquist sampling theorem", or "Nyquist-Shannon theorem", provides a prescription for the sampling frequency required for a "good enough" sampling for a perfectly periodic signal into a digital (square pulse) transformation. It is stated simply, and wrongly (as Nyquist never said this!!!!!), as follows (and should not bear the name "theorem" as it is only an engineering practice and not a general perfect theorem!!!!!):

Theorem 16.1. The sampling frequency of a signal $s(t)$ should equal twice the highest frequency contained in the signal. Or in mathematical terms:

$$f_s = 2f_{\text{max}} \tag{16.3.302}$$

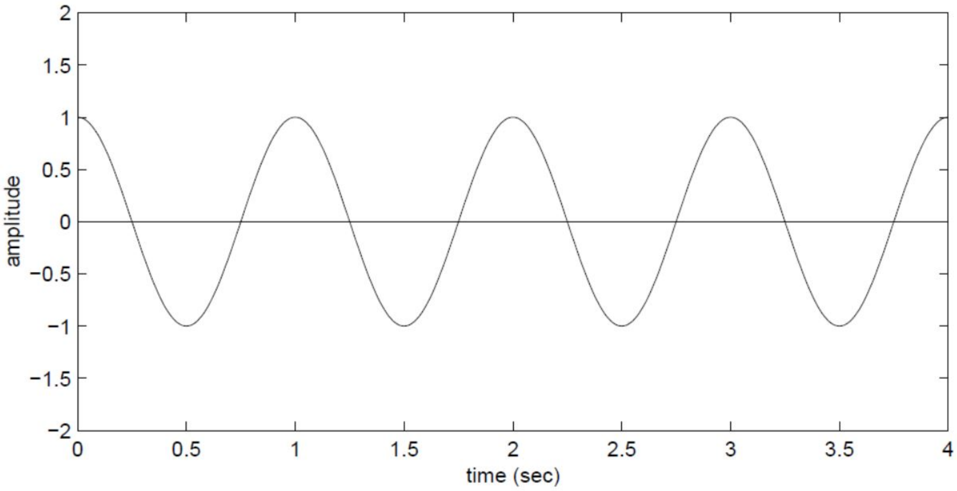
where f_s is the sampling frequency (how often samples are taken per unit of time or space), in this special case named "Nyquist rate", and f_{max} is the highest frequency contained in the signal. Under the assumption that the signal must not contain a sinusoidal component at exactly frequency f_{max} (see further below the example to understand why this assumption...)!

Remark

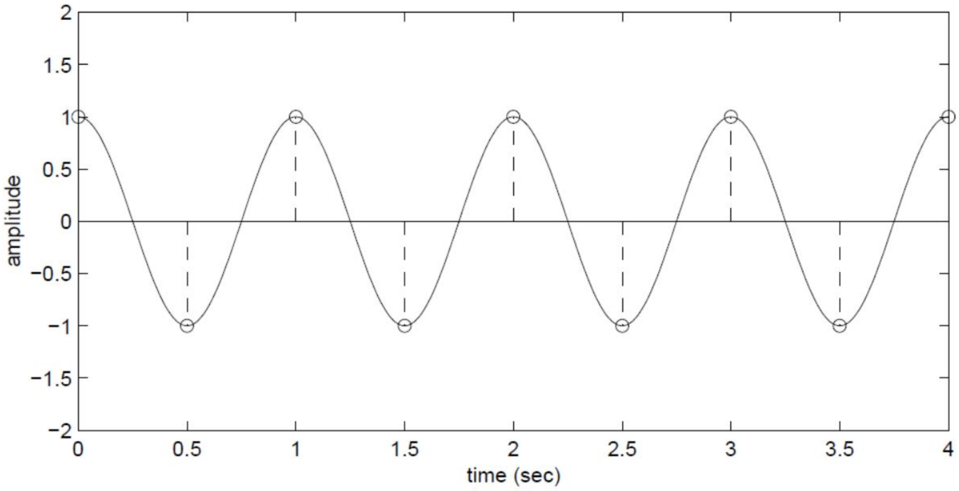
In reality, even if ideal sampling could be achieved, for a lot of manipulations and analyses, the original signal needs to be reconstructed at a higher sample frequency. So what sampling frequency should we use? Well, the answer is application dependent and my require careful statistical analysis of error rates between the original signal and the rebuild one based on the sampling. A rule of thumb in practice seems to consider 2 samples per period (Nyquist criteria) for very repetitive signals, 800 samples per period for non-repetitive signals where extreme precision is required.

The first explanation that we can find in many textbooks is the following (even if it's wrong, it is a first approach that helps to understand the real explanation we will see later further below):

Let us consider for example a signal composed of a single cosine wave at a frequency of 1 [Hz]:



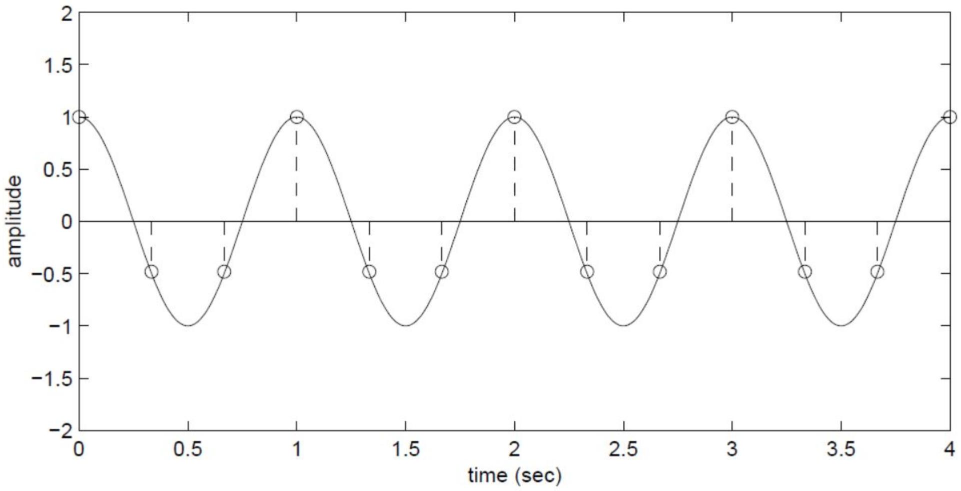
If we sample this waveform at 2 [Hz] (as dictated by the Nyquist theorem), this is sufficient to capture each peak of the signal[12]:



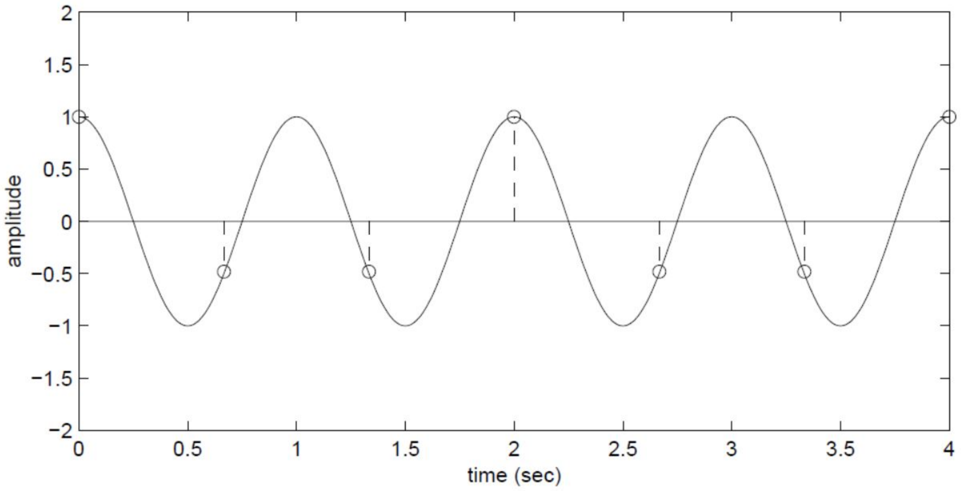
If we sample at a frequency higher than this, for example 3 [Hz], then there are more than enough samples to capture the variations in the signal:

---

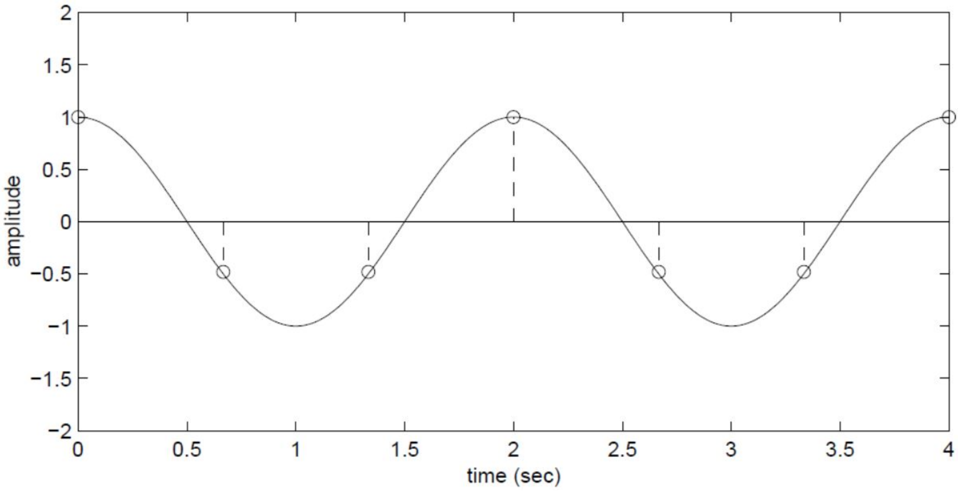
[12] Obviously if the signal was a sine instead of a cosine, we see that it would be wrong as we would have a 0 sampling everywhere, hence the precision about the sine component in the theorem...



If however we sample at a frequency lower than 2 [Hz], for example at 1.5 [Hz], then there are now not enough samples to capture all the peaks and troughs in the signal:

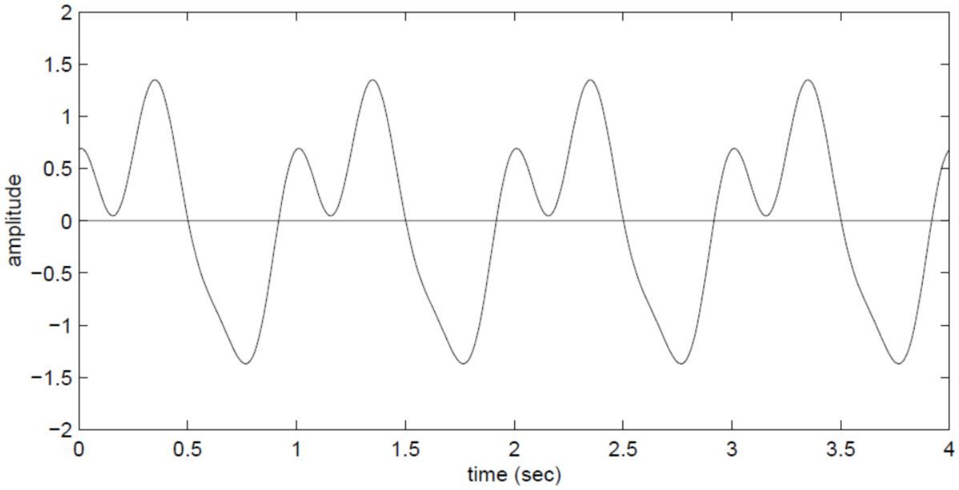


Note here that we are not only losing information, but we are getting the wrong information about the signal. The person receiving these samples, without any previous knowledge of the original signal, may well be mislead into thinking that the signal has quite a different form:

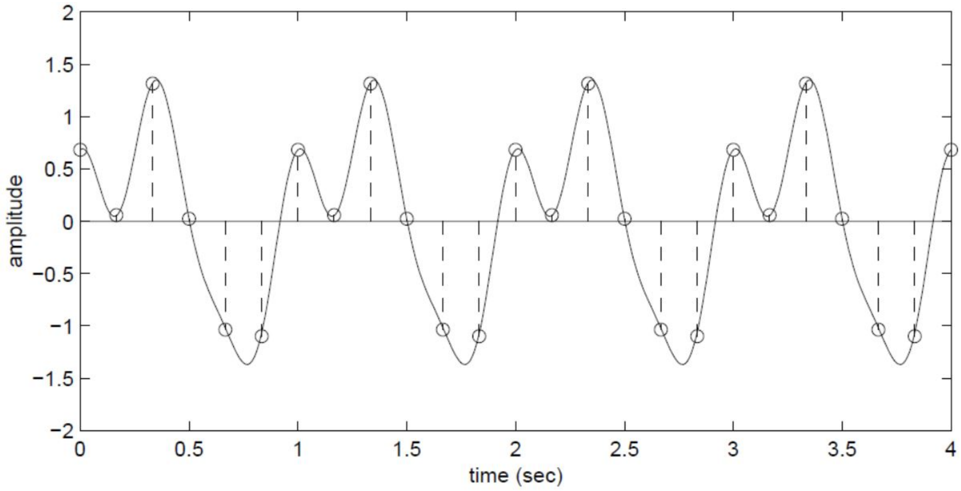


From this example, we can see the reason for the term "signal aliasing". That is, the signal now takes on a different "persona" or a false presentation, due to being sampled at an insufficiently high frequency.

Now we are ready to think about the sampling of little bit more perfectly periodic complex signal composed of some frequency components. By Fourier's theorem, we know that any continuous signal may be decomposed in terms of a sum of sines and cosines at different frequencies. For example, the following waveform was composed by adding together sinewaves at frequencies of 1 [Hz], 2 [Hz], and 3 [Hz]:



According to the Nyquist sampling "theorem", the signal must be sampled at twice the highest frequency contained in the signal. In this case, we have $f_c = 3$ [Hz], and so the Nyquist theorem tells us that the sampling frequency, f_s, must be at least 6 [Hz]. And sure enough, this appears to be sufficient (keep in mind that the example below is still a perfect periodic signal!):



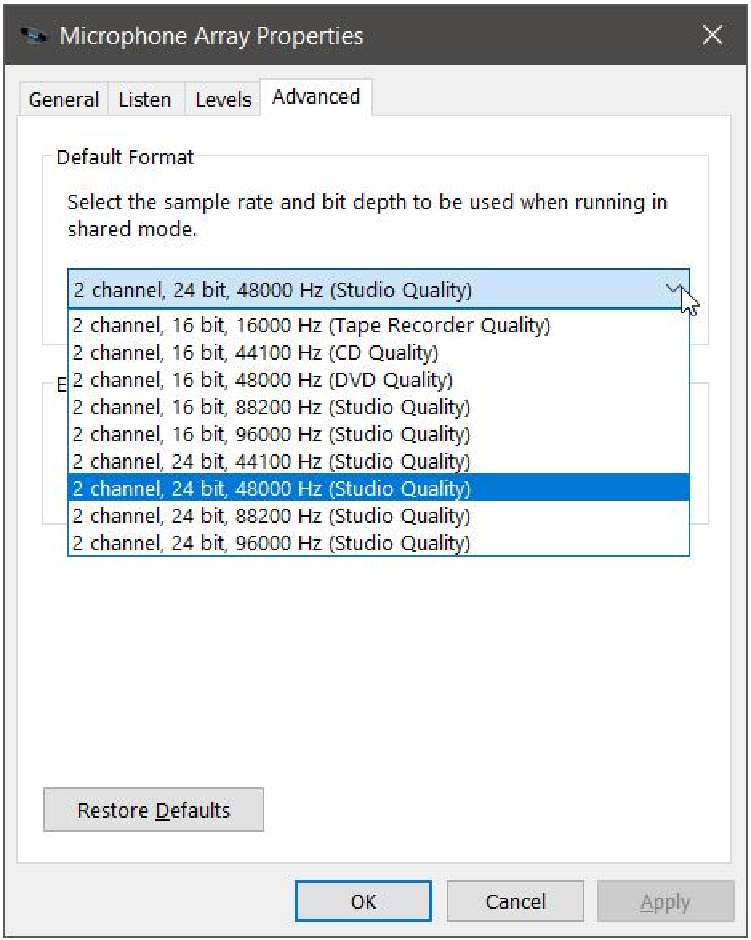
Thus, when a signal contains not just one but many different frequencies added together, the minimal sampling rate recommended to avoid aliasing at least that of the highest frequency, irrespective of how many other frequency components there are.

The human ear capabilities is between 20 [Hz] to $20,050$ [Hz] (see section Music Mathematics page 8198) hence the fact that many standard sampling rate are at satisfactory sampling rate of[13]:

$$20,050 \cdot 2 = 44,100\text{ [Hz]} = 44.1\text{ [kHz]} \tag{16.3.303}$$

But for telephony the usable voice range is for example 300 [Hz] to $3,400$ [Hz], so a sampling frequency of 8 [kHz] should be satisfactory enough in such a case.

By the way, on a computer operating system like Microsoft Windows, and for most microphone, the user can choose the sampling rate as illustrated below:



Default Format

Select the sample rate and bit depth to be used when running in shared mode.

2 channel, 24 bit, 48000 Hz (Studio Quality)

- 2 channel, 16 bit, 16000 Hz (Tape Recorder Quality)
- 2 channel, 16 bit, 44100 Hz (CD Quality)
- 2 channel, 16 bit, 48000 Hz (DVD Quality)
- 2 channel, 16 bit, 88200 Hz (Studio Quality)
- 2 channel, 16 bit, 96000 Hz (Studio Quality)
- 2 channel, 24 bit, 44100 Hz (Studio Quality)
- 2 channel, 24 bit, 48000 Hz (Studio Quality)
- 2 channel, 24 bit, 88200 Hz (Studio Quality)
- 2 channel, 24 bit, 96000 Hz (Studio Quality)

Figure 16.121: **Microsoft Windows 10 Microphone Array Properties**

Obviously the choices may depend on your material (computer/microphone).

---

[13] The rate 44.1 [kHz] was chosen in fact following debate between manufacturers, notably Sony and Philips, and its implementation by Sony, yielding a de facto standard.

✍**Example:**

An audiostream sampled at 44.1 [kHz] with an amplitude coded on 16 bits in stereo (2 channels) will have a bit rate of:

$$44100\cdot 16\cdot 2=1,411,200\;[\text{b}\cdot\text{s}^{-1}]\cong 1,441\;[\text{kbps}] \tag{16.3.304}$$

This is the typical CD quality (for those who know what is Compact Disc).

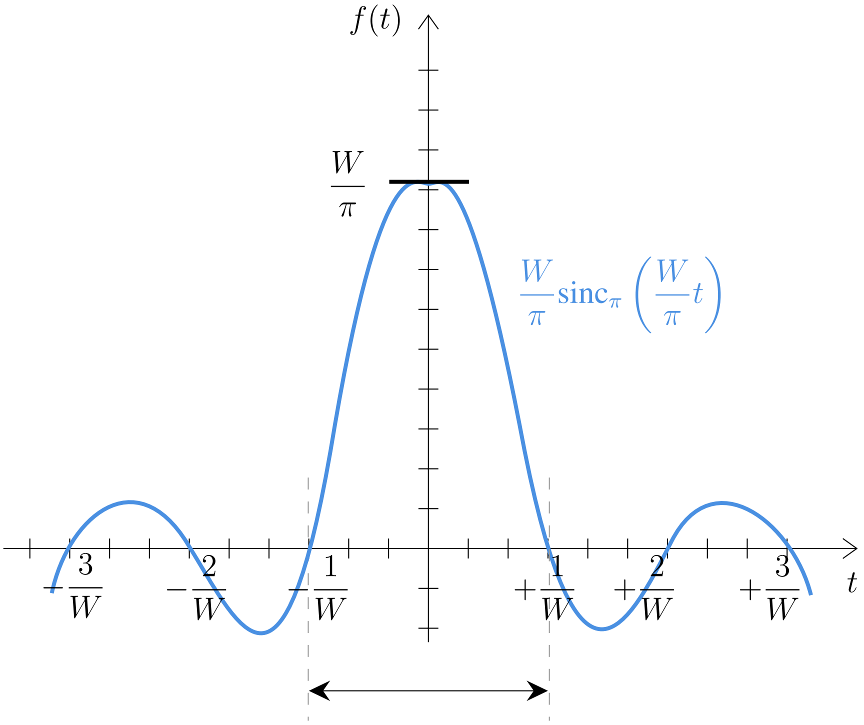
Most DAB+ broadcast (Digital Audio Broadcasting) emitter have much lower bitrate! The recommended one being 192 [kbps] (but the reader must keep in mind that this include the fact it is MPG compressed (using at least a Huffman algorithm as seen at page 7209) and also have additional error correcting code bits). Furthermore, best DAB+ methods seems to implements a technique named "VBR" for "Variational Bitrate" where the simple idea is that the bitrate change dynamically depending on the complexity of the signal.

Remark

Digital signal encoding based on uniformly distributed samples seems to be named "Linear Pulse Code Modulation" (abbreviated LPCM or simply PCM). It is used for example by CD (with a sample rate of 44.1 [Khz] and an amplitude binary coded on 16 bits) and also by some broadcasting techniques. For sounds like jazz, classic music, acoustic that have a lot of dynamics (variations) an amplitude of 24 bits is recommended... it is also used by movies theatres!

But if the reader was attentive when reading this first "pseudo explanation" maybe the latter has seen that the argumentation is a little bit weak...

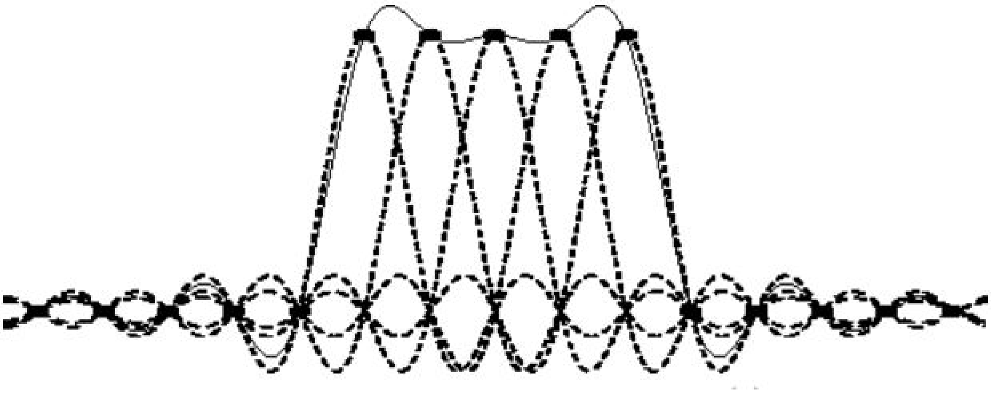
So here is the original one: In practice, for historical reasons, when we sample a continuous signal, we transform it into series of square pulses in the frequency domain (pulses of different lengths and amplitudes). To get the original signal back, we inverse Fourier transform the pulses and maybe if you remember our study and examples of inverse Fourier transform, the inverse Fourier transform of a square pulse of width $2W$ (this width being named "Nyquist bandwidth") in the frequency domain gives in the time domain the sinc function (see section Sequences and Series page 1766):



width of the main lobe is equal to $2/W$

Therefore sinc-shaped pulses possess a rectangular spectrum, enabling data to be encoded in a minimum spectral pulsation (i.e. frequency) bandwidth of $[-W,+W]$.

The final result for a series of square impulses in the frequency space is that we get a series of shifted sinc functions in the time space as illustrated below with a special example, named sometimes a "Nyquist sinc pulse":



The dots show the signal samples, the dashed lines show the component shifted sinc functions, and the solid line shows the unique bandlimited reconstruction from the samples obtained by summing the component sinc functions.

Looking to the figure above the reader can't ignore (in a practical point of view!) the fact that if the distance pic-to-pic of each sine cardinal is equal to $1/W$ it will greatly improve DAC (Digital to Analogic Converters) to detect points of interest for the conversion as they are significantly spaced. Keep in mind this information for later!

Remark

The reader can notice that we have intersymbol interference in the previous figure, this effect is named "intersymbol interference" or abbreviated "ISI". As we will see further below, the Nyquist sampling theorem prove in fact that this interferences cancels each other!

In communications, we name "Nyquist ISI criterion" the conditions which, when satisfied by a communication channel (including responses of transmit and receive filters), result in no intersymbol interference!

The idea of the processes is illustrated below (the step with the sine cardinal is not visible):

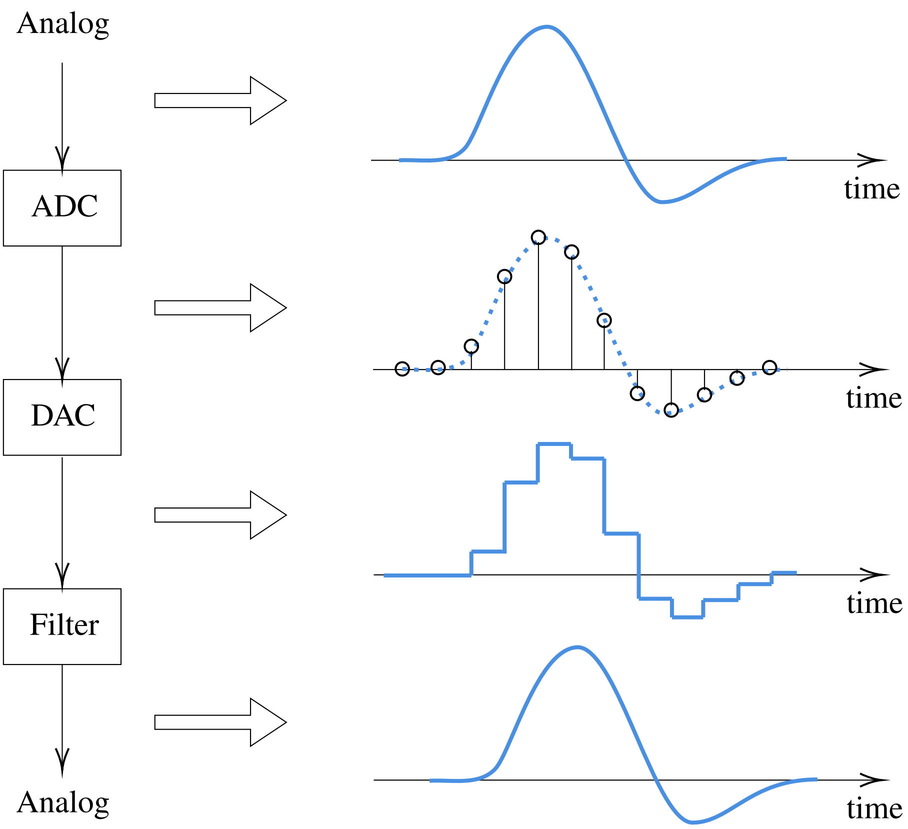


Figure 16.122: DAC and ADC converter concepts

And this was the real idea (we should rather speak of "question") of Harry Nyquist and Claude Shannon!!!!!!!!! Is it possible using only sine cardinal as kernels under and under certain conditions to rebuild any given original signal that is perfectly periodic and using a sampling time spaced?

So here it comes... the real technical version of the theorem:

Theorem 16.2. If $s(t)$ and $F(\omega)$, the Fourier transform of $s(t)$, is supported on the interval $[-f_c,+f_c]$ then:

$$s(t)=\sum_{n\in\mathbb{Z}} \underbrace{f\left(\frac{n}{2f_c}\right)}_{\text{amplitue of Nyquist pulse}} \underbrace{\operatorname{sinc}\left(2f_c\left(t-\frac{n}{2f_c}\right)\right)}_{\text{Nyquist pulse}} \qquad (16.3.305)$$

In other words, the theorem says that if an absolutely integrable function $s(t)$ contains no frequencies higher than f_c [Hz], then it is completely determined by its samples at a uniform grid spaced at distances $1/(2f_c)$ apart via the relation above where the ideal interpolation kernel is proportional to the sinc function (at the time the theorem was written, the cardinal sine was considered as a nice symmetrical decreasing function to describe and interpolate a frequency spectrum[14]!).

Remark

At the opposite of what most textbooks or Internet websites say, the Nyquist sampling theorem doesn't says what is the ideal sample frequency but just says that the above relation exists!!!

Proof 16.2.1. The spectral analysis theorem shows that any signal can be decomposed into a sum of sinusoids of different frequencies, amplitudes and phases. We consider a signal inscribed between a minimum frequency and a maximum frequency. Experience determines which frequency range is of interest. Even if the frequency coefficients outside this range are not zero, they are neglected since they do not contribute significantly to the total mean square value.

Let us recall that the Fourier Transform $F(\omega)$ of a function $f(t)$ is given by (see section Sequences and Series page 1758 or section Functional Analysis page 2305):

$$\mathcal{F}(f(t))(\omega)=F(\omega)=\int\limits_{-\infty}^{+\infty} f(t)e^{\mathrm{i}\omega t}\mathrm{d}t \tag{16.3.306}$$

To avoid any notation confusion for what follows we will write it (the s stand for "signal"):

$$\mathcal{F}(s(t))(\omega)=F(\omega)=\int\limits_{-\infty}^{+\infty} s(t)e^{\mathrm{i}\omega t}\mathrm{d}t \tag{16.3.307}$$

The Fourier transform described the signal by its frequencies f that it contains, expressed in these equations by the means of the pulsation $\omega=2\pi f$.

As we know the inverse Fourier transform gives $s(t)$ in function of $F(\omega)$:

$$\mathcal{F}^{-1}\left(F(\omega)\right)(t)=s(t)=\dfrac{1}{2\pi}\int\limits_{-\infty}^{+\infty} F(\omega)e^{\mathrm{i}\omega t}\mathrm{d}\omega \tag{16.3.308}$$

The signal of which the theorem deals is limited in frequency (the square pulse as we know). Beyond $f_{\max}$, corresponding to a pulsation $\omega_{\max}=2\pi f_{\max}$, the frequency coefficients are considered as negligible.

Therefore:

$$\mathcal{F}^{-1}\left(F(\omega)\right)(t)=s(t)=\dfrac{1}{2\pi}\int\limits_{-\omega_{\max}}^{+\omega_{\max}} F(\omega)e^{\mathrm{i}\omega t}\mathrm{d}\omega \tag{16.3.309}$$

---

[14] Hence this theorem is more a "communication engineering theorem" than a purely general math theorem!

Let us look for the value of the samples e_n regularly spaced taking the values of $s(t)$ for t multiple of a given fraction of highest frequency component of the signal:

$$t_n = n\frac{1}{kf_{\text{max}}} = \frac{nT_{\text{max}}}{k} \tag{16.3.310}$$

Hence:

$$e_n = s\left(\frac{nT_{\text{max}}}{k}\right) = \frac{1}{2\pi}\int\limits_{-\omega_{\text{max}}}^{+\omega_{\text{max}}} F(\omega)e^{\mathrm{i}\omega\frac{nT_{\text{max}}}{k}}\mathrm{d}\omega \tag{16.3.311}$$

Now let us recall that we have proved that the coefficient of a Fourier series was given by:

$$c_n = \frac{1}{T}\int\limits_{-\frac{T}{2}}^{+\frac{T}{2}} f(t)e^{-\mathrm{i}\frac{2\pi n}{T}t}\mathrm{d}t = \frac{1}{T}\int\limits_{-\frac{T}{2}}^{+\frac{T}{2}} f(t)e^{-\mathrm{i}\omega nt}\mathrm{d}t \tag{16.3.312}$$

Let us imagine this latter Fourier coefficient (that is for recall in time space) but in frequency (i.e. pulsation) space (!!!), then it would be written:

$$c_n = \frac{1}{c_1^{te}\omega}\int\limits_{-c_2^{te}\omega}^{+c_2^{te}\omega} f(\omega)e^{-\mathrm{i}Tn\omega}\mathrm{d}\omega \tag{16.3.313}$$

In the case of our square pulse that has a frequency domain limited between $[-\omega_{\text{max}}, +\omega_{\text{max}}]$ (hence a width of $2\omega_{\text{max}}$), we then rewrite the latter relation with:

$$c_n = \frac{1}{2\omega_{\text{max}}}\int\limits_{-\omega_{\text{max}}}^{+\omega_{\text{max}}} F(\omega)e^{-\mathrm{i}\frac{T_{\text{max}}}{k}n\omega}\mathrm{d}\omega \tag{16.3.314}$$

For recall we divide by $2\omega_{\text{max}}$ because:

- It is the width of our square pulse
- Because we need the average value

Hence:

$$c_{-n} = \frac{1}{2\omega_{\text{max}}}\int\limits_{-\omega_{\text{max}}}^{+\omega_{\text{max}}} F(\omega)e^{\mathrm{i}\frac{T_{\text{max}}}{k}n\omega}\mathrm{d}\omega = \frac{\pi e_n}{\omega_{\text{max}}} \tag{16.3.315}$$

The reconstruction of $F(\omega)$ in Fourier series is given as we know by:

$$F(\omega) = \sum_{n=-\infty}^{+\infty} c_n e^{\mathrm{i}\omega n\frac{T_{\text{max}}}{k}} = \sum_{n=-\infty}^{+\infty} c_{-n} e^{-\mathrm{i}\omega n\frac{T_{\text{max}}}{k}} = \sum_{n=-\infty}^{+\infty} c_{-n} e^{-\mathrm{i}\omega n\frac{2\pi}{k\omega_{\text{max}}}} \tag{16.3.316}$$

Therefore:

$$\begin{aligned}
\mathcal{F}^{-1}\left(F(\omega)\right)(t)=s(t)&=\frac{1}{2\pi}\int\limits_{-\infty}^{+\infty}F(\omega)e^{\mathrm{i}\omega t}\mathrm{d}\omega=\frac{1}{2\pi}\int\limits_{-\omega_{\max}}^{+\omega_{\max}}F(\omega)e^{\mathrm{i}\omega t}\mathrm{d}\omega\\
&=\frac{1}{2\pi}\int\limits_{-\omega_{\max}}^{+\omega_{\max}}\left(\sum_{n=-\infty}^{+\infty}c_{-n}e^{-\mathrm{i}\omega n\frac{2\pi}{k\omega_{\max}}}\right)e^{\mathrm{i}\omega t}\mathrm{d}\omega\\
&=\frac{1}{2\pi}\int\limits_{-\omega_{\max}}^{+\omega_{\max}}\left(\sum_{n=-\infty}^{+\infty}c_{-n}e^{\mathrm{i}\omega\left(t-n\frac{2\pi}{k\omega_{\max}}\right)}\right)\mathrm{d}\omega\\
&=\frac{1}{2\pi}\int\limits_{-\omega_{\max}}^{+\omega_{\max}}\left(\sum_{n=-\infty}^{+\infty}\left(\frac{\pi e_n}{\omega_{\max}}\right)e^{\mathrm{i}\omega\left(t-n\frac{2\pi}{k\omega_{\max}}\right)}\right)\mathrm{d}\omega\\
&=\frac{1}{2\omega_{\max}}\int\limits_{-\omega_{\max}}^{+\omega_{\max}}\left(\sum_{n=-\infty}^{+\infty}e_n e^{\mathrm{i}\omega\left(t-n\frac{2\pi}{k\omega_{\max}}\right)}\right)\mathrm{d}\omega\\
&=\frac{1}{2\omega_{\max}}\sum_{n=-\infty}^{+\infty}\left(\int\limits_{-\omega_{\max}}^{+\omega_{\max}}s\left(\frac{nT_{\max}}{k}\right)e^{\mathrm{i}\omega\left(t-n\frac{2\pi}{k\omega_{\max}}\right)}\mathrm{d}\omega\right)\\
&=\frac{1}{2\omega_{\max}}\sum_{n=-\infty}^{+\infty}s\left(\frac{nT_{\max}}{k}\right)\left(\int\limits_{-\omega_{\max}}^{+\omega_{\max}}e^{\mathrm{i}\omega\left(t-n\frac{2\pi}{k\omega_{\max}}\right)}\mathrm{d}\omega\right)
\end{aligned}\tag{16.3.317}$$

Now we will focus on the integral only:

$$\begin{aligned}
\int\limits_{-\omega_{\max}}^{+\omega_{\max}}e^{\mathrm{i}\omega\left(t-n\frac{2\pi}{k\omega_{\max}}\right)}\mathrm{d}\omega&=\frac{1}{\mathrm{i}\left(t-n\frac{2\pi}{k\omega_{\max}}\right)}\left[e^{\mathrm{i}\omega\left(t-n\frac{2\pi}{k\omega_{\max}}\right)}\right]\Bigg|_{-\omega_{\max}}^{+\omega_{\max}}\\
&=\frac{1}{\mathrm{i}\left(t-n\frac{2\pi}{k\omega_{\max}}\right)}\left[e^{\mathrm{i}\omega_{\max}\left(t-n\frac{2\pi}{k\omega_{\max}}\right)}-e^{-\mathrm{i}\omega_{\max}\left(t-n\frac{2\pi}{k\omega_{\max}}\right)}\right]\\
&=\frac{\omega_{\max}}{t\omega_{\max}-n\frac{2\pi}{k}}\left[\frac{e^{\mathrm{i}\left(t\omega_{\max}-n\frac{2\pi}{k}\right)}-e^{-\mathrm{i}\left(t\omega_{\max}-n\frac{2\pi}{k}\right)}}{\mathrm{i}}\right]\\
&=\frac{\omega_{\max}}{t\omega_{\max}-n\frac{2\pi}{k}}2\sin\left(t\omega_{\max}-n\frac{2\pi}{k}\right)\\
&=2\omega_{\max}\mathrm{sinc}\left(t\omega_{\max}-n\frac{2\pi}{k}\right)
\end{aligned}\tag{16.3.318}$$

Therefore:

$$\begin{aligned}\mathcal{F}^{-1}\left(F(\omega)\right)(t)=s(t)&=\frac{1}{2\omega_{\text{max}}}\sum_{n=-\infty}^{+\infty}s\left(\frac{nT_{\text{max}}}{k}\right)\left(\int\limits_{-\omega_{\text{max}}}^{+\omega_{\text{max}}}e^{\mathrm{i}\omega\left(t-n\frac{2\pi}{k\omega_{\text{max}}}\right)}\mathrm{d}\omega\right)\\&=\frac{1}{2\omega_{\text{max}}}\sum_{n=-\infty}^{+\infty}s\left(\frac{nT_{\text{max}}}{k}\right)\left(2\omega_{\text{max}}\text{sinc}\left(t\omega_{\text{max}}-n\frac{2\pi}{k}\right)\right)\\&=\sum_{n=-\infty}^{+\infty}s\left(\frac{nT_{\text{max}}}{k}\right)\text{sinc}\left(t\omega_{\text{max}}-n\frac{2\pi}{k}\right)\\&=\sum_{n=-\infty}^{+\infty}s\left(\frac{n}{kf_{\text{max}}}\right)\text{sinc}\left(t2\pi f_{\text{max}}-n\frac{2\pi}{k}\right)\\&=\sum_{n=-\infty}^{+\infty}s\left(\frac{n}{kf_{\text{max}}}\right)\text{sinc}\left(2\pi f_{\text{max}}\left(t-\frac{n}{kf_{\text{max}}}\right)\right)\end{aligned}\tag{16.3.319}$$

Hence:

$$s(t)=\sum_{n=-\infty}^{+\infty}s\left(\frac{n}{kf_{\text{max}}}\right)\text{sinc}\left(2\pi f_{\text{max}}\left(t-\frac{n}{kf_{\text{max}}}\right)\right)\tag{16.3.320}$$

In technical words we say that: By time-frequency symmetry, we have equally a Fourier series expansion of a band-limited Fourier transform!

Let us focus on the sinc term and plot if in Maple™ 4.00 for $k=1,k=2,k=3$ and three different pulses (we choose $f_{\text{max}}=50$ but the value of the frequency doesn't change at all the conclusion):

```
>with(plots):
>k:=1;
>plot([sin(2*Pi*50*t)/(2*Pi*50*t),sin(2*Pi*50*(t-1/(k*50)))/(2*Pi*50*(t-1/(k*50))),
sin(2*Pi*50*(t-2/(k*50)))/(2*Pi*50*(t-2/(k*50)))],t=-0.1..0.1);
>k:=2;
>plot([sin(2*Pi*50*t)/(2*Pi*50*t),sin(2*Pi*50*(t-1/(k*50)))/(2*Pi*50*(t-1/(k*50))),
sin(2*Pi*50*(t-2/(k*50)))/(2*Pi*50*(t-2/(k*50)))],t=-0.1..0.1);
>k:=3;
>plot([sin(2*Pi*50*t)/(2*Pi*50*t),sin(2*Pi*50*(t-1/(k*50)))/(2*Pi*50*(t-1/(k*50))),
sin(2*Pi*50*(t-2/(k*50)))/(2*Pi*50*(t-2/(k*50)))],t=-0.1..0.1);
```

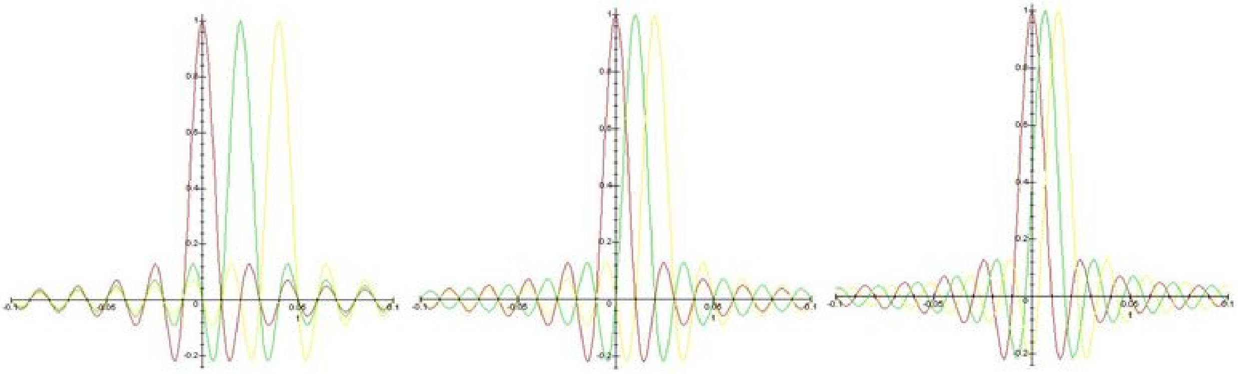

Figure 16.123: A Nyquist sinc pulses for $k=1,2,3$ and $f_{\text{max}}=50$ in Maple™ 4.00b

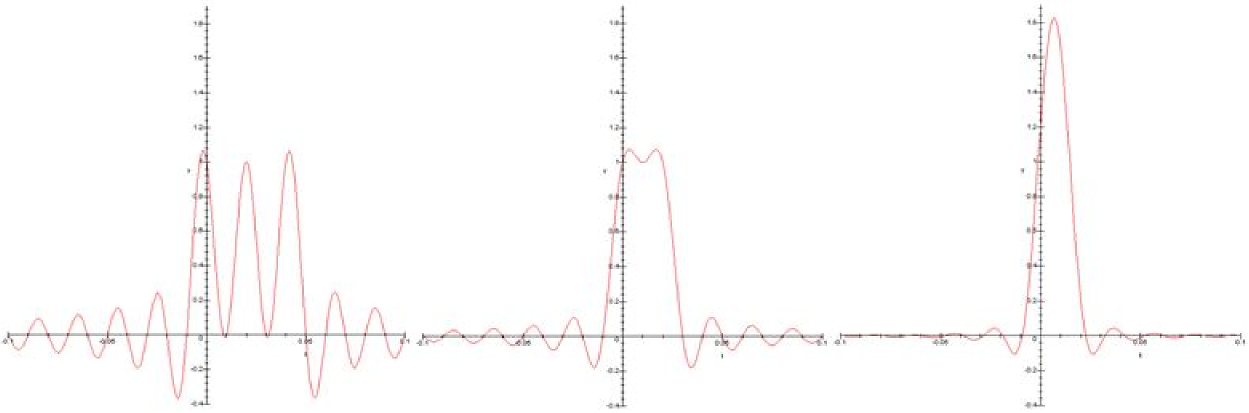
We clearly see that it is the middle one ($k=2$) that satisfies the previously criteria of the Nyquist sine pulse. The sum of the three pulses gives respectively:



So with the plots we see that we need $k=2$ (in other words the sampling frequency must be twice the frequency of the highest frequency term of the Fourier series) to fall back on the Nyquist and Shannon best practice recommendation for perfect periodic signals sent original by square pulse signal in the frequency domain. Hence the final result:

$$s(t)=\sum_{n=-\infty}^{+\infty} s\left(\frac{n}{2f_{\text{max}}}\right)\operatorname{sinc}\left(2\pi f_{\text{max}}\left(t-\frac{n}{2f_{\text{max}}}\right)\right)=\sum_{n=-\infty}^{+\infty} s\left(\frac{n\pi}{\omega_{\text{max}}}\right)\operatorname{sinc}\left(\omega_{\text{max}}\left(t-\frac{\pi n}{\omega_{\text{max}}}\right)\right) \tag{16.3.321}$$

Thus after simplification:

$$\boxed{s(t)=\sum_{n=-\infty}^{+\infty} s\left(\frac{n\pi}{\omega_{\text{max}}}\right)\operatorname{sinc}\left(\omega_{\text{max}}t-n\pi\right)} \tag{16.3.322}$$

So the reader must keep in mind that is, in general, the value k is not uniquely determined for $s(t)$, however, sufficient smoothness, e.g., continuity, implies its unique definition.

■ Q.E.D.

16.3.7 Semiconductor devices

16.3.7.1 Diodes

We will deal now with pn-junctions that are of importance for several modern (120th and 121th century according to holocene calendar) electronic devices like diodes (e.g. optical detectors, solar cells, light emitting diodes, LASER diodes), bipolar transistors, thyristor and field effect transistors. In the following the operating principle of pn-junctions will be discussed starting from the semiconductor materials. The ideal diode equation will be derived. Furthermore, an equivalent circuit for pn-junctions will be presented.

💣Caution! We are actually very not satisfied of what we wrote below. The text is sometimes confusing, and the series of successive approximations of the mathematical models don't help and should be highlighted even more that it already is! Lot more of figures and remarks should also very likely be added to make the whole more comprehensible. So we apologize in advance. If anyone want to help us to improve what follows, he or she is welcome to contact us.

The main characteristic of a pn-junction, or a diode, is that for positive voltages ("forward bias") the diode is conductive, whereas for negative voltages ("reverse bias") the current flow is blocked. Due to this properties a diode can be used for several applications like rectifiers, sampling circuits, demodulators, logic gates and so on.

Remark

For the readers interested in further reading, we strongly recommend the following references: [523] and [508] and finally [553].

A silicon pn-junction can be realized by the formation of a junction between an n-type and a p-type doped region. The junction can be formed by the implantation or diffusion of dopants in a wafer. For example a silicon pn-junction can be formed by the implantation of Boron (B) atoms in a n-type Silicon wafer.

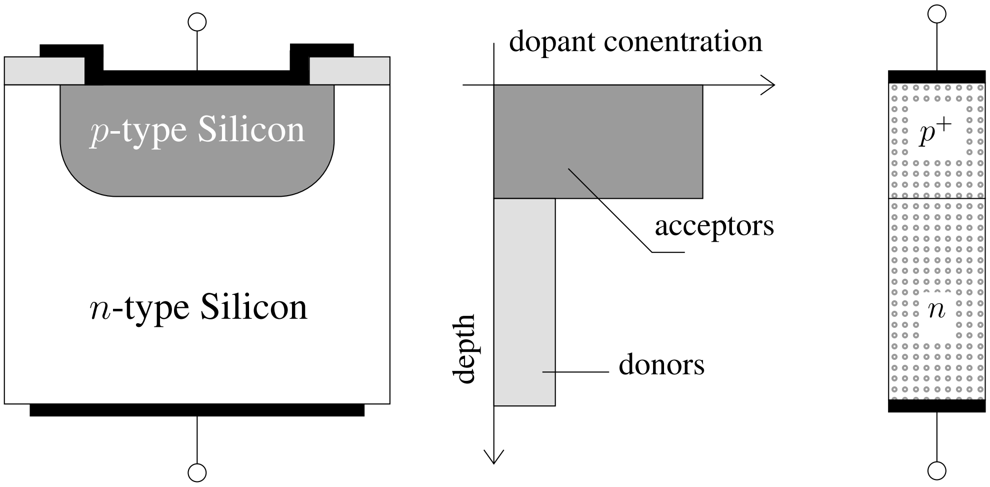


Figure 16.124: Silicon pn-junction: (left) Fabricated by the implantation or diffusion of boron atoms into an n-type (phosphorus doped) silicon wafer. (middle) Concentration of donors and acceptors in the wafer. (right) Cross section of a pn-junction.

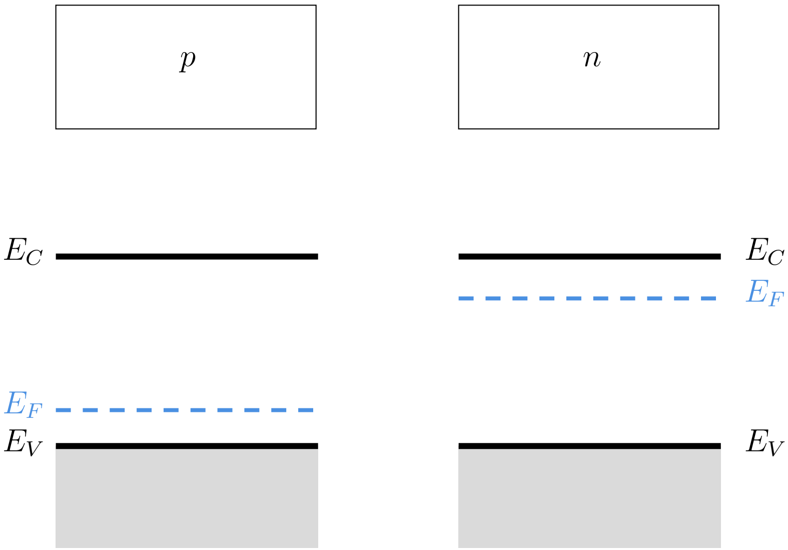
In order to understand the operating principle of a pn-junction we will start with two separate n-type and p-type semiconductors. For the p-type semiconductor the Fermi level (see section Wave Quantum Physics page 4807) is close to the valence band, whereas for the n-type semiconductor the Fermi level is close to the conduction band:



In our case we assume that the semiconducting materials are silicon and the band gaps for both pieces of materials are equal. In this case we speak about a "homo-junction".

As the Fermi level in both pieces of silicon is constant, the semiconductors are in thermal equilibrium.

When the p-type and the n-type semiconductors are jointed together a carrier concentration gradient is observed at the interface of the n- and p-region. The gradient leads to the diffusion of carriers. The diffusion occurs because the concentration of electrons in the n-type semiconductor is much higher than the concentration of electrons in the p-type semiconductor. The opposite behaviour is observed for the holes. The hole concentration in the p-type semiconductor is much higher than the hole concentration in the n-type semiconductor. Consequently, holes from the p-side diffuse towards the $n$side and vice versa. Despite the flow of electrons and holes the device is still in thermal equilibrium.

16.3.7.1.1 Ideal Diode Equation

Before entering a quantitative analysis of the diode characteristics, it is useful to review the relationships that determine carrier concentrations. To avoid confusion with exponential functions the symbol q_e will be used for the electronic charge instead of e.

16.3.7.1.1.1 Carrier concentrations in pure semiconductors

In thermal equilibrium the probability that an electron state in the conduction band is filled is given by the Fermi–Dirac distribution (see section Statistical Mechanics page 3571):

$$f_{FD}(E)=\frac{1}{e^{(E-E_F)/kT}+1} \tag{16.3.323}$$

The parameter E_F is as we know the Fermi level energy (or chemical potential). The density of atoms in a Si or Ge crystal is about $5\cdot 10^{22}\,[\text{atoms}\cdot\text{cm}^{-3}]$. Since the minimum carrier density of interest in practical devices is of order 10^{10} to $10^{11}\,[\text{cm}^{-3}]$, very small occupancies are quite important.

In silicon the band gap is $1.12\,[\text{eV}]$. If the Fermi level is at midgap, the band-edges will be $0.56\,[\text{eV}]$ above and below E_F. Relatively large deviations from the Fermi level, i.e. extremely small occupancies, will still yield significant carrier densities.

The number of occupied electron states N_e is determined by summing over all available states multiplied by the occupation probability for each individual state:

$$N_e=\sum_i p_i f(E_i) \tag{16.3.324}$$

Since the density of states near the band edge tends to be quite high, this can be written as an integral:

$$N_e=\int\limits_{E_c}^{+\infty} f(E)g(E)\mathrm{d}E \tag{16.3.325}$$

where $g(E)$ is the density of states. Solution of this integral requires knowledge of the density of states. Fortuitously, to a good approximation the density of states near the band edge has a parabolic distribution:

$$g(E)\mathrm{d}E\propto(E-E_C)^{1/2} \tag{16.3.326}$$

As the energy increases beyond the band edge, the distribution will deviate from the simple parabolic form, but since the probability function decreases very rapidly, the integral will hardly be affected.

The second obstacle to a simple analytical solution of the integral is the intractability of integrating over the Fermi distribution (at least outside the simple case where the bounds of the integral range from 0 to $+\infty$). Fortunately, if $E-E_F$ is at least several times kT, the Fermi distribution can be approximated by a Boltzmann distribution. Indeed, we have:

$$1+e^{(E-E_F)/kT}\cong e^{(E-E_F)/kT} \tag{16.3.327}$$

Therefore:

$$f_{FD}(E) \cong \frac{1}{e^{(E-E_F)/kT}} = f_B(E) = e^{-(E-E_F)/kT} \tag{16.3.328}$$

At energies $2.3\,kT$ beyond the Fermi level the difference between the Boltzmann approximation and the Fermi distribution is $< 10\%$, for energies $> 4.5\,kT$ it is less than 1%.

Applying the approximation to the occupancy of hole states, the probability of a hole state being occupied, i.e. a valence state being empty, is:

$$f_h(E) = 1 - f_e(E) = \frac{1}{e^{(E_F-E)/kT}+1} \cong e^{-(E_F-E)/kT} \tag{16.3.329}$$

The conditions for the Boltzmann approximation are fulfilled for excitation across the band gap, as the band gap is of order $1\,[\text{eV}]$ and kT at room temperature is 0.026 [eV].

With these simplifications the number of electrons in the conduction band in thermal equilibrium is given by (see page 4296):

$$n_e \propto (kT)^{3/2} e^{-(E_c-E_F)/kT} \tag{16.3.330}$$

or:

$$n_e = N_C e^{-(E_C-E_F)/kT} \tag{16.3.331}$$

where N_C is the effective density of states at the band edge. Correspondingly, the hole concentration is given and denoted by:

$$p = N_V e^{-(E_F-E_V)/kT} \tag{16.3.332}$$

Under thermal equilibrium the quasi Fermi levels for electrons and holes are identical, so that the Fermi potential is identical for electrons and holes.

In an ideal semiconductor the only source of mobile carriers is thermal excitation across the band gap (additional impurity atoms or crystal imperfections that would allow other excitation mechanisms are absent), so the concentrations of electrons and holes are equal:

$$n = p = n_i \tag{16.3.333}$$

n_i is named the "intrinsic carrier concentration". As we have already seen it in a table (see section Electrokinetis page 4303), in Silicium ($E_g = 1.12\,[\text{eV}]$) the intrinsic concentration $n_i = 1.45 \cdot 10^{10}\,[\text{cm}^{-3}]$ at 300 [K] and in Germanium ($E_g = 0.66\,[\text{eV}]$), $n_i = 2.4 \cdot 10^{13}\,[\text{cm}^{-3}]$. For comparison, the purest semiconductor material that has been fabricated is Ge with active impurity levels of about $3 \cdot 10^{10}\,[\text{cm}^{-3}]$ (these numbers must be compared to the fact that such solids have a density of atoms of the order of $10^{22}\,[\text{cm}^{-3}]$).

Using the above results:

$$n_i = N_C e^{-(E_C-E_F)/kT} = N_V e^{-(E_F-E_V)/kT} \tag{16.3.334}$$

which one can solve to get:

$$E_F = E_i = \frac{E_C+E_V}{2} - \frac{kT}{2}\ln\left(N_c/N_V\right) \tag{16.3.335}$$

If the band structure is symmetrical ($N_C = N_V$), the intrinsic energy level E_i lies near the middle of the band gap. Even rather substantial deviations from a symmetrical band structure will not affect this result significantly, as N_c/N_V enters logarithmically and kT is much smaller than the band gap.

A remarkable result is that the product of the quasi-electron and quasi-hole concentrations, named the "law of the junction":

$$\boxed{np = n_i^2 = N_C N_V e^{-(E_C - E_V)/kT} = N_C N_V e^{-E_g/kT}} \tag{16.3.336}$$

depends only on the band gap E_g and not on the Fermi level.

Remark

This relation can also be found in the following (ambiguous) form in many textbooks:

$$np = n_i^2 e^{-\left(E_F^{(n)} - E_F^{(p)}\right)/kT} = n_i^2 e^{qU/kT} \tag{16.3.337}$$

This result, the law of mass action, is very useful in semiconductor device analysis. It requires only that the Boltzmann approximation holds! Qualitatively, it says that if one carrier type exceeds this equilibrium concentration, recombination will decrease the concentrations of both electrons and holes to maintain $np = {n_i}^2$, a relationship that also holds in doped crystals.

16.3.7.1.1.2 Carrier concentrations in doped crystals

The equality $n_e = n_h$ only holds for pure crystals, where all of the electrons in the conduction band have been thermally excited from the valence band. In practical semiconductors the presence of impurities tips the balance towards either electrons or holes.

Impurities are an unavoidable byproduct of the crystal growth process, although special techniques can achieve astounding results. For example, as noted above, in the purest semiconductor crystals – "ultrapure" Ge – the net impurity concentration is about $3 \cdot 10^{10}\;[\text{cm}^{-3}]$.

In semiconductor device technology impurities are introduced intentionally to control the conductivity of the semiconductor. Let ${N_d}^+$ be the concentration of ionized donors and ${N_a}^-$ the concentration of ionized acceptors. Overall charge neutrality is preserved, as each ionized dopant introduces a charged carrier and an oppositely charged atom, but the net carrier concentration is now:

$$\Delta n = n - p = N_d^+ - N_a^- \tag{16.3.338}$$

or:

$$p + N_d^+ = n + N_a^- \tag{16.3.339}$$

Let us assume that the activation energy of the donors and acceptors is sufficiently small so that they are fully ionized. Then ${N_d}^+ = N_d$ and ${N_a}^- = N_a$, so:

$$p + N_d = n + N_a \tag{16.3.340}$$

which, using $np = {n_i}^2$, becomes:

$$\begin{aligned} p + N_d &= \frac{n_i^2}{p} + N_a \\ \frac{p}{N_a} + \frac{N_d}{N_a} &= \frac{n_i}{p}\frac{n_i}{N_a} + 1 \end{aligned} \tag{16.3.341}$$

If the acceptor concentration $N_a \gg N_d$ and $N_a \gg n_i$, the hole and electron concentrations:

$$p \approx N_a \quad \text{and} \quad n \approx \frac{n_i^2}{N_a} \ll N_a \tag{16.3.342}$$

i.e. the conductivity is dominated by holes. Conversely, if the donor concentration $N_d \gg N_a$ and $N_d \gg n_i$ the conductivity is dominated by electrons such that:

$$n \approx N_d \quad \text{and} \quad n \approx \frac{n_i^2}{N_d} \ll N_d \tag{16.3.343}$$

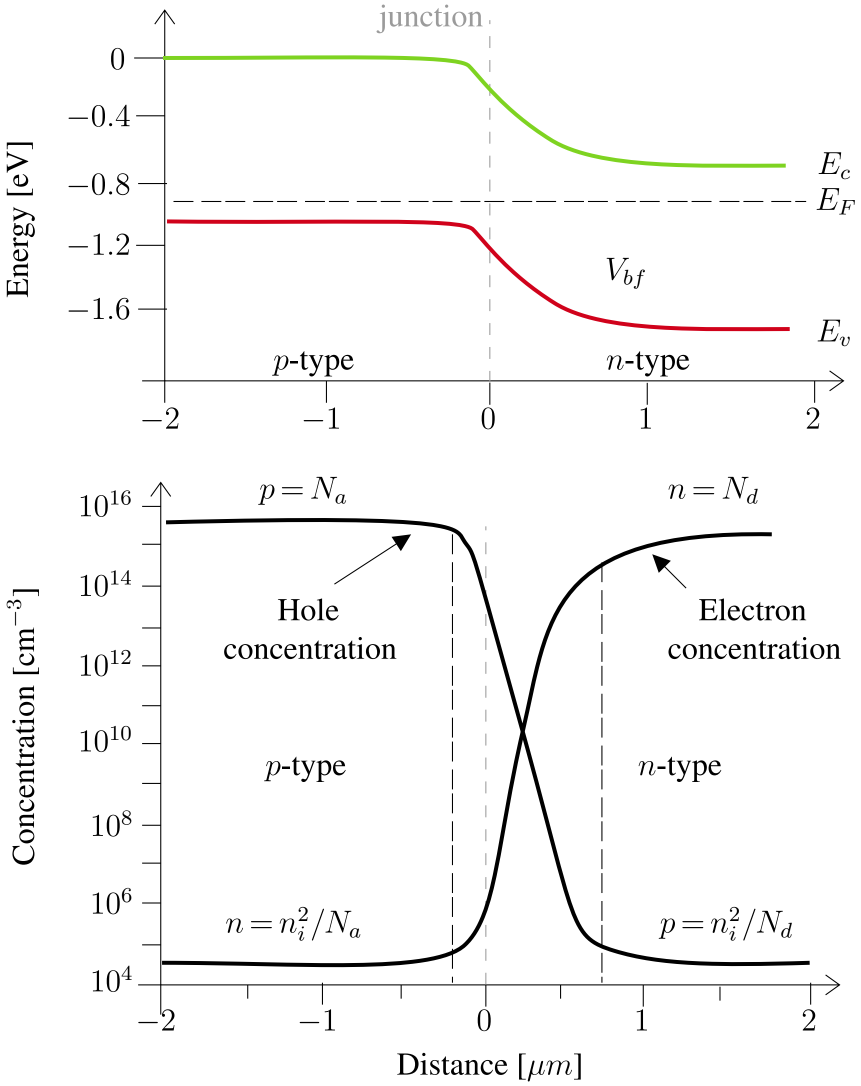

Figure 16.126: **Energy band diagram and carrier concentration for a silicon pn-junction at zero bias**

If the conductivity is dominated by only one type of carrier, the Fermi level is easy to determine. If, for example, $n \gg p$ then the Boltzmann approximation can be written as:

$$n = N_d - N_a = N_C e^{-(E_C - E_F)/kT} \tag{16.3.344}$$

yielding:

$$\frac{E_C - E_F}{kT} = \ln\left(\frac{N_C}{N_d - N_a}\right) \tag{16.3.345}$$

If $N_d \gg N_a$, then $E_C - E_F$ must be small, i.e. the Fermi level lies close to the conduction band edge.

In reality the impurity levels of common dopants are not close enough to the band edge for the Boltzmann approximation to hold, so the calculation must use the Fermi distribution and solve numerically for E_F. Nevertheless, the qualitative conclusions derived here still apply.

It is often convenient to refer all of these quantities to the intrinsic level E_i, as it accounts for both E_C and E_V. Then:

$$\begin{aligned} n &= N_C e^{-(E_C - E_F)/kT} = n_i e^{-(E_F - E_i)/kT} \\ p &= N_V e^{-(E_F - E_V)/kT} = n_i e^{-(E_i - E_F)/kT} \end{aligned} \tag{16.3.346}$$

Obviously the reader must keep in mind that all this lead from as series of successive approximations!

16.3.7.1.1.3 pn-junctions

A pn-junction is formed at the interface of a p- and an n-type region. Since the electron concentration in the n-region is greater than in the p-region, electrons will diffuse into the p-region. Correspondingly, holes will diffuse into the n-region. As electrons and holes diffuse across the junction, a space charge due to the ionized donor and acceptor atoms builds up. The field due to this space charge is directed to impede the flow of electrons and holes.

The situation is dynamic. The concentration gradient causes a continuous diffusion current to flow, whereas the field due to the space charge drives a drift current in the opposite direction. Equilibrium is attained when the two currents are equal, i.e. the sum of the diffusion current (caused by the gradient of the carrier concentration) and drift current (caused by the electric field) is zero. The net hole current density is the sum of the diffusion current density (see section Thermodynamics page 3699) and of the drift current density (see section Electrokinetics page 4229):

$$J_p = J_{\text{diff}} + J_{\text{drift}} = -q_e D_p \frac{\mathrm{d}p}{\mathrm{d}x} + q_e p \mu_p E_p = q_e\left(D_p \frac{\mathrm{d}p}{\mathrm{d}x} - p\mu_p E_p\right) \tag{16.3.347}$$

where D_p is the diffusion constant for holes and E_p is the electric field in the p-region, p is the holes density and μ_p the holes mobility.

Remark

Remember that first Fick's law (i.e. "diffusion equation" or "transport equation" as derived at page 3698) will be written:

$$J_{p,\text{diff}}=-q_e D_p\frac{\mathrm{d}p}{\mathrm{d}x} \qquad J_{n,\text{diff}}=q_e D_p\frac{\mathrm{d}n}{\mathrm{d}x} \tag{16.3.348}$$

where the first diffusion equation is also often denoted:

$$J_{p,\text{diff}}=-q_e D_p\frac{\mathrm{d}n_p}{\mathrm{d}x} \tag{16.3.349}$$

At zero bias the drift current (caused by the electric field) and the diffusion current (caused by the gradient of the carrier concentration) compensate each other, therefore:

$$J_p=q_e\left(D_p\frac{\mathrm{d}p}{\mathrm{d}x}-p\mu_p E_p\right)=0 \tag{16.3.350}$$

To solve this equation we make use of the following relationships that gives the hole concentration:

$$p=n_i e^{-(E_i-E_F)/kT} \tag{16.3.351}$$

and therefore if we derive it relatively to x we get:

$$\frac{\mathrm{d}p}{\mathrm{d}x}=n_i e^{-(E_i-E_F)/kT}\frac{-\left(\frac{\mathrm{d}E_i}{\mathrm{d}x}-\frac{\mathrm{d}E_F}{\mathrm{d}x}\right)}{kT}=-\frac{p}{kT}\left(\frac{\mathrm{d}E_i}{\mathrm{d}x}-\frac{\mathrm{d}E_F}{\mathrm{d}x}\right) \tag{16.3.352}$$

Since the force on a charge q_e due to an electric field E is equal to the negative gradient of the potential energy:

$$q_e E=-\frac{\mathrm{d}E_C}{\mathrm{d}x}=-\frac{\mathrm{d}E_V}{\mathrm{d}x}=-\frac{\mathrm{d}E_i}{\mathrm{d}x} \tag{16.3.353}$$

As only the gradient is of interest and E_C, E_V, and E_i differ only by a constant offset, any of these three measures can be used. We'll use the intrinsic Fermi level E_i, since it applies throughout the sample.

Therefore the first term in the differential equation above can be written:

$$\frac{\mathrm{d}p}{\mathrm{d}x}=\frac{p}{kT}\left(\frac{\mathrm{d}E_F}{\mathrm{d}x}+q_e E_p\right) \tag{16.3.354}$$

The remaining ingredient is the Einstein relationship, which relates the mobility to the diffusion constant:

$$\mu_p=\frac{q_e D_p}{kT} \tag{16.3.355}$$

Using these relationships the net hole current becomes:

$$\begin{aligned}J_p&=q_e\left(D_p\frac{\mathrm{d}p}{\mathrm{d}x}-p\mu_p E_p\right)=q_e\left(D_p\frac{p}{kT}\left(\frac{\mathrm{d}E_F}{\mathrm{d}x}+q_e E_p\right)-p\frac{q_e D_p}{kT}E_p\right)=q_e p\frac{D_p}{kT}\frac{\mathrm{d}E_F}{\mathrm{d}x}\\&=\mu_p p\frac{\mathrm{d}E_F}{\mathrm{d}x}=0\end{aligned} \tag{16.3.356}$$

Accordingly, the net electron current is given by:

$$J_n = -q_e n\frac{D_n}{kT}\frac{\mathrm{d}E_F}{\mathrm{d}x} = -\mu_n n\frac{\mathrm{d}E_F}{\mathrm{d}x} = 0 \tag{16.3.357}$$

Since, individually, the net hole and electron currents in equilibrium must be zero, the derivative of the Fermi level is then:

$$\frac{\mathrm{d}E_F}{\mathrm{d}x} = 0 \tag{16.3.358}$$

In thermal equilibrium the Fermi level must be constant throughout the junction region.

For the Fermi level to be flat, the band structure must adapt, since on the p-side the Fermi level is near the valence band, whereas on the n-side it is near the conduction band. If we assume that the dopants are exclusively donors on the n-side and acceptors on the p-side, the difference in the respective Fermi levels is:

$$\Delta E_F = kT\ln\left(\frac{N_a N_d}{n_i^2}\right) \tag{16.3.359}$$

Indeed, to prove this relation remember that we have (we changed a bit the notations):

$$N_d = n = n_i e^{-(E_F - E_{i,n})/kT} \qquad N_a = p = n_i e^{-(E_{i,p} - E_F)/kT} \tag{16.3.360}$$

Extracting the intrinsic energy we get:

$$E_{i,n} = kT\ln\left(\frac{N_d}{n_i}\right) + E_F \qquad E_{i,p} = -kT\ln\left(\frac{N_a}{n_i}\right) + E_F \tag{16.3.361}$$

Therefore:

$$\Delta E_F = E_{i,n} - E_{i,p} = kT\left(\frac{N_d}{n_i} + \frac{N_a}{n_i}\right) = kT\ln\left(\frac{N_a N_d}{n_i^2}\right) \tag{16.3.362}$$

This corresponds to an electric potential:

$$\boxed{\Delta U_F = \frac{1}{q_e}\Delta E_F = \frac{kT}{q_e}\ln\left(\frac{N_a N_d}{n_i^2}\right) \equiv U_{bi}\;[\mathrm{J}\cdot\mathrm{C}^{-1}]} \tag{16.3.363}$$

equivalently measured in Volts [V], often referred to as the "built-in voltage" or "contact potential" of the junction (keep in mind that in reality it is an approximation!).

As either N_a or N_d increases relative to n_i, the respective Fermi level moves closer to the band edge, increasing the built-in voltage. With increasing doping levels the built-in voltage approaches the equivalent potential of the band gap E_g/q_e.

Remark

Notice that we can rearrange to get:

$$N_a = \frac{n_i^2}{N_d}e^{q_e\Delta U_F/kT} = N_{a0}e^{q_e\Delta U_F/kT} \quad \text{or} \quad N_d = \frac{n_i^2}{N_a}e^{q_e\Delta U_F/kT} = N_{d0}e^{q_e\Delta U_F/kT} \tag{16.3.364}$$

These two relations will be useful to us further below.

16.3.7.1.1.4 Forward-biased pn-junction

Applying an external bias leads to a condition that deviates from thermal equilibrium, i.e. the Fermi level is no longer constant throughout the junction. If a positive voltage is applied to the p-electrode relative to the n-electrode, the total variation of the electric potential across the junction will decrease. Since this reduces the electric field across the junction (i.e. the build-in tension), the drift component of the junction current will decrease. Since the concentration gradient is unchanged, the diffusion current will exceed the drift current and a net current will flow.

This net current leads to an excess of electrons in the p-region and an excess of holes in the n-region. This "injection" condition leads to a local deviation from equilibrium, i.e. $pn > {n_i}^2$. Equilibrium will be restored by recombination.

Note that a depletion region exists even under forward bias, although its width is decreased. The electric field due to the space charge opposes the flow of charge, but the large concentration gradient overrides the field.

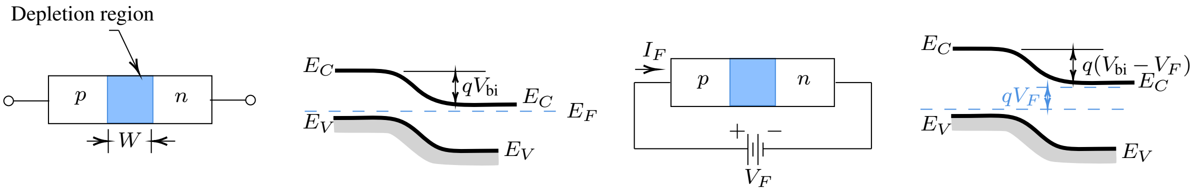

Figure 16.127: Depletion layer width and energy diagram of a pn-junction under two different biasing conditions. (left) Thermal equilibrium (right) Forward bias

Consider holes flowing into the n-region. They will flow through the depletion region with small losses due to recombination, as the electron concentration is small compared with the bulk. When holes reach the n-side boundary of the depletion region the concentration of electrons available for recombination increases and the concentration of holes will decrease with distance, depending on the cross-section for recombination, expressed as a diffusion length. Ultimately, all holes will have recombined with electrons. The required electrons are furnished through the external contact from the power supply.

On the p-side, electrons undergo a similar process. The holes required to sustain recombination are formed at the external contact to the p-region by electron flow toward the power supply, equal to the electron flow toward the n-contact. The following derivation follows the discussions by Shockley (11949, 11950 according to holocene calendar) and Grove (11967 according to holocene calendar).

The steady-state distribution of charge is determined by solving the diffusion equation (see section Thermodynamics page 3688):

$$D_n \frac{\mathrm{d}^2 n_p}{\mathrm{d}x^2} - \frac{n_p - n_{p0}}{\tau_n} = 0 \qquad (16.3.365)$$

where the parameter τ_n is the electron lifetime.

Electrons flowing into the p-region give rise to a local concentration n_p in excess of the equilibrium concentration n_{p0}. This excess will decay with a recombination time τ_n, corresponding to a diffusion length L_n.

Remark

Again, the above relation can often by found in textbooks with the following notation:

$$D_p\frac{\mathrm{d}^2p_n}{\mathrm{d}x^2}-\frac{p_n-p_{n0}}{\tau_{pl}}=0 \tag{16.3.366}$$

The first boundary condition required for the solution of the diffusion equation is that the excess concentration of electrons vanish at large distances x:

$$n_p(x\rightarrow+\infty)=n_{p0} \tag{16.3.367}$$

The second boundary condition is that the carriers are injected at the origin of the space charge region $x=0$ with a concentration $n_p(0)$. This yields the solution:

$$n_p(x)=n_{p0}+(n_p(0)-n_{p0})\,e^{-x/\sqrt{D_n\tau_n}} \tag{16.3.368}$$

often written:

$$n_p(x)-n_{p0}=(n_p(0)-n_{p0})\,e^{-x/L_n} \tag{16.3.369}$$

with $L_n=\sqrt{D_n\tau_n}$ named the "electron diffusion length ".

Remarks

R1. The Diffusion equation can be solved by using the following general solution:

$$n_p(x)-n_{p0}=A\exp\left(\frac{x}{\sqrt{D_n\tau_n}}\right)+B\exp\left(-\frac{x}{\sqrt{D_n\tau_n}}\right)=A\exp\left(\frac{x}{L_n}\right)+B\exp\left(-\frac{x}{L_n}\right) \tag{16.3.370}$$

and applying both boundary conditions mentioned earlier we obviously fall back on the solution above!

R2. The differential equation above and it's corresponding solution are a special case named the "short diode case". The "long" diode expression applies to p-n diodes in which recombination/generation occurs in the quasi-neutral region only. This is the case if the quasi-neutral region is much larger than the carrier diffusion length. The "short" diode expression applies to p-n diodes in which recombination/generation occurs at the contacts only. In a short diode, the quasi-neutral region is much smaller than the diffusion length. In the long diode case the solution can be found in some textbooks in the following shape:

$$n_p(x)-n_{p0}=A\exp\left(\frac{x-x_n}{\sqrt{D_n\tau_n}}\right)+B\exp\left(-\frac{x-x_n}{\sqrt{D_n\tau_n}}\right)=A\exp\left(\frac{x-x_n}{L_n}\right)+B\exp\left(-\frac{x-x_n}{L_n}\right) \tag{16.3.371}$$

and applying both boundary conditions mentioned earlier we obviously fall back on the solution above!

From this we obtain the electron current (see section Thermodynamics page 3701) entering the p-region :

$$J_{np}=-q_eD_n\left.\frac{\mathrm{d}n_p}{\mathrm{d}x}\right|_{x=0}=q_eD_n\frac{n_p(0)-n_{p0}}{L_n} \tag{16.3.372}$$

This says that the electron current is limited by the concentration gradient determined by the carrier density at the depletion edge $n_p(0)$ and the equilibrium minority carrier density n_{p0}.

Determining the equilibrium density n_{p0} is easy as we know:

$$n_{p0}=n_i^2/N_a \tag{16.3.373}$$

The problem is that $n_p(0)$ is established in a non-equilibrium state, where the previously employed results do not apply!

To analyse the regions with non-equilibrium carrier concentrations Shockley introduced a simplifying assumption by postulating that the product pn is constant. In this specific quasi-equilibrium state this constant will be larger than ${n_i}^2$, the pn-product in thermal equilibrium. In analogy to thermal equilibrium, this quasi-equilibrium state is expressed in terms of a "quasi-Fermi level", which is the quantity used in place of E_F that gives the carrier concentration under non-equilibrium conditions.

The postulate $pn=c^{te}$ is equivalent to stating that the non-equilibrium carrier concentrations are given by a Boltzmann distribution, so the concentration of electrons is:

$$n\cong n_ie^{-(E_F^{(n)}-E_i)/kT} \tag{16.3.374}$$

where $E_F^{(n)}$ is the quasi-Fermi level for electrons, and:

$$p\cong n_ie^{-(E_i-E_F^{(p)})/kT} \tag{16.3.375}$$

where $E_F^{(p)}$ is the quasi-Fermi level for holes. The product of the two carrier concentrations in non-equilibrium is:

$$pn=n_i^2e^{-(E_F^{(n)}-E_F^{(p)})/kT} \tag{16.3.376}$$

If pn is constant throughout the space-charge region, then $E_F^{(n)}-E_F^{(p)}$ must also remain constant.

Using the quasi-Fermi level and the Einstein relationship, the electron current entering the p-region becomes (following the same developments as we did earlier above):

$$J_{np}=-q_eD_n\left.\frac{\mathrm{d}n_p}{\mathrm{d}x}\right|_{x=0}=-q_eD_n\frac{\mathrm{d}}{\mathrm{d}x}\left(n_ie^{-(E_F^{(n)}-E_i)/k_BT}\right)=-\mu_nn\frac{\mathrm{d}E_F^{(n)}}{\mathrm{d}x} \tag{16.3.377}$$

These relationships describe the behaviour of the quasi-Fermi level in the depletion region. How does this connect to the neutral region?

In the neutral regions the majority carrier motion is dominated by drift (in contrast to the injected minority carrier current, which is determined by diffusion). Consider the n-type region. Here the bulk electron current that provides the junction current is given by:

$$J_{nn}=-\mu_n n\frac{\mathrm{d}E_i}{\mathrm{d}x} \tag{16.3.378}$$

Since the two electron currents must be equal:

$$J_{nn}=J_{np} \tag{16.3.379}$$

it follows that:

$$\frac{\mathrm{d}E_F^{(n)}}{\mathrm{d}x}=\frac{\mathrm{d}E_i}{\mathrm{d}x} \tag{16.3.380}$$

i.e. the quasi-Fermi level follows the energy band variation. Thus, in a neutral region, the quasi-Fermi level for the majority carriers is the same as the Fermi level in equilibrium. At current densities small enough not to cause significant voltage drops in the neutral regions, the band diagram is flat, and hence the quasi-Fermi level is flat.

In the space charge region, pn is constant, so the quasi-Fermi levels for holes and electrons must be parallel, i.e. both will remain constant at their respective majority carrier equilibrium levels in the neutral regions.

If an external bias U is applied, the equilibrium Fermi levels are offset by U, so it follows that the quasi-Fermi levels are also offset by U:

$$E_F^{(p)}-E_F^{(n)}=q_eU \tag{16.3.381}$$

Consequently, the pn-product in non-equilibrium can be written under the form of the "law of the junction":

$$pn=n_i^2e^{-(E_F^{(n)}-E_F^{(p)})/kT}=n_i^2e^{q_eU/kT} \tag{16.3.382}$$

If the majority carrier concentration is much greater than the concentration due to minority carrier injection ("low-level injection"), the hole concentration at the edge of the p-region remains essentially at the equilibrium value. Consequently, the enhanced pn-product increases the electron concentration:

$$n_p(0)=n_{p0}e^{q_eU/kT}\Leftrightarrow\frac{n_p(0)}{n_{p0}}=e^{q_eU/kT} \tag{16.3.383}$$

Correspondingly, the hole concentration in the n-region at the edge of the depletion zone becomes:

$$p_n(0)=p_{n0}e^{q_eU/kT}\Leftrightarrow\frac{p_n(0)}{p_{n0}}=e^{q_eU/kT} \tag{16.3.384}$$

Remark

The two relations are derived from the previous remark we made earlier where for recall we derived:

$$N_a=\frac{n_i^2}{N_d}e^{q_e\Delta U_F/kT}=N_{a0}e^{q_e\Delta U_F/kT}\quad\text{and}\quad N_d=\frac{n_i^2}{N_a}e^{q_e\Delta U_F/kT}=N_{d0}e^{q_e\Delta U_F/kT}\tag{16.3.385}$$

Now remember that we get earlier above the following solution to the diffusion equation:

$$n_p(x)-n_{p0}=(n_p(0)-n_{p0})\,e^{-x/L_n}\tag{16.3.386}$$

We can now rewrite that latter:

$$n_p(x)-n_{p0}=n_{p0}\left(\frac{n_p(0)}{n_{p0}}-1\right)e^{-x/L_n}=n_{p0}\left(e^{q_eU/kT}-1\right)e^{-x/L_n}\tag{16.3.387}$$

Remembering that we have:

$$n_{p0}=\frac{n_i^2}{N_a}\quad\text{and}\quad p_{n0}=\frac{n_i^2}{N_d}\tag{16.3.388}$$

the components of the diffusion current only (not including the drift as the latter can be neglected due to the dominance of the diffusion current!) due to holes and electrons are (see section Thermodynamics page 3699):

$$\begin{aligned}J_n\cong J_{n,\text{diff}}&=-q_eD_n\left.\frac{\mathrm{d}n_e}{\mathrm{d}x}\right|_{x=0}=-qD_n\frac{\mathrm{d}}{\mathrm{d}x}\left.\left[n_{p0}\left(e^{q_eU/kT}-1\right)e^{-x/L_n}\right]\right|_{x=0}\\&=q_eD_n\frac{n_i^2}{N_aL_n}\left(e^{q_eU/kT}-1\right)\end{aligned}\tag{16.3.389}$$

The same development lead us to:

$$J_p\cong J_{p,\text{diff}}=q_eD_p\frac{n_i^2}{N_dL_p}\left(e^{q_eU/kT}-1\right)\tag{16.3.390}$$

The -1 has an influence only when J is very small. We can interpret his presence by the need of having $J=0$ when $U=0$.

The total diffusion current is the sum of the electron and hole components:

$$J=J_n+J_p\cong J_0(e^{q_eU/kT}-1)\tag{16.3.391}$$

where:

$$J_0=q_en_i^2\left(\frac{D_n}{N_aL_n}+\frac{D_p}{N_dL_p}\right)\tag{16.3.392}$$

is named the "saturation density current".

Or explicitly:

$$\boxed{J=J_n+J_p=q_en_i^2\left(\frac{D_n}{N_aL_n}+\frac{D_p}{N_dL_p}\right)(e^{q_eU/kT}-1)}\tag{16.3.393}$$

This is the famous "ideal diode equation" , also named "Shockley equation", which describes the current–voltage characteristic both under forward and reverse bias.

Remark

A comparison of the "short" diode expression with the "long" diode expression reveals that they are the same except for the use of either the diffusion length or the quasi-neutral region width in the denominator, whichever is smaller.

Under forward bias the current increases exponentially. Under reverse bias (negative U), the exponential term vanishes when the bias exceeds several kT/q_e and the current becomes the reverse saturation current $J = -J_0$. For a uniform junction cross-section the current densities J_n, J_p, and J_0 can be replaced by their respective currents so that we get the famous relation known by most engineers (and a significant number of solid state physicists):

$$\boxed{I = I_0(e^{q_eU/kT} - 1)} \tag{16.3.394}$$

Or also sometimes denoted and approximated (when $U \gg U_{\text{th}}$):

$$I = I_0(e^{U/U_{\text{th}}} - 1) \cong I_0 e^{U/U_{\text{th}}} \tag{16.3.395}$$

This last relation can be interpreted in a different way. To pass a current I in a diode, we have to apply to his extremities a potential such that:

$$U \cong U_{\text{th}} \ln\left(\frac{I}{I_0}\right) \tag{16.3.396}$$

The reader must keep in mind that most relations above are not strict equalities since we get them from successive approximations!

Note that in the diode equation:

1. The band gap does not appear explicitly (only implicitly in J_0 via n_i).
2. The total current has two distinct components, due to electrons and holes.
3. The electron and hole currents are generally not equal. The ratio

$$\frac{J_n}{J_p} = \frac{N_d}{N_a} \quad \text{if} \quad \frac{D_n}{L_n} = \frac{D_p}{L_p} \tag{16.3.397}$$

4. Current flows for all values of U. However, when plotted on a linear scale, the exponential appears to have a knee, often referred to as the "turn-on voltage".
5. The magnitude of the turn-on voltage is determined by J_0. Diodes with different band gaps will show the same behaviour if J_0 is the same.

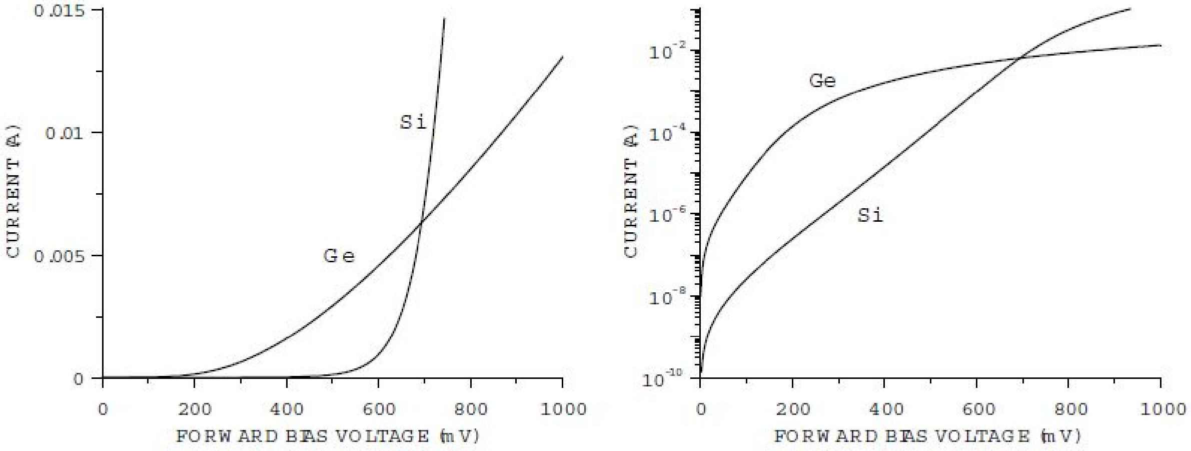

Figure 16.128: **Current vs voltage for forward biased** Si **and** Ge **diodes**

The figure above shows measured I-U curves for commercial Si and Ge junction diodes (1N4148 and 1N34A). On a linear scale the Ge diode "turns on" at $200-300\,[\text{mV}]$, whereas the Si diode has a threshold of $500-600\,[\text{mV}]$. However, on a logarithmic scale it becomes apparent that both diodes pass current at all voltages >0.

The discrepancies in the forward current between the measured results and the simple theory require the analysis of all processes in the depletion zone:

1. Generation-recombination in the depletion region
2. Diffusion current (as just calculated for the ideal diode).
3. High-injection region where the injected carrier concentration affects the potentials in the neutral regions.
4. Voltage drop due to bulk series resistance.

So although we got to the ideal diode equation there is one small problem here. It doesn't really match the experimental data! While with some germanium diodes, it works, for some silicon diodes it fails. Which is why in 11954 (holocene calendar), Bill Pfann and W. van Roosbroek, modified the equation as:

$$I=I_0(e^{q_eU/\eta kT}-1) \qquad (16.3.398)$$

Where η is the "ideality constant" to overcome this problem and balance out the side effects of approximations. For a discussion of these effects see [508].

Finally to close that topic, notice that the dynamic resistance R_d of the ideal diode is defined by:

$$R_d=\frac{\mathrm{d}U}{\mathrm{d}I}\cong\frac{\mathrm{d}}{\mathrm{d}I}\left[U_{\text{th}}\ln\left(\frac{I}{I_0}\right)\right]=\frac{U_{\text{th}}}{I}=\frac{U_{\text{th}}}{I_0}e^{-U/U_{\text{th}}} \qquad (16.3.399)$$

16.3.7.2 Amplifiers

An "amplifier" or "electronic amplifier" is an electronic device that can increase the power of a signal (a time-varying voltage or current). An amplifier functions by using electric power from a power supply to increase the amplitude of the voltage or current signal.

An amplifier can either be a separate piece of equipment or an electrical circuit contained within another device. Amplification is fundamental to modern electronics, and amplifiers are widely used in almost all electronic equipment. Amplifiers can be divided into voltage amplifiers, current amplifiers, transconductance amplifiers, and transresistance amplifiers.

We can make a very simple amplifier using the circuit shown below:

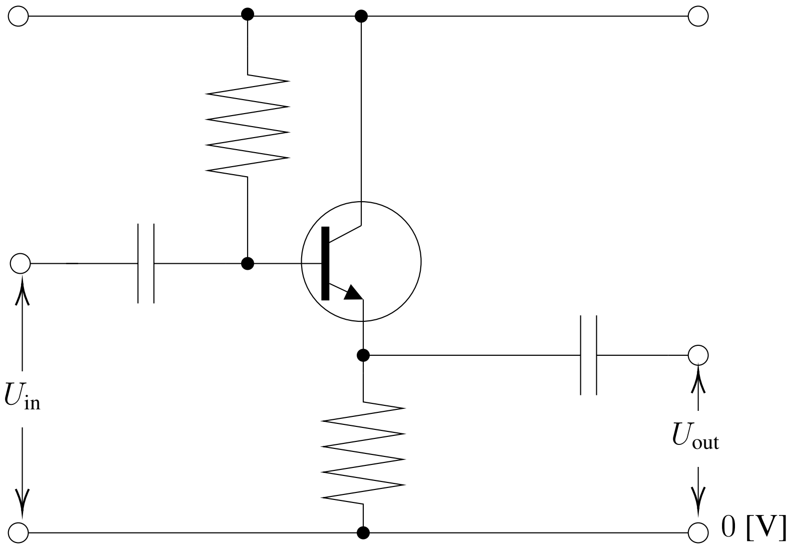

Figure 16.129: **Simple amplifier (follower)**

This circuit is named a "follower" because the output follows closely the input voltage. The voltage gain is slightly less than 1, but there is a high current gain.

16.4. Civil Engineering

CIVIL ENGINEERING represents all the techniques for civil constructions and tools associated with it. Civil engineers are involved in the design, implementation, operation and rehabilitation of construction works and urban infrastructure that they manage to meet the needs of society, while ensuring public safety and environmental protection at least in theory. Very interesting and varied, their achievements are distributed mainly in five major areas: structures, geotechnics, hydraulics, transport and environment. As usual in this textbook, we will focus only on the mathematical formalization of very common cases that have a practical application in everyday life.

Civil Engineering is traditionally broken into several sub-disciplines including architectural engineering, environmental engineering, geotechnical engineering, control engineering, structural engineering, earthquake engineering, transportation engineering, forensic engineering, municipal or urban engineering, water resources engineering, materials engineering, wastewater engineering, offshore engineering, facade engineering, quantity surveying, coastal engineering, construction surveying, and construction engineering. Civil engineering takes place in the public sector from municipal through to national governments, and in the private sector from individual homeowners through to international companies.

Let us notice that in civil engineering it is sometimes made use of the calculation of minimal surfaces. This has been already covered by a concrete examples in the section of Analytical Mechanics (see page 3182). Regarding the efforts of the heat on beams, this is also already been discussed in the section of Thermodynamics (see page 3615). Regarding the problem of resonance this has also already been discussed in the section of Acoustics (see page 8227).

We will limit ourselves in this section to provable accurate calculations and not on experimental formulas and this in order to have a general introduction to civil engineering techniques and become familiar with the language and some methods of calculation used by engineers in this field. In practice, civil engineers make use of a standard packages with formulas including coefficients or based on tables or maps. For example, in Switzerland, the civil engineers refer to SIA standards (Swiss Society of Engineers and Architects), which contain among others a lot of empirical formulas that engineer use without knowing where they come from. The theoretical approach is obviously insufficient and any training in this field should be obviously completed by practical laboratory work.

Remark

It would be pretentious to claim to do with this section as well and also as complete as the *Statique* free French PDF of Nicolet Gaston Raymond that is a priori unrivaled in content and quality to this date (even compared to non-free books on the subject!). It is therefore strongly recommended to refer to it if the reader wants to drive full information about civil engineering (see the download section of the companion website or directly his own website `http://www.raymondnicolet.ch`). Same recommendation applies to the reader about the master pieces that are the English books *Mechanics of Materials* ([246]) and *Structural and Stress Analysis* ([384])!

Notice as for physics and mechanics that have plenty of ISO standards that increase the quality of the work, the efficiency of the collaboration and communication, civil engineering also has plenty of ISO standards that increase the quality and security of the final result but however highly increase the costs and the time of constructions. You can see a small sample of these standards below (for example seismic/earthquakes standards and technical documentation standards are not represented):

Figure 16.132: Some important ISO standard in Civil Engineering for building construction

16.4.1 Static

Civil engineering uses a lot the tools of the Static for constructions. We're not going here obviously to rewrite the whole section here of Classical Mechanics with the fundamental principle of statistics and everything that goes with it (see page 3194), nor static analysis of beams that has already be done in the section of Mechanical Engineering (see page 8388), but only introduce some applicative aspects of the principle.

To begin this section, let's look at least the smaller non-trivial cases encountered in practice. We would like to put against a wall a solid object and we would like to know the strength that will endure this wall. We can represent this basically by the following scheme:

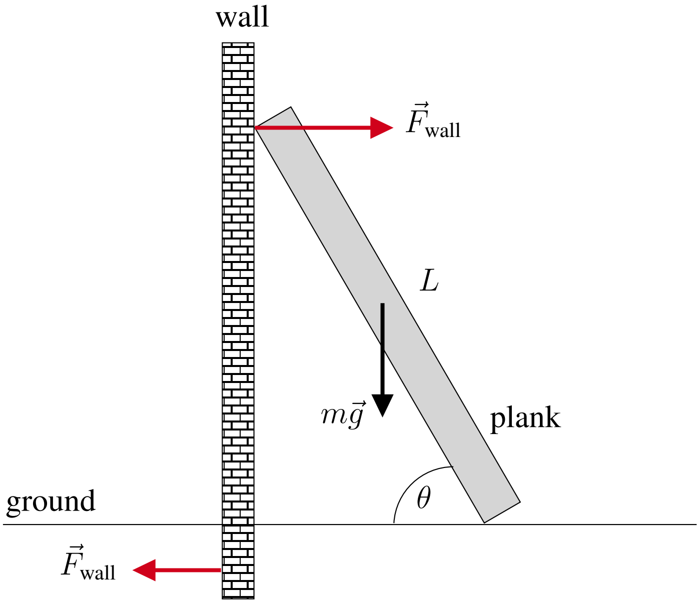

Figure 16.133: Massive object (high density plank) against a wall

For the wall holds it is necessary (but not a sufficient condition, it is just necessary!!!) that the force momentum of gravity equalizes the moment of force of the wall. Then we have:

$$mg\frac{L}{2}\cos(\theta)=F_{\text{wall}}L\sin(\theta) \tag{16.4.1}$$

Therefore:

$$F_{\text{wall}}=\frac{1}{2}\frac{mg}{\tan(\theta)} \tag{16.4.2}$$

Verbatim, the foundations of the wall must be able to opposite to the force momentum.

16.4.2 Pulleys

A "pulley" is a wheel with a grooved rim around which a cord passes, which acts to change the direction of a force applied to the cord and is used to raise heavy weights.

In the context of the study of static forces, there is an industrial example that is famous and that we meet almost every week by walking or driving in front of working sites (construction cranes), train stations (stretchers), ports (ships) or by going to fitness hall or garages: the pulley! Its origin is once again an Archimedes idea (it seems...) who used it for the movement of large masses needed in various projects of his time. The relation with the civil engineering is then completely justified! Let us see this more closely (exceptionally there are very few equations).

Let us consider the following situation named "simple fixed pulley" with a mass of 10 [kg] (i.e. a force of 100 [N] with Earth gravity rounded gravity to the nearest ten) hung to rope slipped into the gutter of a pulley:

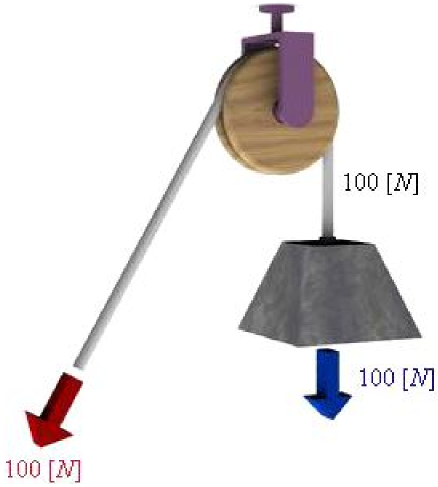

Figure 16.134: **Simple fixed pulley (source: Wikipedia)**

A simple fixed pulley has the only mechanical advantage to be able to exert the force in a different direction to that of the movement, the force that has to be applied is the same as that required to move the object without the pulley!

The anchor point of the pulley must support the force required to move the object plus the traction force, thus twice this force in the worst case. Otherwise the total load that must support the anchor point is a function of the "pull angle" of the rope (between 90° and 180°) of course:

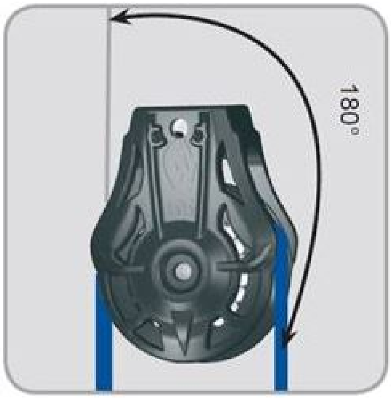

Figure 16.135: **Pull angle at** 180°

For an angle of 180° the load factor is 200% (don't forget it's the load factor on the center of the pulley!!!). A load of 10 [kg] on the rope will represent a load of 20 [kg] on the pulley.

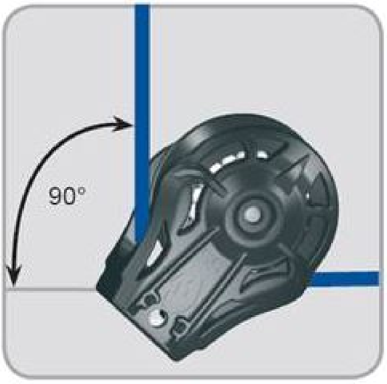

Figure 16.136: **Pull angle at** 90°

For an angle of 90°, the load factor is 140% (don't forget it's the load factor on the center of the pulley!!!). A load of 10 [kg] on the rope is a load of 14 [kg] on the pulley.

A simple device that runs over pulleys used to study the laws of motion and forces is known as "Atwood's machine". This machine is applicable in various scenarios in the study of mechanics. Basically, this machine is a perfect illustration of tension force, gravitational force and the downward force acting on a particular system of masses that are hung using a string and pulley arrangement.

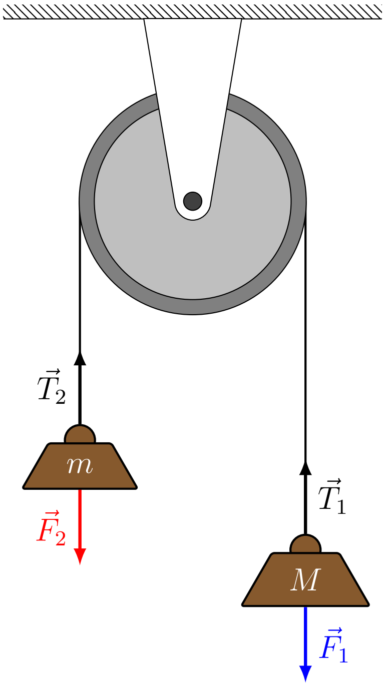

Figure 16.137: Atwood's machine

Using the standard labelling, let the smaller mass be m, and the larger mass is M, and since the forces are only acting in the vertical direction, we will use the summation equation for the forces along the y-axis only.

It can be clearly seen that only two forces are acting on each of the masses, that is, their own weight acting downwards and the tension in the string acting upwards.

Hence, the summation equation for forces on each mass can be written using the standard sign convention, the upward force is taken as positive, and the downward force is taken as negative.

We have obviously:

$$T-mg=ma \qquad \text{and} \qquad T-Mg=-Ma \tag{16.4.3}$$

Where T is the tension in the string and a is the magnitude of the acceleration of two masses. On solving the both we get

$$a=g\frac{M-m}{M+m} \tag{16.4.4}$$

Now let us consider a situation where we set one end of the rope to the support and we draw with the other end to move both the pulley AND the load of 10 [kg]. This configuration is named "simple moving pulley" or "reverse pulley" (the legend says that it is this system that Archimedes used it to pull an entire boat):

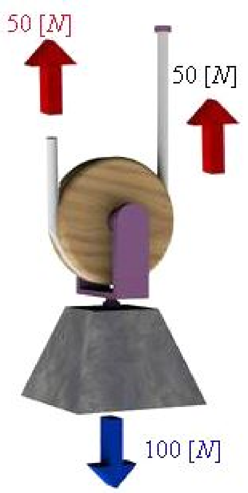

Figure 16.138: Single mobile pulley (source: Wikipedia)

In fact in this system (set up vertically or horizontally whatever!) it is as if there were two people who shared the effort of displacement: the wall and the free end of the rope (which is pulled).

The single mobile pulley therefore reduces the force required to move the load to half (the anchor supporting the other half) and thus adding other mobile pulleys, we continue to divide the action to apply! It was a simple enough idea, somebody just had to think of it!

But this system requires a pull movement of the rope end equal to twice the distance of movement of the load regardless of the radius of the pulley.

Let us also indicate that more the pulley has a large radius, more the force momentum will be big too! So in the case of very heavy loads we will favour large radii for the pulleys if the system that pulls can provide only weak force.

A more realistic configuration (as we will rarely put us above the anchor point to pull the rope and furthermore the previous system is not very stable mechanically speaking ...) of the single mobile pulley presented above is as follows:

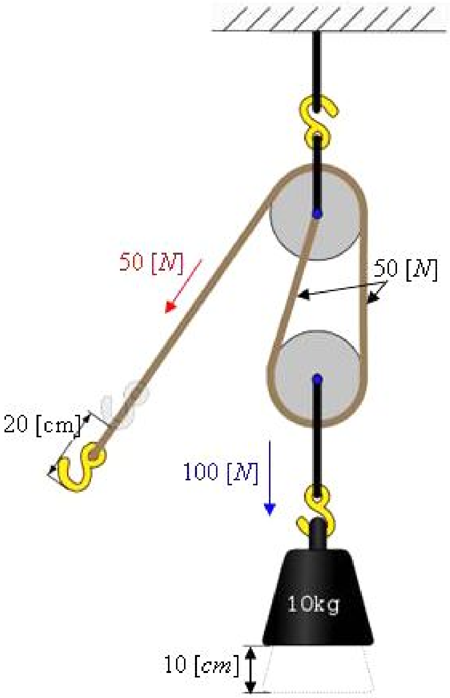

Figure 16.139: **Single fixed and mobile mixed pulleys (source: Wikipedia)**

Obviously, when we represent systems like these in schools, we neglect for simplification purposes the mass of the pulleys themselves that we should strictly speaking take into consideration!

When we use several pulleys systems working together, we say that we have a configuration of "composed pulleys". The most common type of such a configuration is named a "hoist": the pulleys are distributed in two groups (or block), one fixed and one mobile:

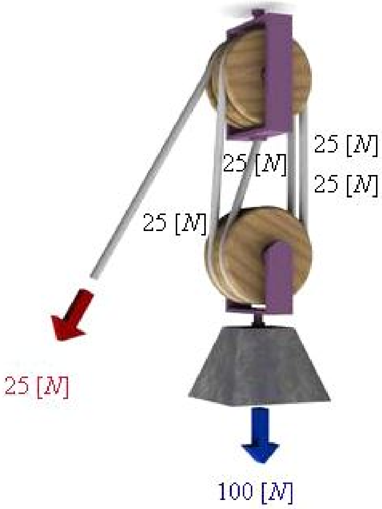

Figure 16.140: **System of combined fixed and moving pulleys (source: Wikipedia)**

In each group we set an arbitrary number of pulleys that demultiply by the same factor the initial load. The load is obviously united with the mobile group.

So we have 25 [N] at the end of the rope. The reader can try to have fun by finding the 4 anchor points in the previous illustration and the two pulleys which each divide by 2 the necessary pull force ... If necessary here is the same configuration but represented in and "unfolded" way:

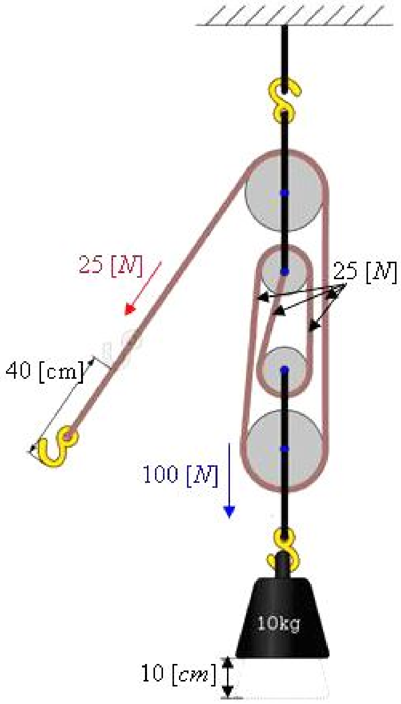

Figure 16.141: Unfolded system of combined fixed and moving pulleys (source: Wikipedia)

We already see that the big top pulley is useless except to change the direction of the pulling force (however if we were not in the assumption of frictionless pulleys it would help to increase the torque). In fact, the two pulleys that are used to divide the force by 2 are the two lower one, the remainder being provided only for convenience for the movement of the rope.

Let us recall to the reader that in reality we would have to take into account the friction of the rope on the pulley (science of tribology) and we have proven in the section of Classical Mechanics (see page 3464) that the real force (stress) of a rope end relatively to the other (end) was given by:

$$T_2 = T_1 e^{\mu_s \beta} \tag{16.4.5}$$

and therefore that the real useful force (stress) to lift a load was given by:

$$\boxed{T_1 = \frac{T_2}{e^{\mu_s \beta}} < T_2} \tag{16.4.6}$$

So the force (stress) supplied to lift the object being equal to T_2, the force (real stress) lifting the weight being T_1, the difference gives the force (stress) making the pulley turn by the intermediate of the friction. Then we have:

$$T_P = T_2 - T_1 = T_1 e^{\mu_s \beta} - T_1 = T_1 \left(e^{\mu_s \beta} - 1 \right) \tag{16.4.7}$$

The moment of force of the pulley of radius R is:

$$M = RT_P = RT_1 \left(e^{\mu_s \beta} - 1 \right) = \frac{v}{\omega} T_1 \left(e^{\mu_s \beta} - 1 \right) \tag{16.4.8}$$

Let us see an another well known application of a system of fixed and mobile pulleys in train stations (and not only!!!):

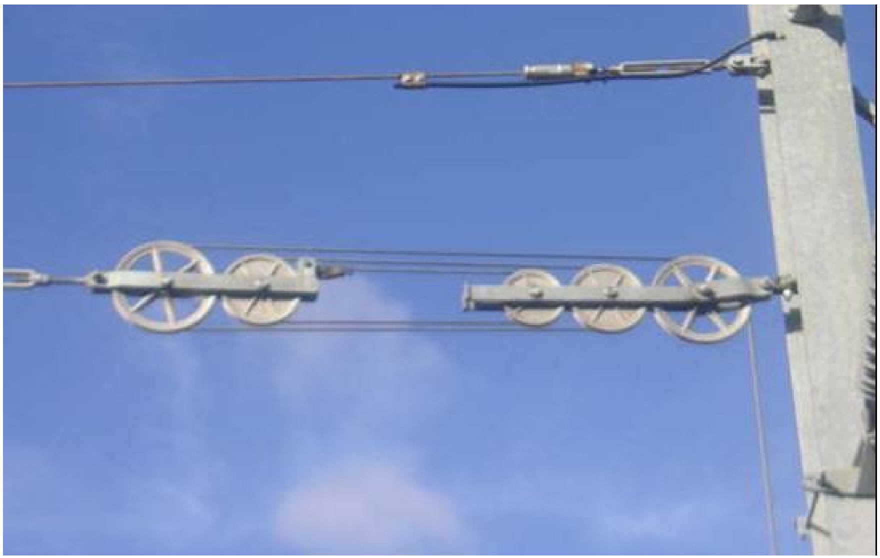

Figure 16.142: **System of mixed fixed and mobile pulley**

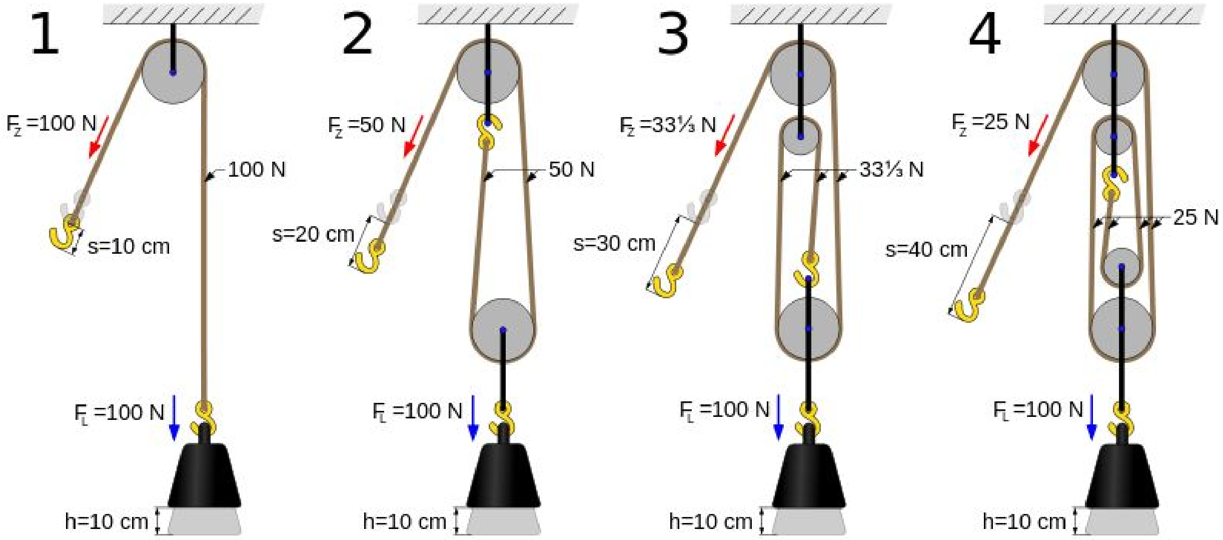
This is a hoist to tension electrical cables with a non-visible counterweight on the photo (bottom right) that ensures a certain strength so some tension. The advantage of this system is that it allows you to add loads gradually as the cable relaxes and these loads are 4 times higher at the electrical cable level thanks to the two movable pulleys (on the left). The pulleys to the right are only here for convenience for the movement of the rope and... the pulling direction for the pulley at the right end.

In the case of a horizontal or vertical load lift, it is easy to determine the gear ratio D. Indeed, if we consider F as the force required to lift vertically the object from a height h by pulling the rope over a length d and F_g the gravitational force on the mass drawn, we then have neglecting the friction and weight of all mobile pulleys:

$$D=\frac{F}{F_g}=\frac{h}{d} \tag{16.4.9}$$

Finally, let us notice that it is possible to play with the radius of the deflection (deviation) pulley to reduce the force to provide while keeping constant the moment of force (we then speak of "differential hoist") but in the end the energy used remain always the same to lift an object at the same height (and we will to pull the rope even more to lift the load at the same height).

To conclude about pulleys the illustration below gives an excellent summary of what we saw until now:



1
F_Z=100 N
100 N
s=10 cm
F_L=100 N
h=10 cm
2
F_Z=50 N
50 N
s=20 cm
F_L=100 N
h=10 cm
3
F_Z=33⅓ N
33⅓ N
s=30 cm
F_L=100 N
h=10 cm
4
F_Z=25 N
25 N
s=40 cm
F_L=100 N
h=10 cm

Figure 16.143: **Summary of typical pulleys (source: Wikipedia)**

(1) Fixed Pulley:

$$F_Z = F_L = mg \qquad s = h \tag{16.4.10}$$

(2) Mobile Pulley:

$$F_Z = \frac{F_L}{2} = \frac{m}{2}g \qquad s = 2h \tag{16.4.11}$$

(3) Simple hoist:

$$F_Z = \frac{F_L}{3} = \frac{m}{3}g \qquad s = 3h \tag{16.4.12}$$

(4) Double hoist:

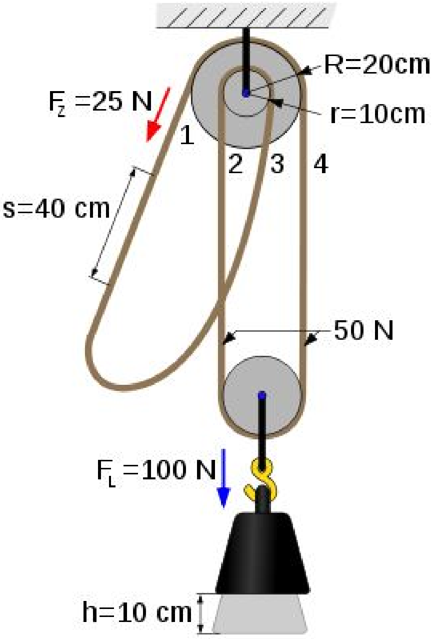
$$F_Z = \frac{F_L}{4} = \frac{m}{4}g \qquad s = 4h \tag{16.4.13}$$

That can be generalized to the n case!

Hence the "ideal mechanical advantage of pulleys" (see section Mechanical Engineering page 8360) given in such situations by:

$$\text{IMA} = \frac{F_{\text{out}}}{F_{\text{in}}} = N \tag{16.4.14}$$

We can also consider the following differential hoist:



R=20cm
r=10cm
F_Z =25 N
1
2
3
4
s=40 cm
50 N
F_L =100 N
h=10 cm

Figure 16.144: **Typical differential pulleys (source: Wikipedia)**

with:

$$F_Z = F_L \frac{R-r}{2R} \qquad s = \frac{2R}{R-r}h \tag{16.4.15}$$

In the below photo the user can see a crane using a system of pulleys to leverage $10,000$ metric tons (i.e. $10,000,000$ kilos...):

SWL 10000mt
SLEIPNIR
HEEREMA

Figure 16.145: **HMC Semi-Submersible** $10,000$ **metric tons Crane vessel**

16.4.2.1 Windlass

The "windlass" is an apparatus for moving heavy weights. Typically, a windlass consists of a horizontal cylinder (barrel), which is rotated by the turn of a crank or belt. A winch is affixed to one or both ends, and a cable or rope is wound around the winch, pulling a weight attached to the opposite end.

Mathematically all equations about windlass can be derived by analogy from pulleys.

Consider for example the simple following windlass:

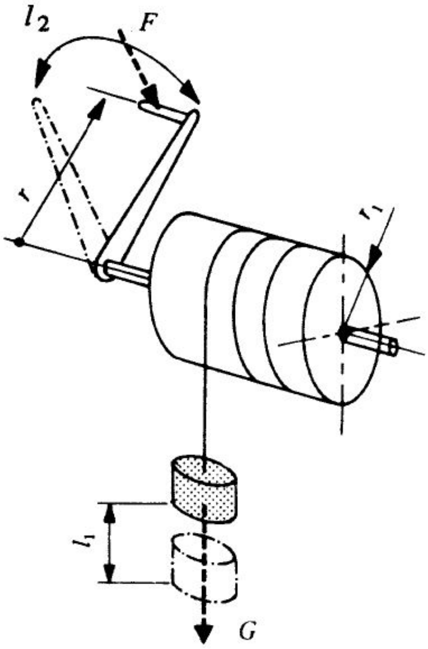


Figure 16.146: **Simple windlass (source: Fortec, Charles Pache)**

For this case we have obviously (gears rules applies as seen in the section of Mechanical Engineering at page 8368):

$$F=G\frac{r_1}{r}=mg\frac{r_1}{r} \qquad l_2=l_1\frac{r}{r_1} \tag{16.4.16}$$

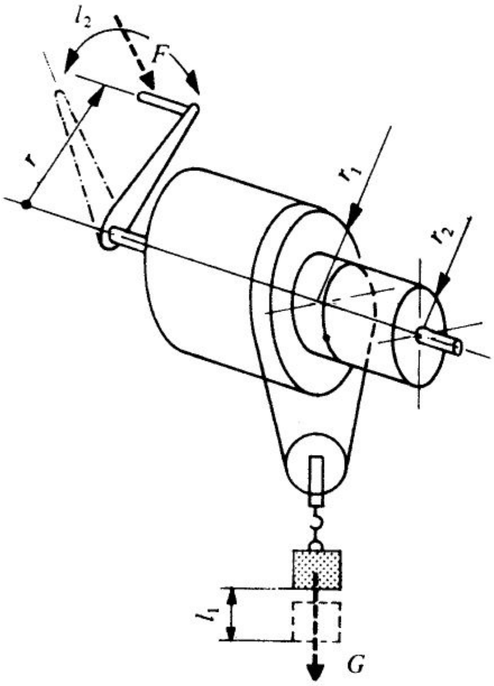

Figure 16.147: **Differential windlass (source: Fortec, Charles Pache)**

For this case we have obviously the same as the differential hoist:

$$F=G\frac{r_1-r_2}{2r}=mg\frac{r_1-r_2}{2r} \qquad l_2=\frac{2r}{r_1-r_2} \tag{16.4.17}$$

16.4.3 Cornu spiral

The "clothoid" is a plane transcendental curve[15] which the curvature is proportional to the curvilinear abscissa. It is also named "Cornu spiral", referring to Alfred Cornu (11841-11902 according to holocene calendar), the French physicist who invented it. More rarely, it may appear under the name of "radioïde arc" or "Euler spiral" or "Fresnel spiral".

This geometry is also suitable for curves for railways because a train following the path of this geometry at a constant speed will be under constant angular acceleration whatever the point of the curve, which reduces both the stresses on the rail or on the wheels and the discomfort of passengers of the train:

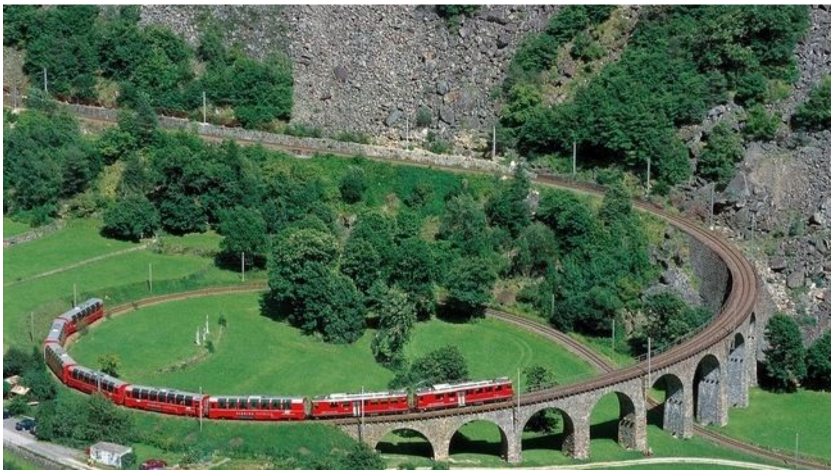

Figure 16.148: **Train loop with a clothoid shape**

Same for cars:

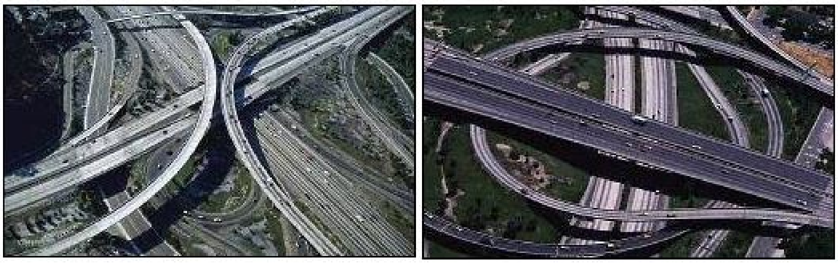

Figure 16.149: **Highway bifurcation with a clothoid shape**

Finally, the railway cable of pylons of cable car and supporting the suspension cable, take this form. Like this, it is possible to circulate the cab at maximum speed on the pylon, without inconveniencing the passengers.

---

[15] A "transcendental curve" is a curve which is not defined by an algebraic equation (typically polynomial or trigonometric), but by a transcendental equation, that is to say, the unknowns are not finite quantities, but differential ($\mathrm{d}x$, $\mathrm{d}y$, representing an infinitesimal variation of the variables x and y). Such a curve can not be constructed geometrically precisely because its equation can not be reduced in a simple form $y = f(x)$.

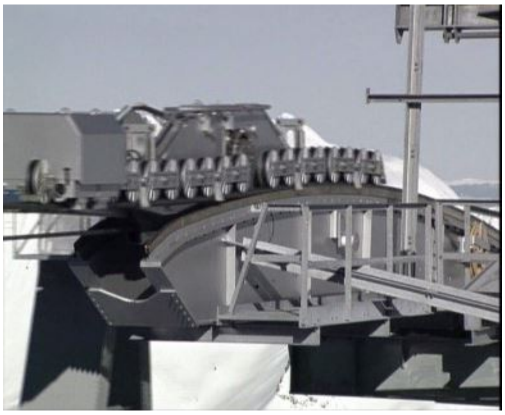

Figure 16.150: Cable car pylon with a clothoid shape

Also this curve is used for vertical loops or loops in the roller coaster for passenger comfort, so that the vertical acceleration is continuous.

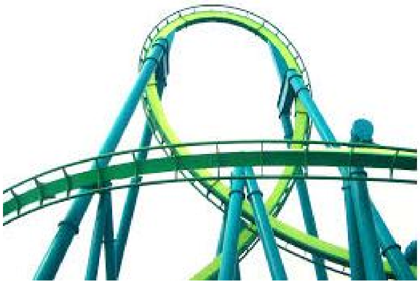

Figure 16.151: Roaller coaster vertical loop with a clothoid shape

When a vehicle moves in a circular motion, it will undergo a force $\vec{F}=m\vec{a}$ perpendicular to its direction (centrifugal force) having for norm (see section Classical Mechanics page 3388):

$$F=m\frac{v^2}{R} \tag{16.4.18}$$

from the start of its entry into the circular curve. This effect is problematic because for some small cars on a highway, the centrifugal force can equal the force of gravity of the car itself (when speed is within the legal values!).

Thus, the acceleration rise brutally from 0 to v^2/R, then the engineers build sometimes the curves with a declination to improve the adhesion, but it is also possible to try to find curves for which the acceleration is more gradual. For example if the curvature C given by (see section Differential Geometry page 2865):

$$C=\frac{1}{R} \tag{16.4.19}$$

is proportional to the path s (curvilinear abscissa) travelled in the curve, we will have at the beginning of the curve $C=0$ so the acceleration will be zero.

So what we seek are then curves such that:

$$C=k\cdot s \tag{16.4.20}$$

where k is a given constant.

For this, let us recall that we can also write naturally for a circle, the curvature into the following form :

$$C=\frac{1}{R}=\frac{\mathrm{d}\theta}{\mathrm{d}s} \tag{16.4.21}$$

Indeed, if we turn of an angle $\mathrm{d}\theta$ then we move of a length $\mathrm{d}s=R\mathrm{d}\theta$ (see section Trigonometry page 2542).

Then we have the relation:

$$k\cdot s=\frac{\mathrm{d}\theta}{\mathrm{d}s} \tag{16.4.22}$$

Thus:

$$\mathrm{d}\theta=ks\mathrm{d}s \tag{16.4.23}$$

hence:

$$\int\limits_0^\theta \mathrm{d}\theta=\int\limits_0^s ks\mathrm{d}s\Rightarrow\theta=\frac{1}{2}ks^2=Ks^2 \tag{16.4.24}$$

But let us recall that the parametric equation of the circle is (see section Analytical Geometry page 2782):

$$\begin{cases}x=R\cos(\theta)\\ y=R\sin(\theta)\end{cases} \tag{16.4.25}$$

We then have:

$$\begin{cases}\mathrm{d}x=\mathrm{d}R\cos(\theta)+R\mathrm{d}(\cos(\theta))=R\cos(\theta)\mathrm{d}\theta=R\cos(\theta)\dfrac{\mathrm{d}s}{R}\\ \mathrm{d}y=\mathrm{d}R\sin(\theta)+R\mathrm{d}(\sin(\theta))=R\sin(\theta)\mathrm{d}\theta=R\sin(\theta)\dfrac{\mathrm{d}s}{R}\end{cases} \tag{16.4.26}$$

Therefore:

$$\begin{cases}\dfrac{\mathrm{d}x}{\mathrm{d}s}=\cos(\theta)\\ \dfrac{\mathrm{d}y}{\mathrm{d}s}=\sin(\theta)\end{cases} \tag{16.4.27}$$

We can now write:

$$\begin{cases}\mathrm{d}x=\cos(\theta)\mathrm{d}s=\cos(Ks^2)\mathrm{d}s\\ \mathrm{d}y=\sin(\theta)\mathrm{d}s=\sin(Ks^2)\mathrm{d}s\end{cases} \tag{16.4.28}$$

Therefore:

$$\begin{cases}x=\int\limits_0^s\cos(Kt^2)\mathrm{d}t\\ y=\int\limits_0^s\sin(Kt^2)\mathrm{d}t\end{cases} \tag{16.4.29}$$

with a small change of variables:

$$u^2 = Kt^2 \Rightarrow u = \sqrt{K}t \Rightarrow \frac{\mathrm{d}u}{\mathrm{d}t} = \sqrt{K} \Rightarrow \mathrm{d}t = \frac{\mathrm{d}u}{\sqrt{K}} \tag{16.4.30}$$

it comes:

$$\begin{cases} x = \dfrac{1}{\sqrt{K}} \int\limits_0^s \cos(u^2)\mathrm{d}u \\ y = \dfrac{1}{\sqrt{K}} \int\limits_0^s \sin(u^2)\mathrm{d}u \end{cases} \tag{16.4.31}$$

by taking $x_0 = y_0 = 0$ (we can always do a translation later).

The two integrals are named "Fresnel integrals" and cannot calculated in a closed form as far as we know. However, we can express them in a Taylor series expansion form (see section Sequences and Series page 1696) as:

$$\begin{aligned} \sqrt{K}x &= s - \frac{s^5}{5 \cdot 2!} + \frac{s^9}{9 \cdot 4!} - \frac{s^{13}}{13 \cdot 6!} + \ldots \\ \sqrt{K}y &= \frac{s^3}{3} - \frac{s^7}{7 \cdot 3!} + \frac{s^{11}}{11 \cdot 5!} - \ldots \end{aligned} \tag{16.4.32}$$

The plot of the Fresnel integral (Euler spiral/Cornu spiral) in Maple™ 4.00b gives:

```
>plot([FresnelC(t),FresnelS(t),t=-5..5]);
```

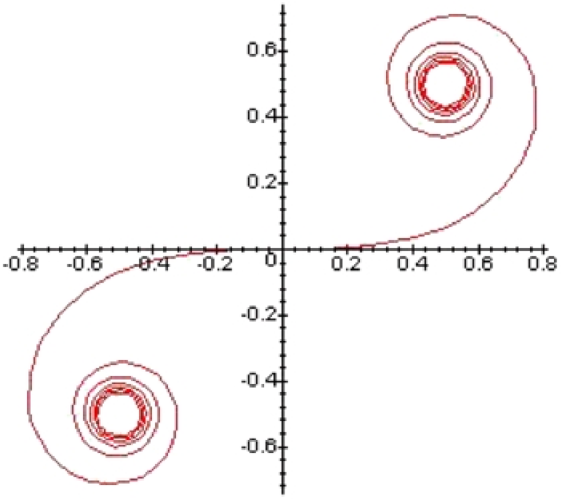

Figure 16.152: **Plot of the Fresnel (Euler spiral/Cornu spiral) integral in Maple™ 4.00b**

By zooming on the part relevant for us:

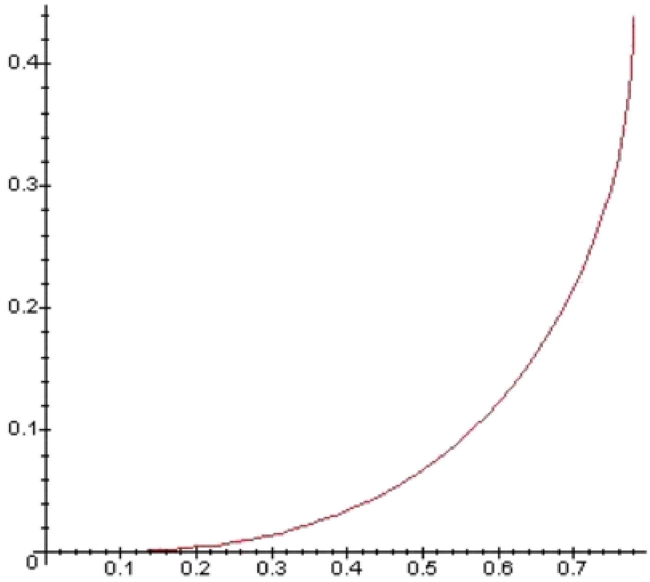

Figure 16.153: **Focus on the origin of the Fresnel integral**

The same thing to a given constant using the Taylor series previously presented:

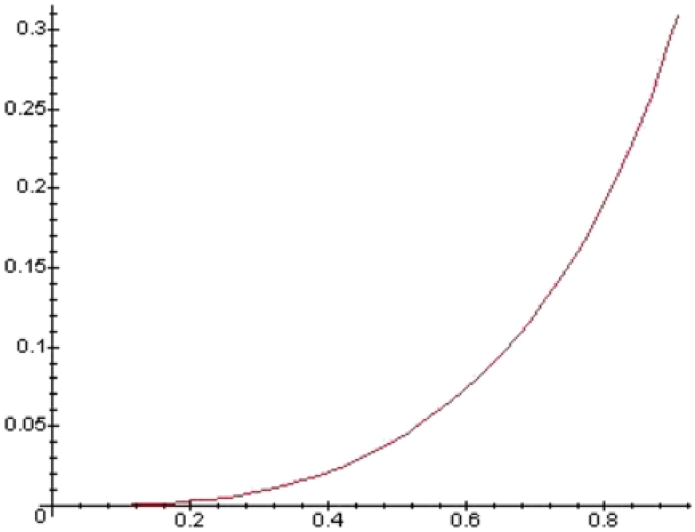

Figure 16.154: **Equivalent Taylor series expansion**

The engineering office use special softwares incorporating clothoids spirals in 2D or 3D environments based on topographic surveys done by GIS specialists (for example AutoCAD has a special dedicated to clothoids design).

16.4.4 Overhead cable

An overhead cable is a cable for the transmission of information, laid on utility poles. Overhead telephone and cable TV lines are common in North America. Elsewhere, overhead cables are laid mainly for telephone connections of remote buildings and temporary mechanisms, as for example building sites. The same poles sometimes carry overhead power lines for the supply of electric power. Power supply companies may also use them for an in-house communication network. Sometimes these cables are integrated in the ground or power conductor. Otherwise an additional line is strung on the masts.

Galilee was probably the first to be interested in the chain overhead cable shape that he interpreted for a parabolic arc. Jean Bernoulli, Huygens and Leibniz found (independently) in response to the challenge of Jakob Bernoulli, his true nature in 11691 (holocene calendar): it is generated by a hyperbolic cosine!

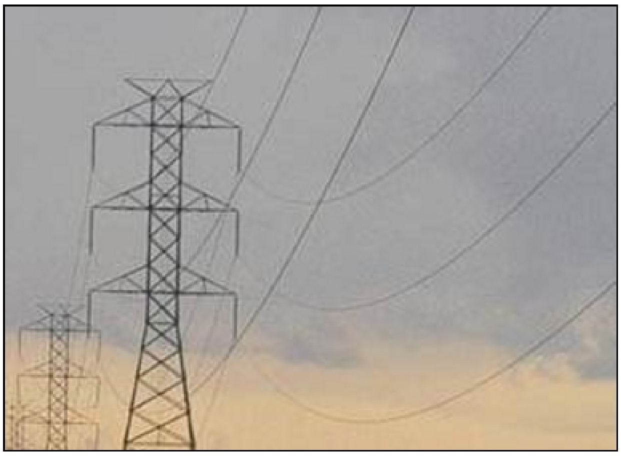

Figure 16.155: **High-voltage overhead cable (source: chronomaths)**

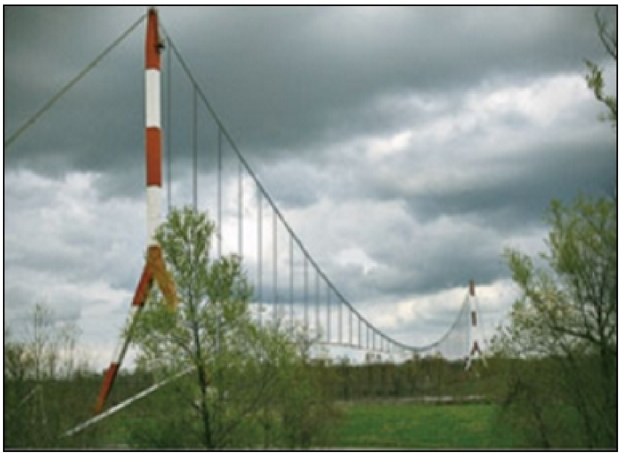

Figure 16.156: **Suspended Pipeline over a river**

16.4.4.1 Free overhead cable (catenary)

Let us consider (source: ChronoMath) for the study a homogeneous free, flexible cable attached at two points A and B. In its equilibrium position, the cable hangs in a vertical plane and seems to take a parabolic shape. In fact, not really ...

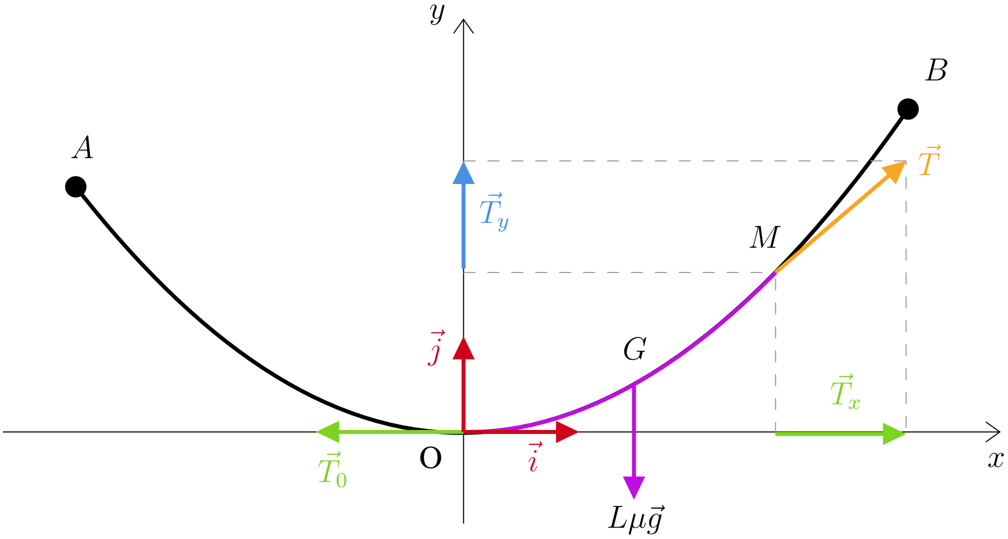

Figure 16.157: **Configuration for studying suspended cables**

Let us create in this plane an orthonormal reference frame $(\mathrm{O},\vec{i},\vec{j})$, where O denotes the lowest point of the cable and let us denote as always the field of gravity $\vec{g}$ that we consider as uniform.

Let us denote by $\vec{T}_0$ the tension (force) at the point O which defeats the tension at the point M so that the cable portion $\overline{\mathrm{O}M}$ of length L, subjected to its linear weight $\mu\vec{g}$ at the point G, is in equilibrium in the static sense:

$$\vec{T}+\vec{T}_0+\mu L\vec{g}=\vec{0} \tag{16.4.33}$$

Remark

The product $\mu\vec{g}$ of the linear mass μ with the gravitational acceleration $\vec{g}$ is also very often denoted $\vec{w}$ as we have already see in the section of Mechanical Engineering to represent the linear load.

Let us project on the coordinate axes by denoting by α the angle $\widehat{\vec{i}\vec{T}}$. We then have the following decomposition:

$$\begin{aligned}\vec{T}&=T_x\vec{i}+T_y\vec{j}=\left(\|\vec{T}\|\cos(\alpha)\right)\vec{i}+\left(\|\vec{T}\|\sin(\alpha)\right)\vec{j}\\ \vec{T}_0&=-\|\vec{T}_0\|\vec{i}\\ \mu L\vec{g}&=-\mu L\|\vec{g}\|\vec{j}\end{aligned} \tag{16.4.34}$$

We can then write the following system:

$$\begin{aligned}&\left(\|\vec{T}\|\cos(\alpha)\right)\vec{i}-\|\vec{T}_0\|\vec{i}=\vec{0}\\&\left(\|\vec{T}\|\sin(\alpha)\right)\vec{j}-\mu L\|\vec{g}\|\vec{i}=\vec{0}\end{aligned}\tag{16.4.35}$$

Either after simplification:

$$\begin{aligned}&\|\vec{T}\|\cos(\alpha)-\|\vec{T}_0\|=0\\&\|\vec{T}\|\sin(\alpha)-\mu L\|\vec{g}\|=0\end{aligned}\tag{16.4.36}$$

Therefore:

$$\begin{aligned}&\|\vec{T}\|\cos(\alpha)=\|\vec{T}_0\|\\&\|\vec{T}\|\sin(\alpha)=\mu L\|\vec{g}\|\end{aligned}\tag{16.4.37}$$

By calculating the ratio:

$$\tan(\alpha)=\frac{\mu L\|\vec{g}\|}{\|\vec{T}_0\|}=L\frac{\mu\|\vec{g}\|}{\|\vec{T}_0\|}=\frac{L}{k}\tag{16.4.38}$$

To get the differential equation... (here this is subtle...):

$$\mathrm{d}(\tan(\alpha))=\frac{\mathrm{d}L}{k}\tag{16.4.39}$$

where $\mathrm{d}L$ is the curvilinear abscissa of the cable (often denoted $\mathrm{d}s$ in the literature according to what is done in Differential Geometry).

Then:

$$\mathrm{d}(\tan(\alpha))=\frac{\sqrt{\mathrm{d}x^2+\mathrm{d}y^2}}{k}=\mathrm{d}x\frac{\sqrt{1+y'^2}}{k}\tag{16.4.40}$$

But the tangent is also the derivative of the function describing the chain. So:

$$\mathrm{d}(\tan(\alpha))=\mathrm{d}(y')=\mathrm{d}x\frac{\sqrt{1+y'^2}}{k}\tag{16.4.41}$$

Therefore it comes:

$$\frac{y''}{\sqrt{1+y'^2}}=\frac{1}{k}\tag{16.4.42}$$

Following the intervention of one of our reader, we will propose two ways to solve this differential equation. The first is the original one and it is a bit complicated and the second one (available much further below) is that proposed by a reader and that is perhaps more elegant and simple.

- First approach:

  Let us put $u=y'$ and seek the primitive of the left member at first (that of the right member being obvious). The calculations made in the section of Differential and Integral Calculus in the determination of the usual primitives (see page 1534) give us:

$$\int \frac{u'}{\sqrt{1+u^2}}\mathrm{d}u = u'\int \frac{1}{\sqrt{1+u^2}}\mathrm{d}u = \ln\left(u+\sqrt{1+u^2}\right)+c^{te} \tag{16.4.43}$$

  So we have:

$$\ln\left(y'+\sqrt{1+y'^2}\right)=\frac{x}{k}+c^{te} \tag{16.4.44}$$

  By passing to the exponential:

$$y'+\sqrt{1+y'^2}=e^{\frac{x}{k}+c^{te}} \tag{16.4.45}$$

  observing that in our problem at $x=0$ we have indeed $y'=0$.

  To find y' we use a trick: We know that the function is symmetric. So if we replace x by $-x$ the tangent also changes sign and passes from y' to $-y'$:

$$-y'+\sqrt{1+(-y')^2}=e^{\frac{-x}{k}+c^{te}} \tag{16.4.46}$$

  By subtracting:

$$y'+\sqrt{1+y'^2}=e^{\frac{x}{k}+c^{te}} \qquad \text{and} \qquad -y'+\sqrt{1+y'^2}=e^{\frac{-x}{k}+c^{te}} \tag{16.4.47}$$

  it comes:

$$2y'=e^{\frac{x}{k}}-e^{-\frac{x}{k}} \Rightarrow y'=\frac{e^{\frac{x}{k}+c^{te}}-e^{-\frac{x}{k}+c^{te}}}{2} \tag{16.4.48}$$

  So after integration:

$$y=k\frac{e^{\frac{x}{k}+c^{te}}-e^{-\frac{x}{k}+c^{te}}}{2}=k\cosh\left(\frac{x}{k}+c_1^{te}\right)+c_2^{te} \tag{16.4.49}$$

  where the expression after the first equality is named the "catenary curve". It comes to the end:

$$\boxed{y=\frac{T_0}{\mu g}\cosh\left(x\frac{\mu g}{T_0}+c_1^{te}\right)+c_2^{te}} \tag{16.4.50}$$

  Where the constant will be determined by the initial conditions.

  We see with Maple™ 4.00b the difference between a parabola and the chain easily:

```
>plot([x^2,cosh(x)],x=-4...4);
```

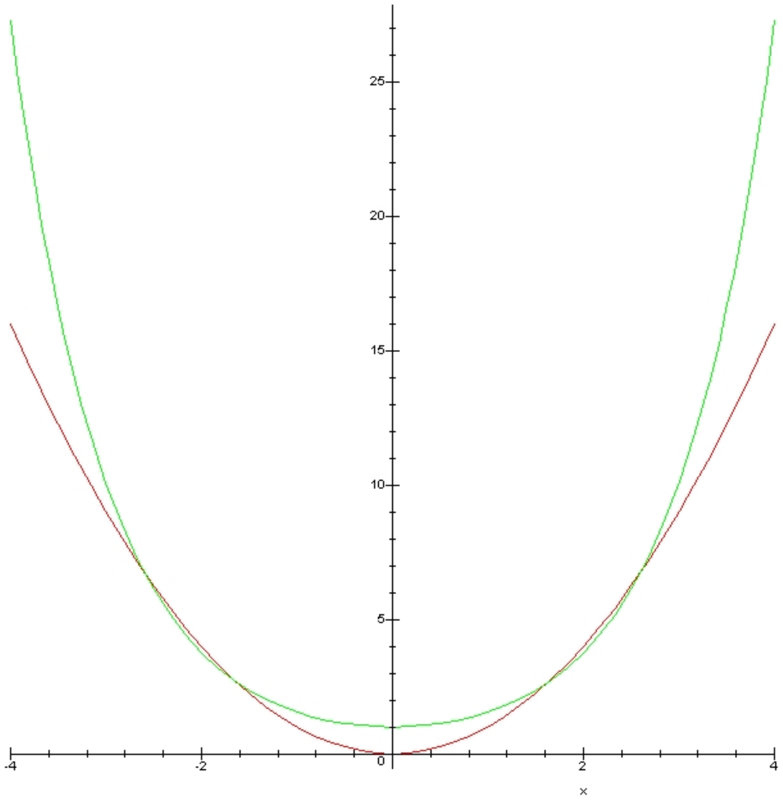

Figure 16.158: **Plot between a chain and parabola in Maple™ 4.00b**

In real life as an artwork:

Figure 16.159: **The Gateway Arch St. Louis arch (source: Wikipedia, author: Daniel Schwen)**

Let us consider now two points (x_1, y_1) and (x_2, y_2) in the plane and let us determine the equation of the chain of length L having these two points as ends.

We have the two equations:

$$\begin{cases} y_1 = k\cosh\left(\dfrac{x_1}{k} + c_1^{te}\right) + c_2^{te} \\ y_2 = k\cosh\left(\dfrac{x_2}{k} + c_1^{te}\right) + c_2^{te} \end{cases} \tag{16.4.51}$$

We obtain a third equation using the length L which is known. Indeed (see section Analytical Mechanics page 3172):

$$\begin{aligned} L &= \int_{x_1}^{x_2} \sqrt{1+y'^2}\mathrm{d}x = \int_{x_1}^{x_2} \sqrt{1+\sinh^2\left(\frac{x}{k}+c_1^{te}\right)} = \int_{x_1}^{x_2} \cosh\left(\frac{x}{k}+c_1^{te}\right)\mathrm{d}x \\ &= k\left(\sinh\left(\frac{x_2}{k}+c_1^{te}\right) - \sinh\left(\frac{x_1}{k}+c_1^{te}\right)\right) \end{aligned} \tag{16.4.52}$$

where we always have:

$$k = \frac{T_0}{\mu g} \tag{16.4.53}$$

Thus, we get a non-linear system of three equations with three unknowns (k, c_1^{te}, c_2^{te}):

$$\begin{cases} y_1 = k\cosh\left(\dfrac{x_1}{k} + c_1^{te}\right) + c_2^{te} \\ y_2 = k\cosh\left(\dfrac{x_2}{k} + c_1^{te}\right) + c_2^{te} \\ L = k\left(\sinh\left(\dfrac{x_2}{k}+c_1^{te}\right) - \sinh\left(\dfrac{x_1}{k}+c_1^{te}\right)\right) \end{cases} \tag{16.4.54}$$

✍**Example:**

Let us determine for example the chain of length 38 [cm] passing through the points $(-9, 0)$ and $(9, 10)$.

The following system must then be solved:

$$\begin{cases} 0 = k\cosh\left(\dfrac{-9}{k} + c_1^{te}\right) + c_2^{te} \\ 10 = k\cosh\left(\dfrac{9}{k} + c_1^{te}\right) + c_2^{te} \\ 38 = k\left(\sinh\left(\dfrac{9}{k}+c_1^{te}\right) - \sinh\left(\dfrac{-9}{k}+c_1^{te}\right)\right) \end{cases} \tag{16.4.55}$$

Here are the Maple™ 4.00b commands that allow us to get the result.

```
> E1:  = 0 = k * cosh (-9 / k + c1) + c2;
> E2:  = 10 = k * cosh (9 / k + c1) + c2;
> E3:  = 38 = k * (sinh (9 / k + c1) -sinh (-9 / k + c1));
> Fsolve (e1, e2, e3, k, c1, c2, k = 0..infinity);
```

Maple™ gives:

```
K = 4.073758798, c1 = .2694982504, c2 = -14.46356329
```

Graphically we have then:

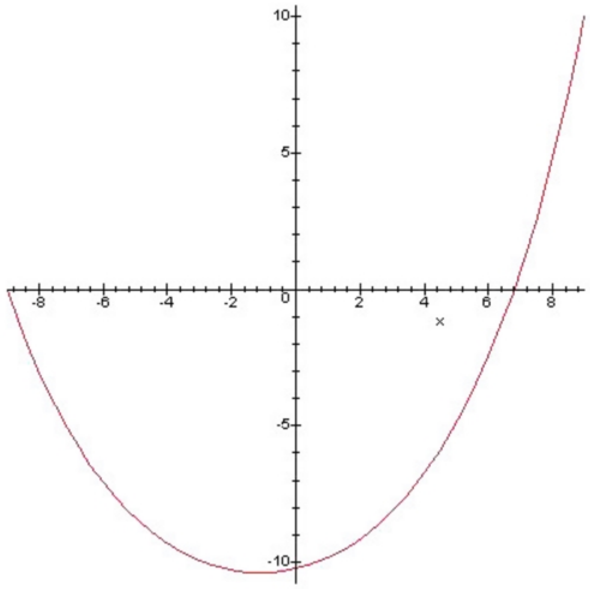

Figure 16.160: Plot of a small overhead cable in Maple™ 4.00b

- Second approach:

  For this second approach of solving the differential equation, we will keep the notation proposed by the reader who contacted us. We start from the differential equation:

$$\frac{\mathrm{d}^2y}{\mathrm{d}x^2}=\frac{1}{k}\sqrt{1+\left(\frac{\mathrm{d}y}{\mathrm{d}y}\right)^2} \tag{16.4.56}$$

  We make the following change of variable:

$$u=\frac{\mathrm{d}y}{\mathrm{d}x} \tag{16.4.57}$$

  Therefore it comes:

$$\frac{\mathrm{d}u}{\mathrm{d}x}=\frac{1}{k}\sqrt{1+u^2} \tag{16.4.58}$$

  and then:

$$\frac{\mathrm{d}u}{\sqrt{1+u^2}}=\frac{\mathrm{d}x}{k} \tag{16.4.59}$$

  The integration gives according to the usual primitive proved in the section of Differential and Integral Calculus (see page 1534):

$$\operatorname{arcsinh}(u)=\frac{x}{k}+c^{te} \tag{16.4.60}$$

  And the condition:

$$\frac{\mathrm{d}y}{\mathrm{d}x}=u=0 \tag{16.4.61}$$

on $x=0$ (lowest point of the overhead string for recall) imposes that the integration constant is zero and therefore that the points of attachment are by symmetry located at the same height. We have then:

$$\text{arcsinh}(u)=\frac{x}{k}\Rightarrow u=\frac{\mathrm{d}y}{\mathrm{d}x}=\sinh\left(\frac{x}{k}\right) \tag{16.4.62}$$

Therefore:

$$\boxed{y=k\cosh\left(\frac{x}{k}\right)+c^{te}} \tag{16.4.63}$$

that has to be compared with the previous method where we had obtained:

$$y=\frac{T_0}{\mu g}\cosh\left(x\frac{\mu g}{T_0}+c_1^{te}\right)+c_2^{te} \tag{16.4.64}$$

The integration constant is determined by the points of attachment of the overhead cable distant from a distance D where we have $y=0$ on $x=-D/2$ and $x=D/2$ (so the ends are on the same horizontal). We have then:

$$y(x)=k\left[\cosh\left(\frac{x}{k}\right)-\cosh\left(\frac{D}{2k}\right)\right] \tag{16.4.65}$$

It is under this last form that the overhead cable was obtained independently by Leibniz, Huygens and Bernoulli at the end of the 117th century (holocene calendar)...!

We can now easily calculate the maximum deviation (the "arrow" as the engineers in civil engineering say, that we will denoted by the letter f as in the section of Mechanical Engineering) with respect to the horizontal passing through the points of attachment:

$$\boxed{y(0)=f=k\left[1-\cosh\left(\frac{D}{2k}\right)\right]} \tag{16.4.66}$$

Finally it can be interesting to calculate the length of the cable at equilibrium. For this, let us recall that we have proved earlier above that:

$$\begin{aligned}L&=\int\limits_{x_1}^{x_2}\sqrt{1+y'^2}\mathrm{d}x=\int\limits_{x_1}^{x_2}\sqrt{1+\sinh^2\left(\frac{x}{k}+c_1^{te}\right)}\mathrm{d}x=\int\limits_{x_1}^{x_2}\cosh\left(\frac{x}{k}+c_1^{te}\right)\mathrm{d}x\\&=k\left(\sinh\left(\frac{x_2}{k}+c_1^{te}\right)-\sinh\left(\frac{x_1}{k}+c_1^{te}\right)\right)\end{aligned} \tag{16.4.67}$$

In the case where the fasteners are at the same height, the chain is symmetrical and we then have:

$$L=2\int\limits_{0}^{D/2}\cosh\left(\frac{x}{k}+c^{te}\right)\mathrm{d}x=2k\left(\sinh\left(\frac{1}{k}\frac{D}{2}\right)-\sinh\left(c^{te}\right)\right) \tag{16.4.68}$$

It remains to determine the constant! If D is zero then L must be zero. The constant is then zero and it remains:

$$\boxed{L=2k\sinh\left(\frac{1}{k}\frac{D}{2}\right)} \tag{16.4.69}$$

In the case of electrified railway lines, we solve the problem of the arrow by a main cable that carries of the catenary: the upper cable (below on the photo) undergoes an accepted deflection, which reduces the tension between the pylons. The catenary thus remains very linear thanks to the multiple auxiliary hooks to an auxiliary cable.

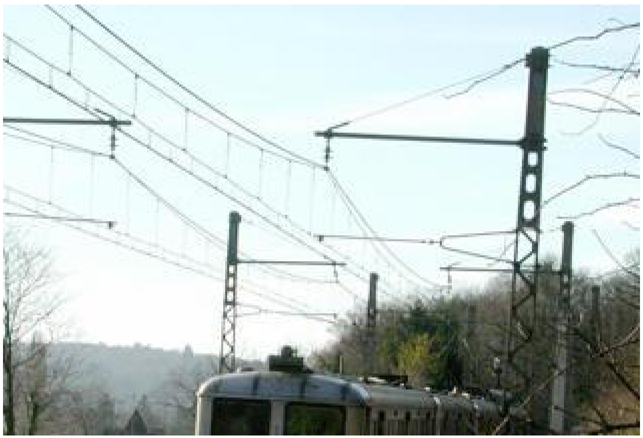

Figure 16.161: **Overhead cable of railways (source: Chronomaths)**

Otherwise let us also notice that we also find the overhead cable in all the places of the life of every day where a cable is suspended between two points on the same horizontal.

✍**Example:**

Consider a suspended cable with the following data:

$$\mu=0.5\,[\text{kg}\cdot\text{m}^{-1}]\qquad g=9.81\,[\text{m}\cdot\text{s}^{-2}]\qquad D=20\,[\text{m}]\qquad T_0=45\,[\text{N}]\tag{16.4.70}$$

We have since the linear load of the cable is constant (taking the notation of the section of Mechanical Engineering on the way...):

$$k=\frac{T_0}{\mu g}=\frac{T_0}{w_0}\cong 9.17\,[\text{m}]\tag{16.4.71}$$

and therefore:

$$y(0)=f=k\left[1-\cosh\left(\frac{D}{2k}\right)\right]=9.17\left[1-\cosh\left(\frac{20}{2\cdot 9.17}\right)\right]\cong -6\,[\text{m}]\tag{16.4.72}$$

Thus the arrow of the cable is 6 meters below the horizontal of the two hangers.

16.4.4.2 Charges overhead cable (suspended bridge)

Let us consider the following suspended bridge carrying a constant linear load, hence the arrow h is imposed by the architect, as well as the distance D between the two pillars:

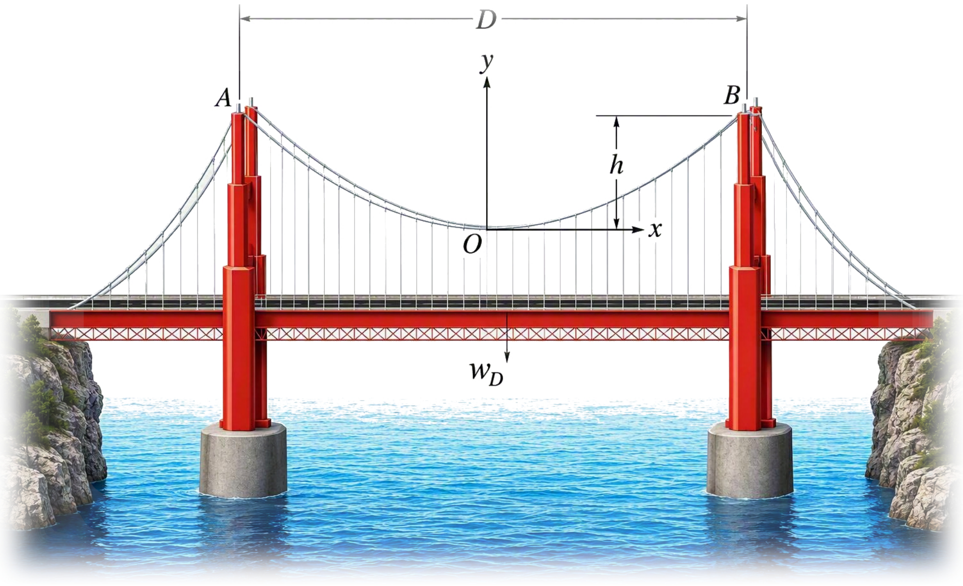

Figure 16.162: **Suspension bridge (source: ISBN 0-13-814929-1)**

Remark

We will assume that Earth's curvature is negligible in this particular example because in reality suspended bridge have their tower that are not parallel like the Verrazzano-Narrows Bridge (New-York/USA) where its monumental 194.76 meters high towers are 41.275 millimetres farther apart at their tops than at their bases because the 1298.448 meters distance between them made it necessary to compensate for the Earth's curvature.

The subtlety of this case study lies in the fact that the linear load is no longer in the cable itself but in the span of the bridge which has a much higher linear mass. We can no longer use the analyses given above. The development we did earlier above for a normal suspended cable remains valid only until the following relation:

$$\mathrm{d}(\tan(\alpha)) = \frac{\mathrm{d}L}{k} \tag{16.4.73}$$

Now, we must remember that we also have:

$$\mathrm{d}(\tan(\alpha)) = \mathrm{d}\left(\frac{\mathrm{d}y}{\mathrm{d}x}\right) = \frac{\mathrm{d}L}{k} \tag{16.4.74}$$

by rearranging and deriving again by $\mathrm{d}x$:

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\mathrm{d}y}{\mathrm{d}x}\right) = \frac{1}{k}\frac{\mathrm{d}L}{\mathrm{d}x} \tag{16.4.75}$$

On the bridge however, each portion $\mathrm{d}L$ of the cable is negligible in front of the portion $\mathrm{d}x$ of the bridge. This marks the difference between the suspended bridge and the simple overhead cable as we need to replace $\mathrm{d}L$ by $\mathrm{d}x$ (it is quite subtle with this approach but there are several possible approaches to this development). We then have the preceding relation which becomes:

$$\frac{\mathrm{d}^2y}{\mathrm{d}x^2}=\frac{1}{k}\frac{\mathrm{d}x}{\mathrm{d}x}=\frac{1}{k} \tag{16.4.76}$$

Either after rearrangement:

$$\mathrm{d}^2y=\left(\frac{1}{k}\mathrm{d}x\right)\mathrm{d}x \tag{16.4.77}$$

By integrating a first time it comes then:

$$\mathrm{d}y=\left(\frac{1}{k}\mathrm{d}x\right)x+C^{te} \tag{16.4.78}$$

And a second and last time:

$$y=\frac{1}{2k}x^2+C_1x+C_2 \tag{16.4.79}$$

The constants are determined by the initial conditions. The place where we have placed the reference frame imposes that $y=0$ in $x=0$ and that $\mathrm{d}y/\mathrm{d}x=0$ in $x=0$, we have the two constant which are zero and it then remains:

$$y=\frac{1}{2k}x^2=\frac{\mu g}{2T_0}x^2=\frac{w_0}{2T_0}x^2 \tag{16.4.80}$$

It is therefore the equation of a parabola and not of a overhead cable anymore! A small concern is that we do not know the tension (stress) in the cable. We should get rid of it. Now, because the architect requires that the arrow be h at $x=D/2$, then it comes:

$$T_0=\frac{w_0D^2}{8h} \tag{16.4.81}$$

therefore:

$$\boxed{y=\frac{4h}{D^2}x^2} \tag{16.4.82}$$

Again this remains a parable regardless of the weight! This is due to the fact that it is uniform in this case.

We then have to determine the length of the cable. For this we take up the relation already recalled above (proved in the section of Analytical Mechanics at page 3172 and in the section of Geometric Shapes at page 2956):

$$L=\int\limits_{x_1}^{x_2}\sqrt{1+y'^2}\,\mathrm{d}x \tag{16.4.83}$$

By the vertical symmetry of the function of the suspension bridge we can write:

$$\begin{aligned}L&=\int\limits_{x_1}^{x_2}\sqrt{1+y'^2}\mathrm{d}x=2\int\limits_{0}^{D/2}\sqrt{1+\left(\frac{4h}{D^2}x^2\right)'^2}\mathrm{d}x=2\int\limits_{0}^{D/2}\sqrt{1+\left(\frac{8h}{D^2}x\right)^2}\mathrm{d}x\\&=2\frac{8h}{D^2}\int\limits_{0}^{D/2}\sqrt{\left(\frac{D^2}{8h}\right)^2+x^2\mathrm{d}x}\end{aligned}\tag{16.4.84}$$

In the section of Differential and Integral Calculus in our proofs of the usual primitives (see page 1534), we have proved for recall that:

$$\int\sqrt{a^2+x^2}\mathrm{d}x=\frac{a^2}{2}\ln\left(x+\sqrt{a^2+x^2}\right)+\frac{x}{2}\sqrt{a^2+x^2}\tag{16.4.85}$$

Therefore it comes:

$$L=\frac{16h}{D^2}\int\sqrt{\left(\frac{D^2}{8h}\right)^2+x^2\mathrm{d}x}=\frac{16h}{D^2}\left[\frac{1}{2}\left(\frac{D^2}{8h}\right)^2\ln\left(x+\sqrt{\left(\frac{D^2}{8h}\right)^2+x^2}\right)+\frac{x}{2}\sqrt{\left(\frac{D^2}{8h}\right)^2+x^2}\right]\Bigg|_0^{D/2}\tag{16.4.86}$$

Or simplified:

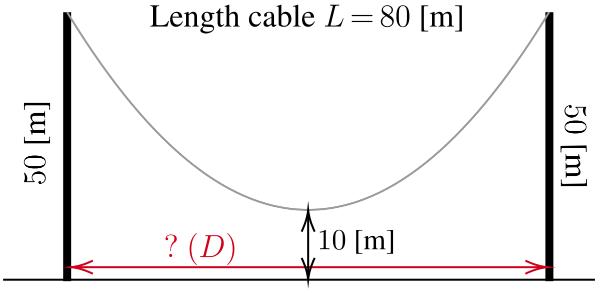
$$L=\frac{4\sqrt{\frac{D^2(D^2+16h^2)}{h^2}}h^2+D^3\ln\left(4D+\sqrt{\frac{D^2(D^2+16h^2)}{h^2}}\right)-2D^3\ln(D)+D^3\ln(h)}{8hD}\tag{16.4.87}$$

✍**Example:**

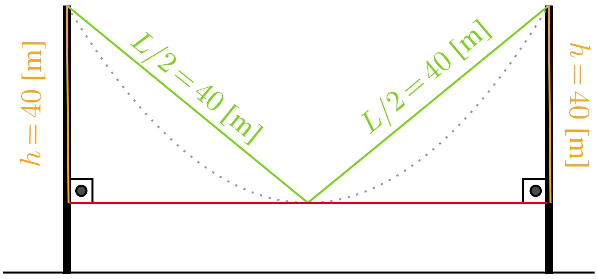
Let us consider the characteristics of the Golden Bridge of San Francisco. Its arrow h is about 230 [m] and its main bearing is $D=1280$ [m]. We have then:

$$L=\frac{4\sqrt{\frac{D^2(D^2+16h^2)}{h^2}}h^2+D^3\ln\left(4D+\sqrt{\frac{D^2(D^2+16h^2)}{h^2}}\right)-2D^3\ln(D)+D^3\ln(h)}{8hD}\cong 1383\,[\mathrm{m}]\tag{16.4.88}$$

Now the reader will be aware why the legendary (myth or reality who knows...?) below Google hiring test is only a logical test (because inverting the above relation would lead to a time-out expected of geniuses):



If you solve the above quite huge equation with Maple™ you get that $L = 80$ [m] when $D \to 0_+$ (but not $D = 0$ otherwise you get a division by zero) using $h = 40$ [m]. What the myth says is that you are supposed (because of the limited time available) to do the following rude approximation by "thinking out of the box":



that leads to the same result anyway using Pythagoras theorem:

$$40^2 = 40^2 + \text{base}^2 \Rightarrow \text{base} = 0 \quad (16.4.89)$$

16.4.4.3 Very tense cable

Let us recall that in the general case we get the following relation:

$$\vec{T}+\vec{T}_0+\mu L\vec{g}=\vec{0} \tag{16.4.90}$$

Let us take the differential:

$$\mathrm{d}\vec{T}+\underbrace{\mathrm{d}\vec{T}_0}_{=0}+\mu\vec{g}\mathrm{d}L=\vec{0} \tag{16.4.91}$$

Thus for the component y:

$$\mathrm{d}\vec{T}_y+\mu g\mathrm{d}L=0 \tag{16.4.92}$$

But we also have:

$$\frac{T_y}{T_x}=\frac{\mathrm{d}y}{\mathrm{d}x}=\tan(\alpha) \tag{16.4.93}$$

So injected into the previous relation this gives:

$$T_x\mathrm{d}\left(\frac{\mathrm{d}y}{\mathrm{d}x}\right)+\mu g\mathrm{d}L=0 \tag{16.4.94}$$

Therefore:

$$T_x\mathrm{d}\left(\frac{\mathrm{d}y}{\mathrm{d}x}\right)=-\mu g\mathrm{d}L \tag{16.4.95}$$

And under the assumption that the cable is very tight (under hight stress):

$$\mathrm{d}L\cong\mathrm{d}x \tag{16.4.96}$$

Therefore it comes:

$$T_x\mathrm{d}\left(\frac{\mathrm{d}y}{\mathrm{d}x}\right)=-\mu g\mathrm{d}x \tag{16.4.97}$$

After a first integration it comes:

$$T_x\frac{\mathrm{d}y}{\mathrm{d}x}=-\mu gx+c^{te} \tag{16.4.98}$$

Before going further, let us notice that the constant is easy to determine since in $x=L/2$, the derivative must be zero. We have then:

$$T_x\frac{\mathrm{d}y}{\mathrm{d}x}=-\mu gx+\mu g\frac{L}{2} \tag{16.4.99}$$

After a second integration (where the integration constant is zero):

$$T_xy=-\frac{\mu g}{2}(xL-x^2) \tag{16.4.100}$$

We then have for the deformation of the string:

$$\boxed{y=-\frac{\mu g}{T_x 2}(xL-x^2)} \tag{16.4.101}$$

Thus, in the middle of the cable (string), the arrow is then:

$$f=-\frac{\mu g}{T_x 2}\left(\frac{L}{2}L-\frac{L^2}{4}\right)=-\frac{\mu g L^2}{8T_x} \tag{16.4.102}$$

Or respectively if the arrow is known and the tension is sought to be determined:

$$T_x=-\frac{\mu g L^2}{8f} \tag{16.4.103}$$

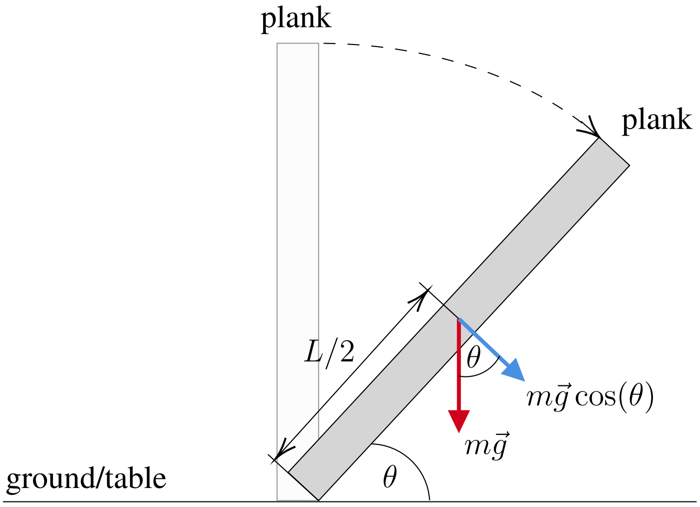
And we could also calculate the length of the cable (string) using the same technique as for the suspension bridge.

16.4.5 Falling chimney (naive approach)

The blasting of a falling chimney problem is a well known study in high-school and an interesting application of circular motion kinematics and moment of inertia. It is especially interesting as we can find many approach to this problem on Internet and textbooks but many known one are vicious as they hide important assumptions or are even wrong but still give the correct final result.

Our purpose here is to give the simplest possible way to determine the result without forgetting to enumerate any assumption! Our purpose is also to take this opportunity to introduce first a physical phenomenon that also appears within the falling chimney study framework that some people consider as "magic": the Hinged Stick and Ball trick (i.e. sometimes named "Galileo Paraxodx")!

Let us consider a plank that is able to pivot about one end, with the other end free to move. As in the figure below:



We assume:

- There is no friction at the pivot point
- We are in vacuum
- The plank is infinitely rigid
- The gravitational force is constant at any point
- The plank is assimilated to a cylinder

It is of interest to find the acceleration of various points on the plank. First, consider the rotational dynamics of the system while the plank is in motion. Once the plank is released from its rest position, the two forces acting on it are gravity and a normal force. The latter is exerted by the table at the pivot, so it does not exert a torque about the pivot. The gravitational force does exert a torque on the plank about the pivot, giving the net torque τ (we change the notation of the torque that is normally M in this textbook because later we will have M for the notation of the whole mass so it would be a mess if we don't change now!) on the plank as:

$$\tau = \frac{1}{2}mgL\cos(\theta) \tag{16.4.104}$$

where m is the mass of the plank, g is the acceleration due to gravity $g = 9.81\;[\text{m}\cdot\text{s}^{-2}]$, l is the plank's length and θ is the angle between the raised plank and the table.

The rotational equivalent of Newton's second law applies to the plank's motion, namely:

$$\tau = J\frac{\mathrm{d}\omega}{\mathrm{d}t} = J\ddot{\theta} \tag{16.4.105}$$

And we have proven in the section of Geometrical Shapes (see page 2959) that the moment of inertia of a cylinder rotating around a fixed extremity point was given by:

$$J = \frac{1}{3}mL^2 \tag{16.4.106}$$

Therefore:

$$\tau = \frac{1}{3}mL^2\ddot{\theta} \tag{16.4.107}$$

Next, the linear acceleration $a(x,\theta)$ of a point on the plank that is at a distance x from the pivot is given by (dimensional analysis):

$$a = x\ddot{\theta} \tag{16.4.108}$$

Therefore we can write:

$$\tau = \frac{1}{3}mL^2\ddot{\theta} = \frac{1}{3}mL^2\frac{a}{x} \tag{16.4.109}$$

And we can equate the both M to get:

$$\frac{1}{2}mgL\cos(\theta) = \frac{1}{3}mL^2\frac{a}{x} \tag{16.4.110}$$

from which it is possible to solve for a, with the result being:

$$\boxed{a = \frac{3gx}{2L}\cos(\theta)} \tag{16.4.111}$$

Let $x = L$, so that the point of consideration is the moving end of the stick. Then it remains (notice that the mass m does not appear!):

$$a = \frac{3}{2}g\cos(\theta) \tag{16.4.112}$$

Therefore we have that $a > g$ for the of the stick when:

$$\cos(\theta) \geq \frac{2}{3} = 0.841\;[\text{rad}] = 48.19^\circ \tag{16.4.113}$$

As we know that:

$$x=x_0+v_0t+\frac{1}{2}at^2 \tag{16.4.114}$$

and in our case the plank has $x_0=0$ and $v_0=0$ it comes:

$$t_{\text{falling}}=\sqrt{\frac{2x}{a}} \tag{16.4.115}$$

The distance x we are looking for depends on the initial angle θ but is trivially given (definition of the radian!) by for the extremity of the plank:

$$x=\theta L \tag{16.4.116}$$

Therefore (notice that the mass m again... does not appear!):

$$t_{\text{falling}}=\sqrt{\frac{2\theta L}{a}}=\sqrt{\frac{2\theta L}{\frac{3}{2}g\cos(\theta)}}=\sqrt{\frac{4}{3}\frac{\theta L}{g\cos(\theta)}} \tag{16.4.117}$$

✍**Example:**

If we consider a plastic ruler of $l=30$ [cm] and of mass $m=68$ [g] with starting angle $\theta=\pi/4$ [rad] we get:

$$t_{\text{falling}}=\sqrt{\frac{4}{3}\frac{\theta L}{g\cos(\theta)}}\cong 0.21\text{ [s]} \tag{16.4.118}$$

OK this basic stuff being done. Let us now focus on the chimney rupture point.

In the frame of the falling chimney we have for a perfect rigid chimney:

$$\mathrm{d}mx\ddot{\theta}=\mathrm{d}mg\cos(\theta) \tag{16.4.119}$$

But first we have:

$$\mathrm{d}m=\frac{M}{L}\mathrm{d}x \tag{16.4.120}$$

Therefore:

$$\frac{M}{L}x\ddot{\theta}\mathrm{d}x=\frac{M}{L}g\cos(\theta)\mathrm{d}x \tag{16.4.121}$$

or what remains the same:

$$-\frac{M}{L}x\ddot{\theta}\mathrm{d}x+\frac{M}{L}g\cos(\theta)\mathrm{d}x=0 \tag{16.4.122}$$

But in reality what we can observe is that a falling object consisting on a of smaller parts (bricks) breaks apart on some points:

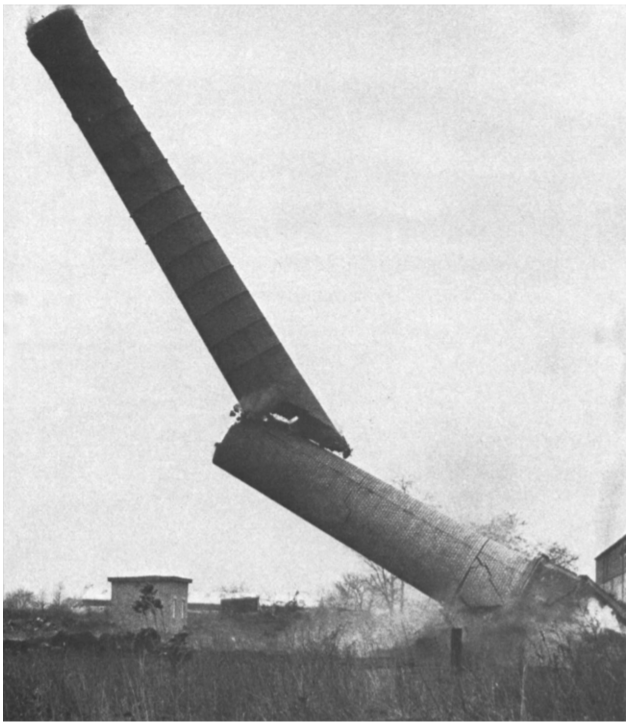


Figure 16.163: **A special case of falling chimney**

Obviously for chimneys the smaller bricks are not independent and the point of rupture depends on the material properties. So we will imagine a chimney made of a stack of bricks without any strengthening. So in this situation we observe that a falling stacks of bricks always break into parts. So the previous relations is not complete. We don't know the origin of the force that breaks apart but we know that we can insert a term that contains all possible sources of internal forces just by writing:

$$-\frac{M}{L}x\ddot{\theta}\mathrm{d}x+\frac{M}{L}g\cos(\theta)\mathrm{d}x=\mathrm{d}F \qquad (16.4.123)$$

Or we also could have written:

$$\frac{M}{L}x\ddot{\theta}\mathrm{d}x-\frac{M}{L}g\cos(\theta)\mathrm{d}x=\mathrm{d}F \qquad (16.4.124)$$

where $\mathrm{d}F$ is the force due to the mass that is above $\mathrm{d}m$.

Remark

Another way to explain this is to remember that we have proved earlier above that:

$$a=\frac{3gx}{2L}\cos(\theta) \qquad (16.4.125)$$

Therefore the angular acceleration depends on the length of the chimney. Now if the force of gravity were the only force acting on $\mathrm{d}m$, the angular acceleration on $\mathrm{d}m$ would be independent of the length of the chimney.

Now we know that what breaks such a hypothetical chimney is a torque!

An element at distance x_0 from 0 experiences a torque due to the rest of the chimney above it.

This torque is given by:

$$\begin{aligned}
\tau_{x_0} &= \frac{M}{L}\ddot{\theta}\int\limits_{x_0}^{L} x(x-x_0)\mathrm{d}x - \frac{M}{L}g\cos(\theta)\int\limits_{x_0}^{L}(x-x_0)\mathrm{d}x \\
&= \frac{M}{L}\left[\ddot{\theta}\int\limits_{x_0}^{L} x(x-x_0)\mathrm{d}x - g\cos(\theta)\int\limits_{x_0}^{L}(x-x_0)\mathrm{d}x\right] \\
&= \frac{M}{L}\left[\ddot{\theta}\left(\int\limits_{x_0}^{L} x^2\mathrm{d}x - x_0\int\limits_{x_0}^{L} x\mathrm{d}x\right) - g\cos(\theta)\left(\int\limits_{x_0}^{L} x\mathrm{d}x - x_0\int\limits_{x_0}^{L}\mathrm{d}x\right)\right] \\
&= \frac{M}{L}\left[\ddot{\theta}\left(\frac{1}{3}x^3 - \frac{1}{2}x_0x^2\right)\Bigg|_{x_0}^{L} - g\cos(\theta)\left(\frac{1}{2}x^2 - x_0x\right)\Bigg|_{x_0}^{L}\right] + c^{te} \\
&= \frac{M}{L}\left[\ddot{\theta}\left(\frac{1}{3}L^3 - \frac{1}{2}x_0L^2 - \frac{1}{3}x_0^3 + \frac{1}{2}x_0x_0^2\right) - g\cos(\theta)\left(\frac{1}{2}L^2 - x_0L - \frac{1}{2}x_0^2 + x_0x_0\right)\right] + c^{te} \\
&= \frac{M}{L}\left[\ddot{\theta}\left(\frac{1}{3}L^3 - \frac{1}{2}x_0L^2 + \frac{1}{6}x_0^3\right) - g\cos(\theta)\left(\frac{1}{2}L^2 - x_0L + \frac{1}{2}x_0^2\right)\right] + c^{te} \\
&= \frac{M}{L}\left[\ddot{\theta}\left(\frac{1}{6}x_0^3 + \frac{1}{3}L^3 - \frac{1}{2}x_0L^2\right) + g\cos(\theta)\left(x_0L - \frac{1}{2}L^2 - \frac{1}{2}x_0^2\right)\right] + c^{te}
\end{aligned} \tag{16.4.126}$$

The extremal torques (maxima and minima) are found by:

$$\frac{\mathrm{d}\tau_{x_0}}{\mathrm{d}x_0} = 0 \tag{16.4.127}$$

Therefore after derivation by x_0 it remains only:

$$0 = \frac{M}{L}\left[\ddot{\theta}\left(\frac{1}{2}x_0^2 - \frac{1}{2}L^2\right) + g\cos(\theta)\left(L - x_0\right)\right] \tag{16.4.128}$$

Or simplified a bit more:

$$\ddot{\theta}\left(\frac{1}{2}x_0^2 - \frac{1}{2}L^2\right) + g\cos(\theta)\left(L - x_0\right) = 0 \tag{16.4.129}$$

So there is a first obvious visible solution $x_0 = L$ that gives:

$$\tau_{x_0=L} = \frac{M}{L}\left[\ddot{\theta}\left(\frac{1}{6}x_0^3 + \frac{1}{3}L^3 - \frac{1}{2}x_0L^2\right) + g\cos(\theta)\left(x_0L - \frac{1}{2}L^2 - \frac{1}{2}x_0^2\right)\right] + c^{te} = 0 \tag{16.4.130}$$

So this is the minima!

Now remember that:

$$\ddot{\theta} = \frac{3}{2}\frac{g\cos(\theta)}{L} \tag{16.4.131}$$

Therefore:

$$\frac{3}{2}\frac{g\cos(\theta)}{L}\left(\frac{1}{2}x_0^2-\frac{1}{2}L^2\right)+g\cos(\theta)\,(L-x_0)=0 \tag{16.4.132}$$

After simplification (assuming $\cos(\theta)\neq 0$):

$$\frac{3}{2L}\left(\frac{1}{2}x_0^2-\frac{1}{2}L^2\right)+L-x_0=0 \tag{16.4.133}$$

Or:

$$\frac{3}{4}x_0^2-\frac{3}{4}L^2+L^2-Lx_0=0 \tag{16.4.134}$$

Hence:

$$\frac{1}{4}L^2-Lx_0+\frac{3}{4}x_0^2=0 \tag{16.4.135}$$

Or:

$$3x_0^2-4Lx_0+L^2=0 \tag{16.4.136}$$

This is a second degree polynomial on x_0. Therefore (see section Calculus page 1383):

$$x_{0(1,2)}=\frac{4L\pm\sqrt{(-4L)^2-4\cdot 3\cdot L^2}}{6}=\frac{4L\pm 2L}{6}=\left\{L,\frac{L}{3}\right\} \tag{16.4.137}$$

The maximum torque is therefore found at distance $x_0=L/3$ from 0. This is where the chimney might POSSIBLY break.

16.4.6 Dams

A dam is a barrier that impounds water or underground streams. Reservoirs created by dams not only suppress floods but also provide water for activities such as irrigation, human consumption, industrial use, aquaculture, and navigability. Hydropower is often used in conjunction with dams to generate electricity. A dam can also be used to collect water or for storage of water which can be evenly distributed between locations. Dams generally serve the primary purpose of retaining water, while other structures such as floodgates or levees (also known as dikes) are used to manage or prevent water flow into specific land regions.

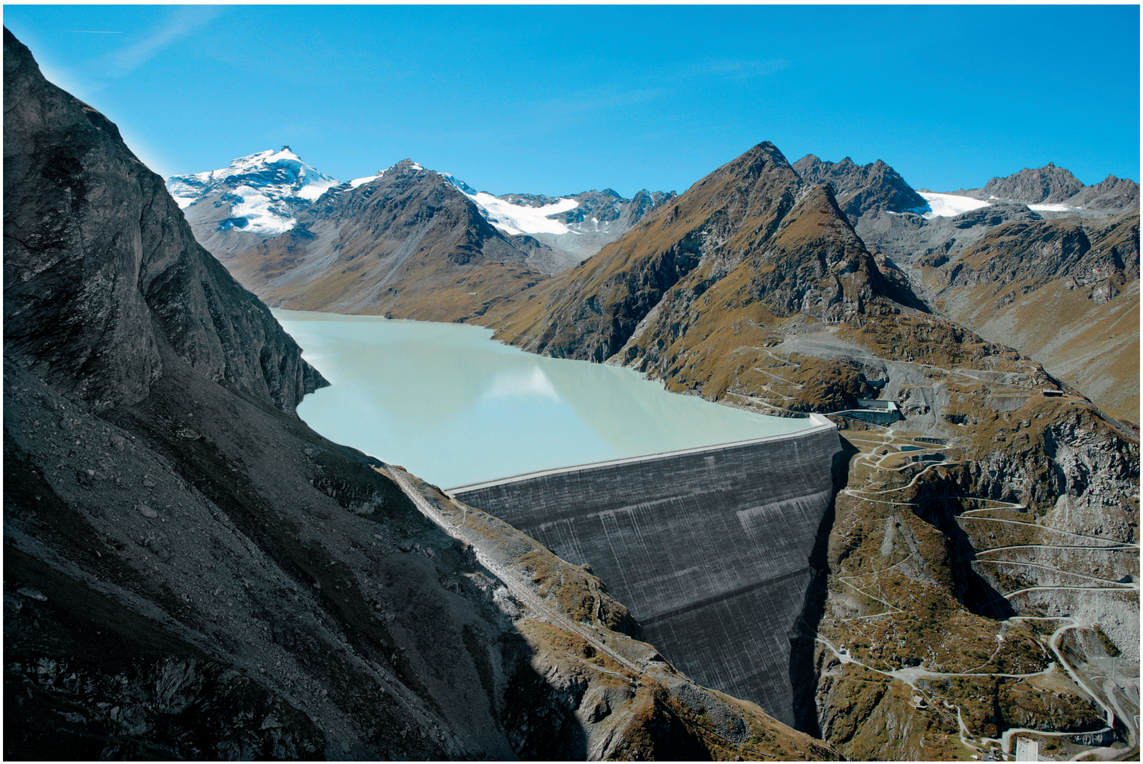

Figure 16.164: **Dixence (Switzerland) dam**

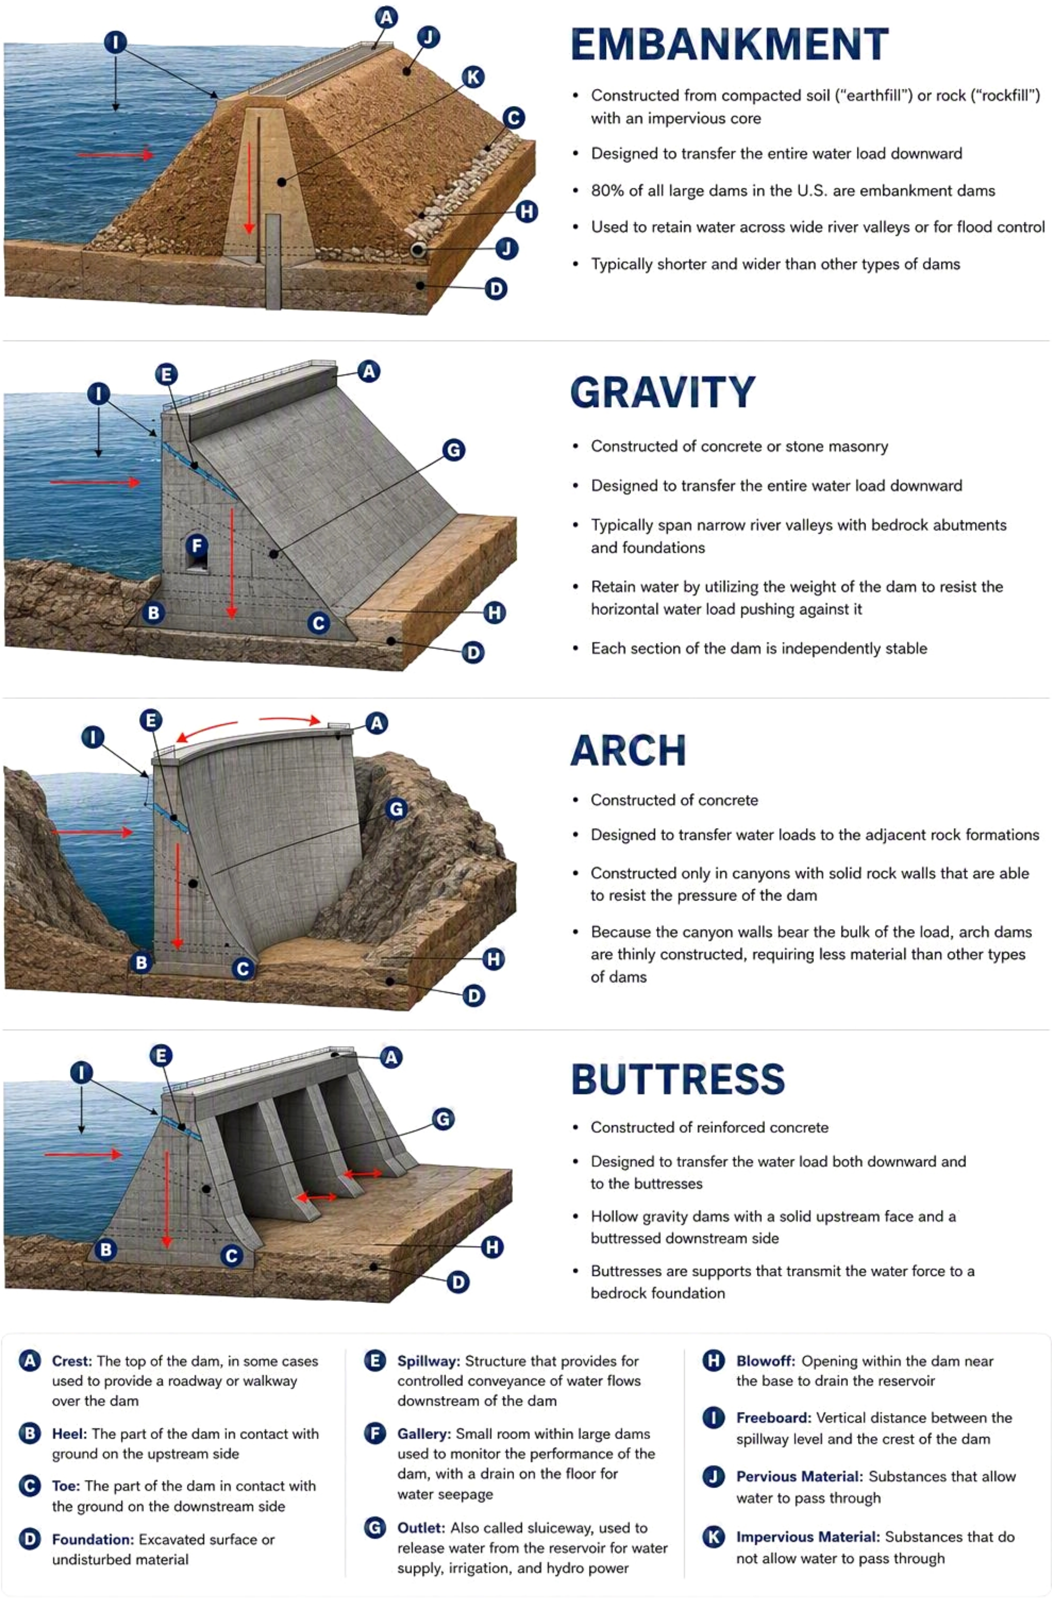
Remark

When dealing with dams or any similar configuration of full recipient, keep in mind this famous value in the field of dams power plants based on the hydrostatic pressure of the section of Continuum Mechanics at page 3791 (the final result is in bar):

$$\Delta P=\Delta(P_0+h\rho g)=\Delta h\rho g\cong 10\,[\text{m}]\cdot 997\,[\text{kg}\cdot\text{m}^{-3}]\cdot 9.81\,[\text{m}\cdot\text{s}^{-2}]\cong 1\,[\text{bar}] \tag{16.4.138}$$

Hence the famous rule, that for a dam, we have a surplus of $1\,[\text{bar}]$ for every $10\,[\text{m}]$! The Romans already knew this! therefore, in order to reduce the pressure, they created intermediate waterfalls to reduce the pressure.

There exist various type of dams as illustrated in the figure below:



EMBANKMENT

- Constructed from compacted soil ("earthfill") or rock ("rockfill") with an impervious core
- Designed to transfer the entire water load downward
- 80% of all large dams in the U.S. are embankment dams
- Used to retain water across wide river valleys or for flood control
- Typically shorter and wider than other types of dams

GRAVITY

- Constructed of concrete or stone masonry
- Designed to transfer the entire water load downward
- Typically span narrow river valleys with bedrock abutments and foundations
- Retain water by utilizing the weight of the dam to resist the horizontal water load pushing against it
- Each section of the dam is independently stable

ARCH

- Constructed of concrete
- Designed to transfer water loads to the adjacent rock formations
- Constructed only in canyons with solid rock walls that are able to resist the pressure of the dam
- Because the canyon walls bear the bulk of the load, arch dams are thinly constructed, requiring less material than other types of dams

BUTTRESS

- Constructed of reinforced concrete
- Designed to transfer the water load both downward and to the buttresses
- Hollow gravity dams with a solid upstream face and a buttressed downstream side
- Buttresses are supports that transmit the water force to a bedrock foundation

Ⓐ **Crest:** The top of the dam, in some cases used to provide a roadway or walkway over the dam

Ⓑ **Heel:** The part of the dam in contact with ground on the upstream side

Ⓒ **Toe:** The part of the dam in contact with the ground on the downstream side

Ⓓ **Foundation:** Excavated surface or undisturbed material

Ⓔ **Spillway:** Structure that provides for controlled conveyance of water flows downstream of the dam

Ⓕ **Gallery:** Small room within large dams used to monitor the performance of the dam, with a drain on the floor for water seepage

Ⓖ **Outlet:** Also called sluiceway, used to release water from the reservoir for water supply, irrigation, and hydro power

Ⓗ **Blowoff:** Opening within the dam near the base to drain the reservoir

Ⓘ **Freeboard:** Vertical distance between the spillway level and the crest of the dam

Ⓙ **Pervious Material:** Substances that allow water to pass through

Ⓚ **Impervious Material:** Substances that do not allow water to pass through

Figure 16.165: **Types of dams**

We will consider here, in a first time, only a "gravity dam" that is by definition a massive sized dam fabricated from concrete or stone masonry. Such dams are designed to hold back large volumes of water. By using concrete, the weight of the dam is actually able to resist the horizontal thrust of water pushing against it. This is why it is named a "gravity dam". Gravity essentially holds the dam down to the ground, stopping water from toppling it over.

Gravity dams are well suited for blocking rivers in wide valleys or narrow gorge ways. Since gravity dams must rely on their own weight to hold back water, it is necessary that they are built on a solid foundation of bedrock.

Therefore let us consider the following gravity dam (consisting of a solid with infinite rigidity and perfectly waterproof...) of height z, of length L and storing water of density ρ:

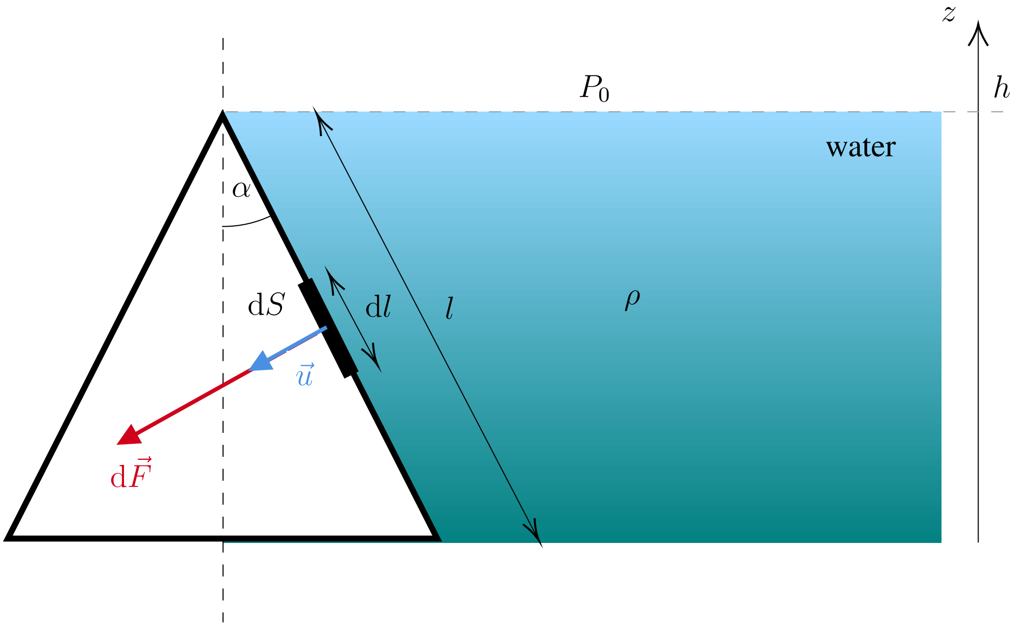


Figure 16.166: Simplified approach for the study of pressure on a gravity dam

We have proved in the section of Continuum Mechanics that the hydrostatic pressure was given by (see page 3791):

$$P = P_0 + h\rho g \tag{16.4.139}$$

But in this situation we obviously have:

$$P = P_0 + (h - z)\rho g \tag{16.4.140}$$

So when we place ourselves on the surface of the water at $z = h$:

$$P = P_0 \tag{16.4.141}$$

thus the pressure of the air at the surface of the dam sea...

On a surface element $\mathrm{d}S$ it applies an elementary force:

$$\mathrm{d}\vec{F} = P\mathrm{d}S = P\mathrm{d}S = \vec{u} = PL\mathrm{d}l\vec{u} \tag{16.4.142}$$

But:

$$\cos(\alpha)=\frac{z}{l}\Leftrightarrow \mathrm{d}l=\frac{\mathrm{d}z}{\cos(\alpha)} \tag{16.4.143}$$

Therefore:

$$\mathrm{d}\vec{F}=PL\mathrm{d}L\vec{u}=(P_0+(h-z)\rho g)L\frac{\mathrm{d}z}{\cos(\alpha)}\vec{u} \tag{16.4.144}$$

hence after integration:

$$F=PL\mathrm{d}l=\int_0^h(P_0+(h-z)\rho g)\frac{L}{\cos(\alpha)}\mathrm{d}z=\frac{Lh}{\cos(\alpha)}\left(P_0+\frac{1}{2}\rho gh\right) \tag{16.4.145}$$

It is therefore the force exerted on the immersed face. The force on the emerged face (left in the illustration) is simply given by putting $\rho=0$. We have therefore for the part due to atmospheric pressure alone:

$$F=\frac{Lh}{\cos(\alpha)}P_0 \tag{16.4.146}$$

and for the part due to water only:

$$\boxed{F=\rho gL\frac{h^2}{2\cos(\alpha)}} \tag{16.4.147}$$

Notice that in many undergraduate textbooks you will found the above relation but with $\alpha=0$.

Remark

On average between the empty state and full state (following what we can read on the Internet) the top of a gravity dam of certain height would sometimes move with an amplitude of the order of 80 [cm].

16.4.6.1 Power extracted from a Dam

A Dam (to simplify) makes electrical power by using the kinetic energy of water to turn a wheel, named a "Pelton wheel[16]" (there are other types of water turbines like the "Francis turbine" or the "Kaplan turbine") because it has a design optimized to extracted almost all of the water's impulse energy, which itself will drive a shaft that connects the turbine runner to the generator, this makes it possible to convert the mechanical energy from the rotating runner into electrical energy.

---

[16] Although Pelton turbines are very efficient, they are not as common as Kaplan and Francis turbines because the Pelton turbine requires a very large head of pressure (difference in elevation between the upper and lower reservoir) to operate; this restricts its use to certain geographical areas only.

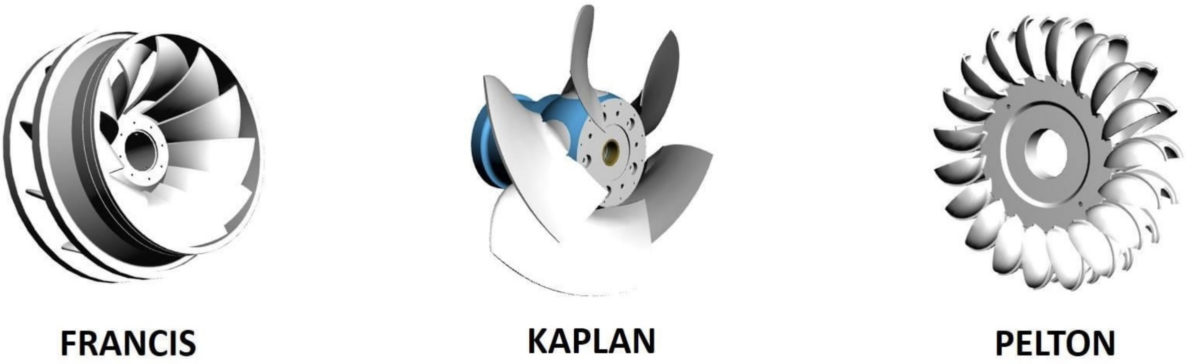

Figure 16.167: **Francis, Kaplan and Pelton wheels**

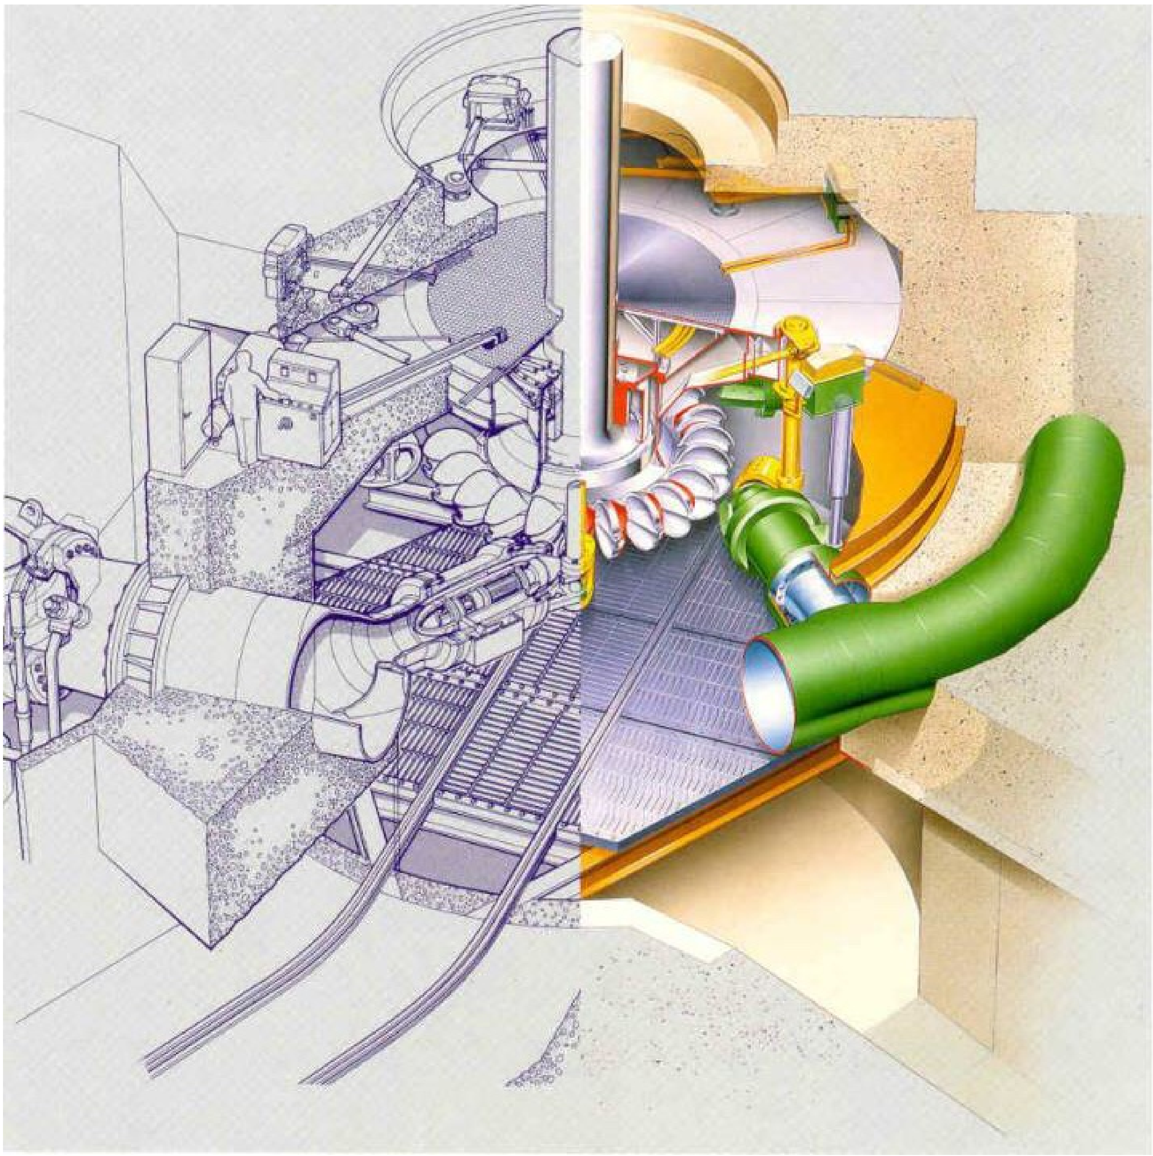
Pelton turbines can be used as prime movers for other rotating assets also e.g. a mechanical pump.



In the ideal (frictionless) case, all of the hydraulic potential energy $(E_p = mgh)$ is converted into kinetic energy $(E_c = mv^2/2)$.

Equating these two relations and solving for the initial jet velocity (v_i) indicates that the theoretical (maximum) jet velocity is:

$$v_i = \sqrt{2gh} \qquad (16.4.148)$$

For simplicity, let assume that all of the velocity vectors are parallel to each other. Defining the velocity of the wheel runner as u, then as the jet approaches the runner, the initial jet velocity relative to the runner is:

$$(v_i - u) \qquad (16.4.149)$$

where for reminder, the initial velocity of jet is v_i.

Assuming that the jet velocity is higher than the runner velocity, if the water is not to become backed-up in runner, then due to conservation of mass, the mass entering the runner must equal the mass leaving the runner. The fluid is assumed to be incompressible (an accurate assumption for most liquids). Also it is assumed that the cross-sectional area of the jet is constant. The jet speed remains constant relative to the runner. So as the jet recedes from the runner, the jet velocity relative to the runner is:

$$-(v_i - u) = -v_i + u \qquad (16.4.150)$$

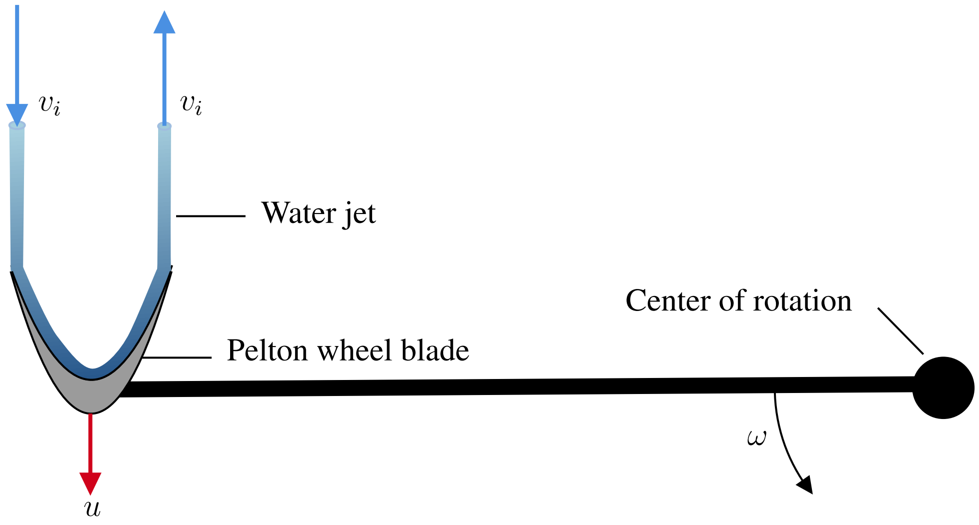


Figure 16.168: **Illustration of a Pelton wheel hydrorotor (source: [285])**

Notice that this assume a frictionless surface on the blade and therefore the output speed of water will remain v_i (.....). That means all our calculations we will have below are an upper limit in comparison to the real situation!!!

The reader must keep in mind what we are willing to calculate here! First we know that we can calculate the power of the water jet flow and in a practical situation we wish to extract all its power. But at a given time, the Pelton wheel will turn so fast that the incoming water jet will almost not accelerate the Pelton wheel but just maintain its optimal radial velocity. And it's the ratio of these both power that we are looking for (the power of the incoming water jet flow and that of the Pelton wheel in this optimal configuration)!

And that's on purpose as the reader must keep in mind that at the final stage we are looking to the efficiency that will be a ratio between the input power of water flow and the ideal maximum power of the torque of the Pelton wheel!

In the standard reference frame (relative to the earth), the final velocity in this ideal case is then:

$$v_f=(-v_i+u)+u=-v_i+2u \tag{16.4.151}$$

The ideal runner speed will cause all of the kinetic energy in the jet to be transferred to the wheel. In this case the final jet velocity must be zero. If:

$$-v_i+2u=0 \tag{16.4.152}$$

then the optimal runner speed will be:

$$u=\frac{v_i}{2} \tag{16.4.153}$$

or half the initial jet velocity!

By Newton's second and third laws, the force F imposed by the jet on the runner is equal but opposite to the rate of momentum change of the fluid, so:

$$F=-m\frac{v_f-v_i}{t}=-\rho\dot{m}\left[(-v_i+2u)-v_i\right]=-\rho\dot{m}\left(-2v_i+2u\right)=2\rho\dot{m}\left(v_i-u\right) \tag{16.4.154}$$

where ρ is the density, and $\dot{m}$ is the volume rate of flow of fluid. If D is the wheel diameter, the torque on the runner is:

$$M=F\frac{D}{2}=\rho\dot{m}D\left(v_i-u\right) \tag{16.4.155}$$

The torque is maximal when the runner is stopped (i.e. when $u=0$, $M=\rho\dot{m}DV_i$). When the speed of the runner is equal to the initial jet velocity, the torque is zero (i.e. when $u=v_i$, then $M=0$)... in the ideal case!

The power (see section Classical Mechanics page 3380):

$$P=Fu=M\omega \tag{16.4.156}$$

where ω is the angular velocity of the wheel. Substituting for F, we have:

$$P=2\rho\dot{m}\left(v_i-u\right)u \tag{16.4.157}$$

To find the runner speed at maximum power, we take the derivative of P with respect to u and set it equal to zero:

$$\frac{\partial P}{\partial u}=2\rho\dot{m}\left(v_i-2u\right)=0 \tag{16.4.158}$$

The maximum therefore power occurs when:

$$u=\frac{v_i}{2} \tag{16.4.159}$$

Therefore:

$$P_{\text{max}} = \rho \dot{m} \frac{v_i^2}{2} \tag{16.4.160}$$

Substituting the initial jet power $v_i = \sqrt{2gh}$, this simplifies to:

$$\boxed{P_{\text{max}} = \rho g h \dot{m}} \tag{16.4.161}$$

This quantity exactly equals the kinetic power of the jet, so in this ideal case, the efficiency is 100%, since all the energy in the jet is converted to shaft output.

A wheel power divided by the initial jet power P_i gives the turbine ideal efficiency:

$$\boxed{\eta_{\text{ideal}} = \frac{P}{P_i} = \frac{2\rho\dot{m}\left(v_i - u\right)u}{\frac{\rho\dot{m}v_i^2}{2}} = \frac{4u\left(v_i - u\right)}{v_i^2} > \eta_{\text{real}}} \tag{16.4.162}$$

It is zero for $u = 0$ and for... $u = v_i$ (that latter may be a little bit counterintuitive) and it is obviously equal to one for $u = v_i/2$ under our previous assumptions! As the equations indicate, when a real Pelton wheel is working close to maximum efficiency, the fluid flows off the wheel with very little residual velocity. In theory, the energy efficiency varies only with the efficiency of the nozzle and wheel, and does not vary with hydraulic head.

From a mechanical efficiency standpoint, considering friction and other losses, most water rotors operate at 90% or higher efficiency. In contrast, the maximum efficiency at which a wind rotor operates is 50% (see section Continuum Mechanics page 3862). The reason for such a large discrepancy in efficiency is the mechanics of energy transfer. With water, the direction of flow of almost all the particles is the same as the overall flow direction and, therefore, it is able to deliver most of the energy to the rotor. If air were used in a Pelton wheel, a significant amount of the energy would be used up to increase the randomness in velocity of air particles as opposed to imparting energy to the rotor.

16.4.7 Tuned Mass Damper

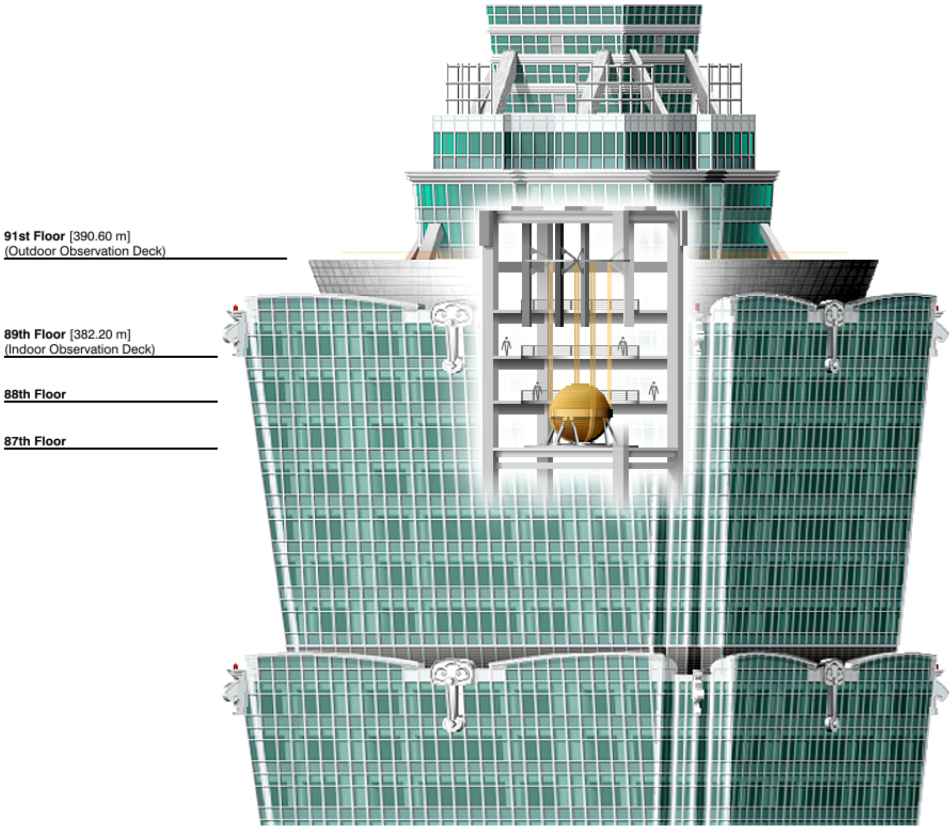
The "tuned mass damper", also known as "seismic damper", is a harmonic dumper that is of main importance in the construction of skyscrapper especially in areas with strong winds and earthquakes. The mathematical details are already provided in the section of Music Mathematics at page 8224.

This device is mounted in structures to reduce mechanical vibrations, consisting of a mass mounted on one or more damped springs. Its oscillation frequency is tuned to be similar to the resonant frequency of the object it is mounted to, and reduces the object's maximum amplitude while weighing much less than it.

TMDs can prevent discomfort, damage, or outright structural failure. They are frequently used in power transmission lines, automobiles, buildings and bridges.

Tuned mass dampers stabilize against violent motion caused by harmonic vibration. They use a comparatively lightweight component to reduce the vibration of a system so that its worst-case vibrations are less intense. Roughly speaking, practical systems are tuned to either move the main mode away from a troubling excitation frequency, or to add damping to a resonance that is difficult or expensive to damp directly. An example of the latter is a crankshaft torsional damper. Mass dampers are frequently implemented with a frictional or hydraulic component that turns mechanical kinetic energy into heat, like an automotive shock absorber.

One of the most impressive mass damper in the early 121st century (holocene calendar) is the one at the top of the Taipei 101 tower in Taiwin (508.2 [m] tall, build in 12005 according to holocene calendar):



91st Floor [390.60 m]
(Outdoor Observation Deck)
89th Floor [382.20 m]
(Indoor Observation Deck)
88th Floor
87th Floor

Figure 16.169: **Schematic view of Taipei 101 tower tuned mass damper (source: Wikipedia)**

Or a real photo of the dumper:

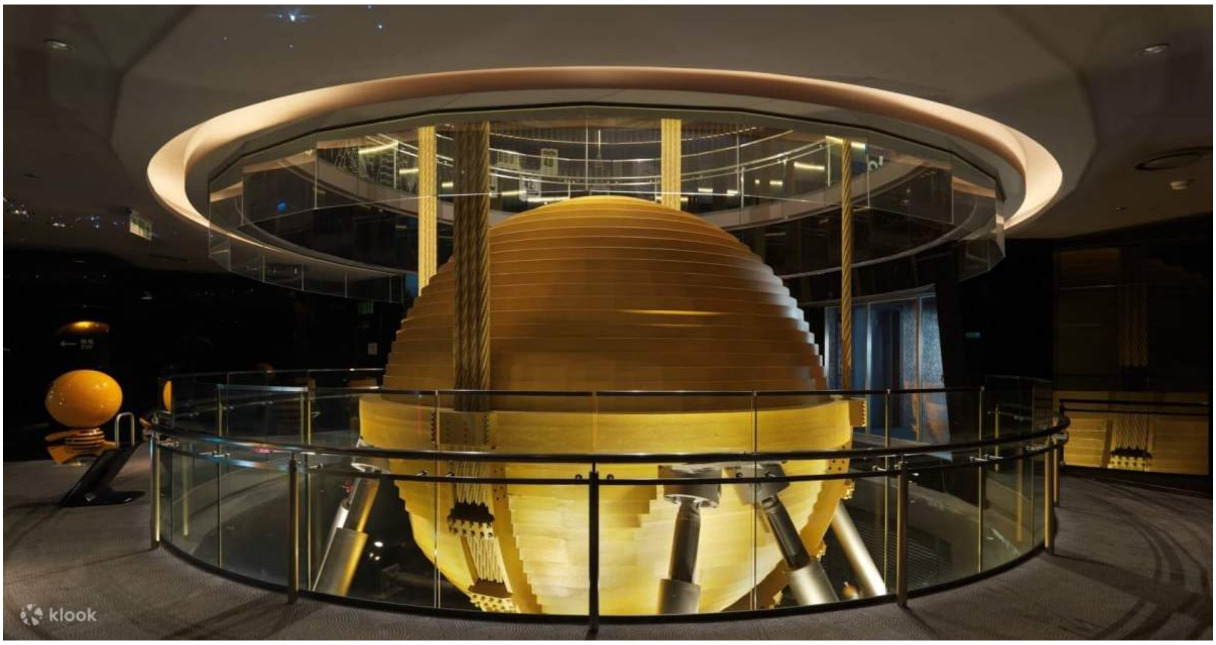


Figure 16.170: **Taipei 101 tower tuned mass damper (source: Klook)**

This damper measures 5.5 [m], its weight is 660 tons (the building itself is estimated at $700,000$

tons). It was made by welding together 41 layers of steel[17] boards, each 12.5 centimeters thick

The reader can see a video of the dumper acting during a 6.8 Richter scale earthquake (in September 18, 12002 according to holocene calendar) in this video:

[17] Density of steel varies from $7,750\,[\mathrm{kg}\cdot\mathrm{m}^{-3}]$ to $8,050\,[\mathrm{kg}\cdot\mathrm{m}^{-3}]$. But, steel is not the densest alloy or metal. Furthermore, the density of aluminum, iron, and gold is more than steel.

16.5. Aerospace Engineering

In this section we will see some useful and simple mathematical practical cases that we studied in the section of Analytic Geometry, Classical Mechanics and Continuum Mechanics and even Astronomy.

Aerospace engineering is the primary field of engineering concerned with the development of aircraft and spacecraft. It is divided into two major and overlapping branches: "aeronautical engineering" and "astronautical engineering". The Aerospace Engineering (astrodynamics) which is the scientific discipline that brings together aerospace engineering techniques (travel in the atmosphere, using airplanes or helicopter, for example) and those of astronautics (space travel, that is to say outside the atmosphere and interplanetary journeys, using shuttles space and rockets).

The reader will certainly notice that the examples below are only the examples that we often find in textbooks as exercises.

We will not here come back on the theory of conical (very important for the orbiting satellites) seen in the section Analytic Geometry (see page 2764), neither the gyroscope theory (see page 3324) very useful in guiding / force the axis of rotation (spin) of satellites and already seen in the section of Classical Mechanics (by cons we can not use the theory of ballistic that can be found in the same section as we had assumed there the constant initial speed...) or the theory of Lagrangian points (see page 5498) seen in the section of Astronomy sometimes useful to put satellites into interesting orbits for deep space observation. Also hypothetically we will consider bodies in a non-relativistic motion which is so far the most frequent case... at least actually...

In this section we will neglect most of times (but not always!) things like friction, vibration, the cases with more than two bodies (stars, planets ...) and many other factors that require computer simulation. We will also do not see the tricks specific to space engineering (like the fact that some satellites have weights attached by adjustable cables to increase or decrease their gyro momentum).

Remark

Some details may seem insignificant to the reader but the latter must be aware that the price per kilo of rocket launch is between $20,000$ USD and $30,000$ UDS on this beginning of the 121st century (holocene calendar) and this excluding insurance... (or $1,400$ USD per kilo for SpaceX Falcon Heavy) So everything that can be optimized without increasing the risk has to be optimized!

16.5.1 Airfoil Lift

A fluid flowing past the surface of a body exerts a force on it (and not magic...). The "lift" is the component of this force that is perpendicular to the oncoming flow direction. It contrasts with the "drag force", which is the component of the surface force parallel to the flow direction. If the fluid is air, the force is named an "aerodynamic force". In water, it is named a "hydrodynamic force".

Because lift is a force, it is a vector quantity, having both a magnitude and a direction associated with it. Lift acts through the center of pressure of the object and is directed perpendicular to the flow direction. There are several factors which affect the magnitude of lift.

There are many explanations for the generation of lift found in encyclopaedias, in basic physics textbooks and on websites. Unfortunately, many of the explanations are misleading or partially incorrect (because oversimplified) and does not quantify the value of the corresponding lift. Therefore it is naturally because of this lack of scientific approach that the generation of lift has become a source of great controversy and a topic for heated arguments (this is why NASA has a special sub-site dedicated to this subject that has significantly inspired us for the below pages).

Lift occurs when a moving flow of gas is turned by a solid object. The flow is turned in one direction, and the lift is generated in the opposite direction, according to Newton's Third Law of action and reaction. Because air is a gas and the molecules are free to move around, any solid surface can deflect a flow. For an aircraft wing, both the upper and lower surfaces contribute to the flow turning. Neglecting the upper surface's part in turning the flow leads to an incorrect theory of lift.

The proponents of the arguments usually fall into two main camps:

1. Those who support the "Bernoulli" position that lift is generated by a pressure difference across the wing
2. Those who support the "Newton" position that lift is the reaction force on a body caused by deflecting a flow of gas

Notice that we place the names in quotation marks because neither Newton nor Bernoulli ever attempted to explain the aerodynamic lift of an object.

Lift is generated by the difference in velocity between the solid object and the fluid. There must be motion between the object and the fluid: no motion, no lift.... It makes no difference whether the object moves through a static fluid, or the fluid moves past a static solid object.

Which camp is correct? How is lift generated? In fact there is no right or wrong camp!!! All different effects are superposed (with others effects not listed above!) and have more or left amplitude depending on the configuration of the wing (Angle Of Attack (AOA)). So a third camp, the one of wisdom, would answer that's complicates as it is most of the times a combination of the following effects (for which the contributions depend on the design of the airplane):

- Newton's lift effect (skipping stone argument)

- Bernoulli's lift effect (equal time argument)
- Euler's lift effect (streamwise acceleration argument)
- Coandă lift effect
- Kutta-Joukowki lift effect

When a gas flows over an object, or when an object moves through a gas, the molecules of the gas are free to move about the object; they are not closely bound to one another as in a solid. Because the molecules move, there is a velocity associated with the gas. Within the gas, the velocity can have very different values at different places near the object. Bernoulli's equation, which was named for Daniel Bernoulli, relates the pressure in a gas to the local velocity; so as the velocity changes around the object, the pressure changes as well. Adding up (integrating) the pressure variation times the area around the entire body determines the aerodynamic force on the body. The lift is the component of the aerodynamic force which is perpendicular to the original flow direction of the gas. The drag is the component of the aerodynamic force which is parallel to the original flow direction of the gas. Now adding up the velocity variation around the object instead of the pressure variation also determines the aerodynamic force. The integrated velocity variation around the object produces a net turning of the gas flow. From Newton's third law of motion, a turning action of the flow will result in a re-action (aerodynamic force) on the object. So both "Bernoulli" and "Newton" are correct. Integrating the effects of either the pressure or the velocity determines the aerodynamic force on an object. We can use equations developed by each of them to determine the magnitude and direction of the aerodynamic force.

What is the argument?

Arguments arise because people mis-apply Bernoulli and Newton's equations and because they over-simplify the description of the problem of aerodynamic lift. The most popular incorrect theory of lift arises from a mis-application of Bernoulli's equation. The theory is known as the "equal transit time" or "longer path" theory which states that wings are designed with the upper surface longer than the lower surface, to generate higher velocities on the upper surface because the molecules of gas on the upper surface have to reach the trailing edge at the same time as the molecules on the lower surface. The theory then invokes Bernoulli's equation to explain lower pressure on the upper surface and higher pressure on the lower surface resulting in a lift force. The error in this theory involves the specification of the velocity on the upper surface. In reality, the velocity on the upper surface of a lifting wing is much higher than the velocity which produces an equal transit time. If we know the correct velocity distribution, we can use Bernoulli's equation to get the pressure, then use the pressure to determine the force. But the equal transit velocity is not the correct velocity. Another incorrect theory uses a Venturi flow to try to determine the velocity. But this also gives the wrong answer since a wing section isn't really half a Venturi nozzle. There is also an incorrect theory which uses Newton's third law applied to the bottom surface of a wing. This theory equates aerodynamic lift to a stone skipping across the water. It neglects the physical reality that both the lower and upper surface of a wing contribute to the turning of a flow of gas.

The real details of how an object generates lift are very complex and do not lend themselves to simplification. For a gas, we have to simultaneously conserve the mass, momentum, and energy in the flow. Newton's laws of motion are statements concerning the conservation of momentum. Bernoulli's equation is derived by considering conservation of energy. So both of these equations are satisfied in the generation of lift; both are correct. The conservation of mass introduces a lot of complexity into the analysis and understanding of aerodynamic problems. For example, from the conservation of mass, a change in the velocity of a gas in one direction results in a change in the velocity of the gas in a direction perpendicular to the original change. This is very different from the motion of solids, on which we base most of our experiences in physics. The simultaneous conservation of mass, momentum, and energy of a fluid (while neglecting the effects of air viscosity) are named the Euler Equations after Leonard Euler (see section Continuum Mechanics page 3831). Euler was a student of Johann Bernoulli, Daniel's father, and for a time had worked with Daniel Bernoulli in St. Petersburg. If we include the effects of viscosity, we have the Navier-Stokes equations. To truly understand the details of the generation of lift, one has to have a good working knowledge of the Euler Equations.

Keep in mind that we may explain the same phenomena in many ways, one doesn't exclude the other. So now let us focus on all common possible calculations of lift in a special configuration case to be able to compare their effect numerically!

Remark

An airplane's altitude is maintained by air density. In level constant velocity flight, all the forces on an airplane are balanced. Lift counteracts Gravity. Thrust counteracts drag. Lift is caused by air flowing around the airplane wings. If an airplane increases altitude without increasing thrust, the reduction in air density means less air is flowing over the wings therefore the lift decreases. Less lift with same gravity means the airplane's altitude will decrease until |lift| = |gravity|. Since the air density gradient follows the curvature of the Earth, airplanes will automatically follow the curvature of the Earth because of the laws of Physics. It's named "Phugoid oscillation".

16.5.1.1 Newton's lift argument (skipping stone argument)

About paper planes... even a flat surface can produce a lift with an angle of attack. But the "equal time argument" (Bernoulli's equation) cannot explain such phenomenon.

The Newton's lift is given by the relation (see section Continuum Mechanics page 3853) that we have determined during out study of Stoke's law:

$$\boxed{F=\rho v^2 L^2 C(\mathrm{Re})=C_D v^2=\frac{1}{2}C\rho S v^2} \tag{16.5.1}$$

Let's use the information we've just learned to evaluate the "skipping stone argument":

1. This theory is concerned with only the interaction of the lower surface of the moving object and the air. It assumes that all of the flow turning (and therefore all the lift) is produced by the lower surface. Experiments shows the upper surface also turns the flow. In fact, when one considers the downwash produced by a lifting airfoil, the upper surface contributes more flow turning than the lower surface. This theory does not predict or explain this effect.

2. Because this theory neglects the action/reaction of molecules striking the upper surface, it does not predict the negative lift present in our experiment when the angle of attack is negative. On the top of the airfoil, no vacuum exists. Molecules are still in constant random motion on the upper surface (as well as the lower surface), and these molecules strike the surface and impart momentum to the airfoil as well.

3. The upper airfoil surface doesn't enter into the theory at all. So using this theory, we would expect two airfoils with the same lower surface but very different upper surfaces to give the same lift. We know this doesn't occur in reality. In fact, there are devices on many airliners named "spoilers" which are small plates on the upper surface, between the leading and trailing edges. They are used to change the lift of the wing to maneuver the aircraft by disrupting the flow over the upper surface. This theory does not predict or explain this effect.

4. If we make lift predictions based on this theory, using a knowledge of air density and the number of molecules in a given volume of air, the predictions are totally inaccurate when compared to actual measurements. The chief problem with the theory is that it neglects the physical properties of the fluid. Lift is created by turning a moving fluid, and all parts of the solid object can deflect the fluid.

But.... this theory is not totally inaccurate. In certain flight regimes, where the velocity is very high and the density is very low, few molecules can strike the upper airfoil surface and the Newtonian theory gives very accurate predictions. These are the conditions which occur on the Space Shuttle during the early phases of its re-entry into the Earth's atmosphere at altitudes above about 80 [km] and at velocities above 13 Mach. For these flight conditions, the theory gives a good prediction. However, for most normal flight conditions, like those on an airliner (10 [km], $800\left[\text{km}\cdot\text{h}^{-1}\right]$), this argument does not give the right answer.

16.5.1.2 Bernoulli's lift argument (equal time argument)

The "equal time argument" states that airfoils are shaped with the upper surface longer than the bottom. The air molecules have farther to travel over the top of the airfoil than along the bottom. In order to meet up at the trailing edge, the molecules going over the top of the wing must travel faster than the molecules moving under the wing. Because the upper flow is faster, then, from Bernoulli's generalized equation (see section Continuum Mechanics page 3936):

$$\boxed{E=H-PV=\frac{1}{\gamma-1}PV+mgh+\frac{1}{2}mv^2=c^{te}} \tag{16.5.2}$$

the pressure is lower. The difference in pressure across the airfoil produces the lift.

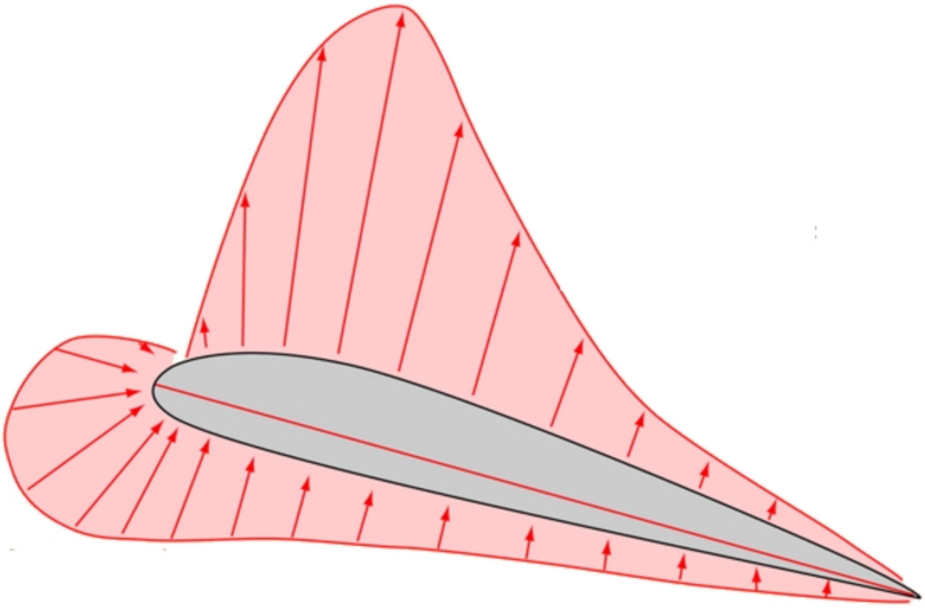

Figure 16.171: **Bernoulli force pressure lift effect illustration (source: HyperPhysics, author: Rod Nave)**

This approach is a beautiful and simple way to explain lift but... in fact, as we have seen in it in the section of Continuum Mechanics, the Bernoulli's equation must be applied on a unique stream line and therefore it is wrong to take for the starting point and endpoint by mixing the both path as they are distinct stream lines!

However it would be a shame that a reader thinks the Bernoulli's lift argument is never applicable to flow around an airfoil! As already mentioned we must be careful with the assumptions of this theorem, but there are still relatively easy to satisfy:

- The flow has to be incompressible. With air, it is not strictly accurate to zero speed. However, as long as one remains in low subsonic, air can reasonably be considered an incompressible fluid (in practice, as long as one remains at a Mach number of less than 0.2 or 0.3). And even the first Bernoulli remains available for all the barotropic compressible fluids along a streamline.
- The fluid must be perfect. The air is a viscous fluid, though the phenomena related to the viscosity remain confined to the boundary layer outside the boundary layer, the fluid can be considered perfect.
- The flow must be irrotational. In fact, it is sufficient that the flow is irrotational globally (this is the general case). The fact that there is locally turbulence does not stop to apply more generally the theorem.

Let's use the information we've just learned to evaluate the various parts of this theory:

- Lifting airfoils are designed to have the upper surface longer than the bottom: This is not always correct. The symmetric airfoil also generates plenty of lift and its upper surface is the same length as the lower surface. Think of a paper airplane. Its airfoil is a flat plate, top and bottom exactly the same length and shape and yet they fly just fine. This part of the theory probably got started because early airfoils were curved and shaped with a longer distance along the top. Such airfoils do produce a lot of lift and flow turning, but it is the turning that's important, not the distance. There are modern, low-drag airfoils which produce lift on which the bottom surface is actually longer than the top. This theory also does not explain how airplanes can fly upside-down which happens often at air shows and in air-to-air combat. The longer surface is then on the bottom!

- Air molecules travel faster over the top to meet molecules moving underneath at the trailing edge: Experiments shows us that the flow over the top of a lifting airfoil does travel faster than the flow beneath the airfoil. But the flow is much faster than the speed required to have the molecules meet up at the trailing edge. Two molecules near each other at the leading edge will not end up next to each other at the trailing edge as shown experiments. This part of the theory attempts to provide us with a value for the velocity over the top of the airfoil based on the non-physical assumption that the molecules meet at the aft end. We can calculate a velocity based on this assumption, and use Bernoulli's equation to compute the pressure, and perform the pressure-area calculation and the answer we get does not agree with the lift that we measure for a given airfoil. The lift predicted by the "equal time argument" theory is much less than the observed lift, because the velocity is too low. The actual velocity over the top of an airfoil is much faster than that predicted by the "equal time argument" theory and particles moving over the top arrive at the trailing edge before particles moving under the airfoil.

- The upper flow is faster and from Bernoulli's equation the pressure is lower. The difference in pressure across the airfoil produces the lift: Experiments show that this part of the theory is correct. In fact, this theory is very appealing because many parts of the theory are correct. In our discussions on pressure-area integration to determine the force on a body immersed in a fluid, we mentioned that if we know the velocity, we can obtain the pressure and determine the force. The problem with the "Equal Transit" theory is that it attempts to provide us with the velocity based on a non-physical assumption as discussed above.

Remark

The misconception that wings must be curved on top and flat on the bottom is commonly associated with the previously-discussed misconception that the air is required to pass above and below the wing in equal amounts of time. In fact, an upside-down wing produces lift by exactly the same principle as a rightside-up wing.

16.5.1.3 Euler's lift argument

Let us recall the Euler equation of the 1st form seen in the section of Continuum Mechanics at page 3828 (still for an incompressible fluid):

$$\rho\left[\partial_t\vec{v}+(\vec{v}\circ\vec{\nabla})\vec{v}\right]=\rho\vec{f}-\vec{\nabla}p \tag{16.5.3}$$

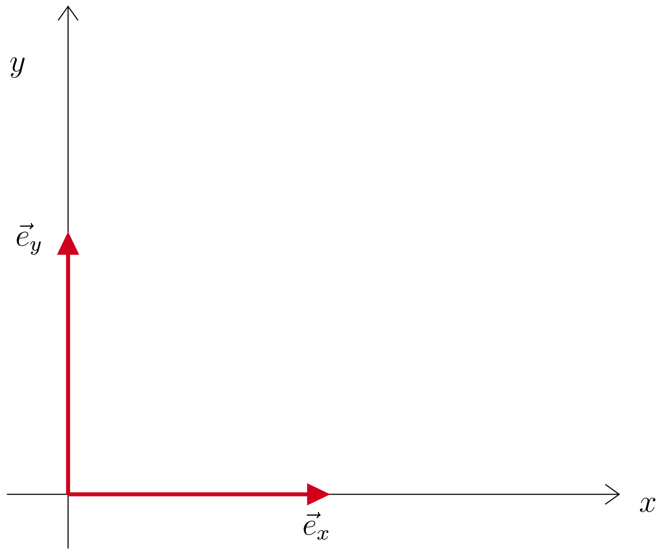
If we neglect the gravitational field:

$$\rho\left[\partial_t\vec{v}+(\vec{v}\circ\vec{\nabla})\vec{v}\right]=-\vec{\nabla}p \tag{16.5.4}$$

Distributing:

$$\rho\partial_t\vec{v}+\rho(\vec{v}\circ\vec{\nabla})\vec{v}=-\vec{\nabla}p \qquad (16.5.5)$$

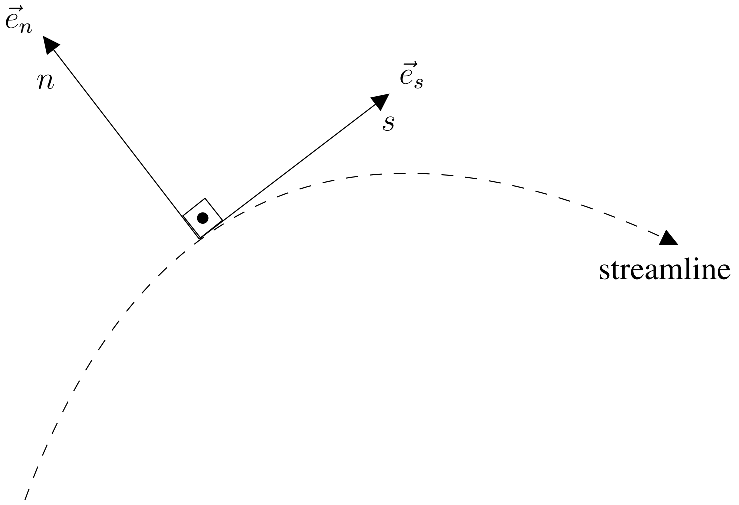
Let us now recall that in cartesian coordinates:



We define the gradient operator in 2D as:

$$\vec{\nabla}=\vec{e}_x\frac{\partial}{\partial x}+\vec{e}_y\frac{\partial}{\partial y} \qquad (16.5.6)$$

And let us introduce another approach, named "streamline coordinates", based on using differential geometry considering the following figure:



We define obviously the gradient identically:

$$\vec{\nabla}=\vec{e}_s\frac{\partial}{\partial s}+\vec{e}_n\frac{\partial}{\partial n} \qquad (16.5.7)$$

The advantage of this approach is that the velocity vector is obviously:

$$\vec{v}=v\vec{e}_s \tag{16.5.8}$$

The disadvantage however is that the unit vectors $\{\vec{e}_s,\vec{e}_n\}$ (Frenet vectors) change along the streamline!

Let us now recall the first Frenet formula (see section Differential Geometry page 2865):

$$\frac{\vec{N}}{R}=\frac{\mathrm{d}\vec{T}}{\mathrm{d}s} \tag{16.5.9}$$

Hence in our case above, this will be written (the "$-$" sign is here to make the perpendicular vector to be outside of the osculating circle as in the figure above):

$$-\frac{\vec{e}_n}{R}=\frac{\mathrm{d}\vec{e}_s}{\mathrm{d}s} \tag{16.5.10}$$

where are we know, R is the radius of curvature at that point on the streamline.

Now let us go back to the Euler equation of the 1st form:

$$\rho\partial_t\vec{v}+\rho(\vec{v}\circ\vec{\nabla})\vec{v}=-\vec{\nabla}p \tag{16.5.11}$$

This equation is steady flow state is simplified as:

$$\rho(\vec{v}\circ\vec{\nabla})\vec{v}=-\vec{\nabla}p \tag{16.5.12}$$

That we will rearrange a bit:

$$\vec{v}\circ\vec{\nabla}\vec{v}=-\frac{1}{\rho}\vec{\nabla}p \tag{16.5.13}$$

Applying the intrinsic definition of $\vec{\nabla}$ and noting that:

$$\vec{e}_s\circ\vec{e}_s=1 \qquad \vec{e}_s\circ\vec{e}_n=0 \tag{16.5.14}$$

and remembering that:

$$\vec{v}=v\vec{e}_s \tag{16.5.15}$$

Then we have successively:

$$\begin{aligned}
\vec{v}\circ\vec{\nabla}\vec{v}&=-\frac{1}{\rho}\vec{\nabla}p && (16.5.16)\\
(v\vec{e}_s)\circ\vec{\nabla}(v\vec{e}_s)&=-\frac{1}{\rho}\vec{\nabla}p && (16.5.17)\\
v\vec{e}_s\left(\vec{e}_s\frac{\partial(v\vec{e}_s)}{\partial s}+\vec{e}_n\frac{\partial(v\vec{e}_s)}{\partial n}\right)&=-\frac{1}{\rho}\left(\vec{e}_s\frac{\partial p}{\partial s}+\vec{e}_n\frac{\partial p}{\partial n}\right) && (16.5.18)\\
v\frac{\partial(v\vec{e}_s)}{\partial s}&=-\frac{1}{\rho}\left(\vec{e}_s\frac{\partial p}{\partial s}+\vec{e}_n\frac{\partial p}{\partial n}\right) && (16.5.19)\\
v\left(\vec{e}_s\frac{\partial v}{\partial s}+v\frac{\partial\vec{e}_s}{\partial s}\right)&=-\frac{1}{\rho}\left(\vec{e}_s\frac{\partial p}{\partial s}+\vec{e}_n\frac{\partial p}{\partial n}\right) && (16.5.20)
\end{aligned}$$

$$\vec{e}_s v\frac{\partial v}{\partial s} - v^2\frac{\vec{e}_n}{R} = -\frac{1}{\rho}\left(\vec{e}_s\frac{\partial p}{\partial s} + \vec{e}_n\frac{\partial p}{\partial n}\right) \tag{16.5.21}$$

Resolving separately in the $\vec{e}_s$ and $\vec{e}_n$ gives (notice that the dimensions are those of an acceleration $[\mathrm{m}^2 \cdot \mathrm{s}^{-1}]$!):

$$v\frac{\partial v}{\partial s} = -\frac{1}{\rho}\frac{\partial p}{\partial s} \tag{16.5.22}$$

$$\frac{v^2}{R} = \frac{1}{\rho}\frac{\partial p}{\partial n} \tag{16.5.23}$$

Where the first relation is say to give the "streamwise acceleration", denoted a_s, and the second relation is say to give the "normal acceleration", denoted a_n.

We see that the second relation describes how streamlines are bent by pressure gradients. So the important stuff to focus on is:

$$\boxed{\frac{v^2}{R} = \frac{1}{\rho}\frac{\partial p}{\partial n}} \tag{16.5.24}$$

that states that when there is flow and the streamlines curve, the pressure p increases in the $\vec{n}$ direction, that is, as one moves away from the local center of curvature.

Remark

Notice that the first relation:

$$v\frac{\partial v}{\partial s} = -\frac{1}{\rho}\frac{\partial p}{\partial s} \tag{16.5.25}$$

can also be rewritten:

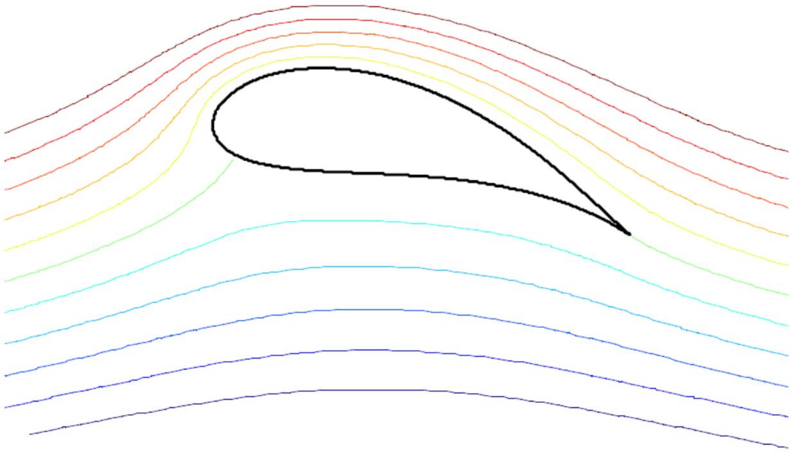
$$\frac{\partial}{\partial s}\left(\frac{1}{2}v^2\right) = -\frac{1}{\rho}\frac{\partial p}{\partial s} \tag{16.5.26}$$

and rearranging we get:

$$\frac{\partial}{\partial s}\left(\frac{1}{2}\rho v^2 + p\right) = 0 \tag{16.5.27}$$

So we fall back on the Bernoulli's theorem that, for recall, states that the sum in the parenthesis remains invariant along a streamline.

Now to illustrate the physical meaning, consider the following illustration:



The difference between the pressure at infinity and at the top of the wing is given by the integration of:

$$\frac{v^2}{R} = \frac{1}{\rho}\frac{\partial p}{\partial n} \tag{16.5.28}$$

from which we see that:

$$p_\infty - p_{\text{top}} = \int_{\text{top}}^{+\infty} \frac{\rho v^2}{R} \mathrm{d}n > 0 \tag{16.5.29}$$

Thus $p_{\text{top}} < p_\infty$ and according to Bernoulli's equation:

$$\frac{\partial}{\partial s}\left(\frac{1}{2}\rho v^2 + p\right) = 0 \tag{16.5.30}$$

it then follows that $v_{\text{top}} > v_\infty$.

16.5.1.4 Coandă lift argument

In its original sense, the Coandă effect refers to the tendency of a fluid jet to stay attached to an adjacent surface that curves away from the flow, and the resultant entrainment of ambient air into the flow.

More broadly, some consider the effect to include the tendency of any fluid boundary layer to adhere to a curved surface, not just the boundary layer accompanying a fluid jet. It is in this broader sense that the Coandă effect is used by some to explain why the air flow remains attached to the top side of an airfoil.

16.5.1.5 Kutta-Joukowski lift argument

Many discussion of airfoil lift invoke a vortex around the moving airfoil and it well known and experimentally proven that there is a lift around a spinning cylinder. This is named the "Kutta-Joukowski theorem" (Kutta–Joukowski theorem relates lift to circulation much like the Magnus effect relates side force (named Magnus force) to rotation).

The two early aerodynamicists, Kutta in Germany and Joukowski in Russia, worked to quantify the lift achieved by an airflow over a spinning cylinder. The lift relation is given by:

$$\boxed{L = -\rho U_\infty \Gamma b} \tag{16.5.31}$$

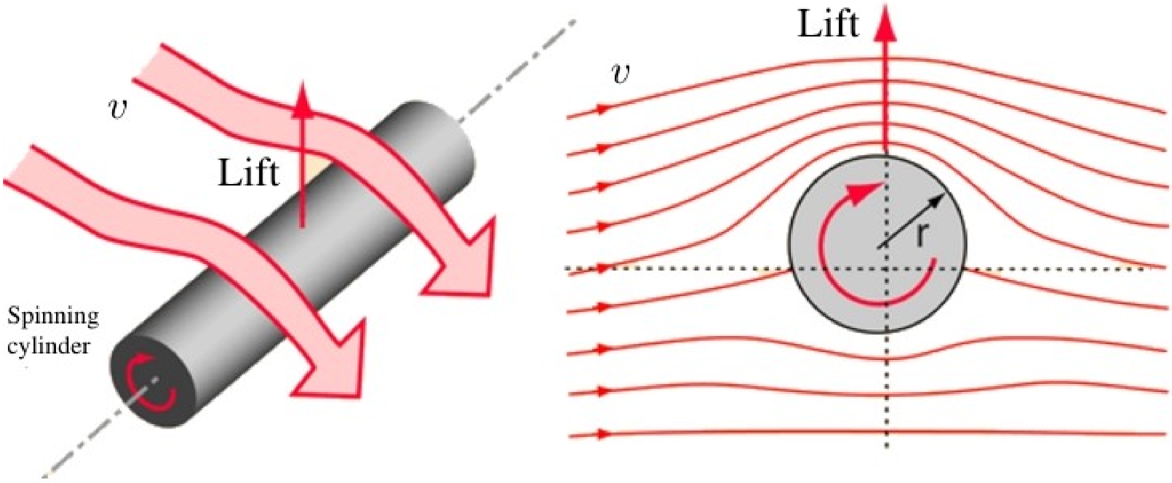


Figure 16.172: **Kutta-Joukowski lift effect illustration (source: HyperPhysics, author: Rod Nave)**

Like all aerodynamic lift, this seems a bit mysterious, but it can be looked at in terms of a redirection of the air motion. If the cylinder traps some air in a boundary layer at the cylinder surface and carries it around with it, shedding it downward, then it has given some of the air a downward momentum. That can act to give the cylinder an upward momentum in accordance with the principle of conservation of momentum. Another approach is to say that you have exerted a downward component of force on the air and by Newton's 3rd law there must be an upward force on the cylinder. Yet another approach is to say that the top of the cylinder is assisting the airstream, speeding up the flow on the top of the cylinder. Then by the Bernoulli equation, the pressure on the top of the cylinder is diminished, giving an effective lift.

We have seen that several physical principles are involved in producing lift. Each of the following statements is correct as far as it goes:

- The wing produces lift "because" it is flying at an angle of attack.
- The wing produces lift "because" of circulation.
- The wing produces lift "because" of Bernoulli's principle.

- The wing produces lift "because" of Newton’s law of action and reaction.

To finish depending on donations

16.5.2 Cosmic speeds

Placing takeoff of a rocket near the equator will be of significant assistance since the tangential velocity (horizontal) of the rotation of the Earth is given by (applying the trivial circular kinematics studied in the section of Classical Mechanics):

$$v=\omega R\cong 465\,[\text{m}\cdot\text{s}^{-1}] \tag{16.5.32}$$

That is to says slightly more than the speed of sound on the ground in standard conditions of temperature and pressure, which represents about 5% of the first cosmic speed we will deal with just a little further below (that's already something to optimize fuel usage!). And obviously, as the Earth rotates on itself from west to east it is better to leave the rocket to the East rather than straight or even worse ... to the West (note in passing that for security reasons of people on the ground it would be even better if the rocket can be sent to the East over the ocean...).

Also note that we are seeking also to acquire of course vertical speed to quickly leave the dense layers of the atmosphere, but we also want to communicate to the launcher a horizontal velocity component: that is to say the velocity that allows to put satellites into orbit of the Earth or of something else less or far away (hence another reason to launch to the East).

As about the difference of the gravitational acceleration it is also a factor to be taken into account. Indeed some specialized book provide:

$$\begin{aligned}g_{\text{equator}}&=9.78039\,[\text{m}\cdot\text{s}^{-2}]\\ g_{\text{north pole}}&=9.78039\,[\text{m}\cdot\text{s}^{-2}]\end{aligned} \tag{16.5.33}$$

Thus, a difference of about 0.527% of the weight of a space shuttle and this is not negligible to once again save fuel.

The "first cosmic speed" or "low-level orbit speed" (or just "orbital speed" or "orbital velocity") is the minimum velocity at which a body should be brought to lie in low orbit around the Earth (for small celestial masses otherwise General Relativity must be involved!). It is determined by the relation balance between centrifugal and centripetal force (see section Classical Mechanics page 3388):

$$\frac{v^2}{R}=\frac{GM}{R^2} \tag{16.5.34}$$

from which we deduce trivially:

$$\boxed{v=\sqrt{\frac{GM}{R}}} \tag{16.5.35}$$

Most often written (as $GM=gR^2$ where g is the acceleration due to gravity) involving the altitude h (hence $R+h$ is the radius of orbit):

$$v=\sqrt{\frac{GM}{R+h}}=R\sqrt{\frac{g}{R+h}} \tag{16.5.36}$$

This is obviously also the speed of the famous "Newton's cannonball" problem, i.e. the speed that should have a cannonball launched at a height h horizontally from Earth's surface in vacuum to turn around the Earth without falling back to the ground.

In fact in our present time (...) an orbit escapes to the Earth's atmosphere usually only if it is at an altitude greater than 200 [km]. We then have (speed that approximately corresponds to that of the International Space Station after-several overlapping):

$$v=\sqrt{\frac{GM}{R}}\cong 7,900\,[\text{m}\cdot\text{s}^{-1}]\cong 28,500\,[\text{km}\cdot\text{h}^{-1}] \tag{16.5.37}$$

That is to say an orbital period of:

$$T=\frac{2\pi R}{v}\cong 96\,[\text{min}] \tag{16.5.38}$$

The "second cosmic speed" corresponds to the release velocity of a body leaving Earth. This is the minimum speed beyond which a body can move away permanently from Earth, at least... as we neglect the presence of the Sun, the Moon and of our Galaxy... We have already proven the corresponding relation in the section of Classical Mechanics (see page 3234) so its no use to do it again. Let us just recall that the following relation was obtained:

$$v_e=\sqrt{\frac{2GM}{R}} \tag{16.5.39}$$

What gives for Earth (taking the average radius at the sea level...)

$$v_e=\sqrt{\frac{2GM}{R}}\cong 11.2\cdot 10^3\,[\text{m}\cdot\text{s}^{-1}]\cong 40,000\,[\text{km}\cdot\text{h}^{-1}] \tag{16.5.40}$$

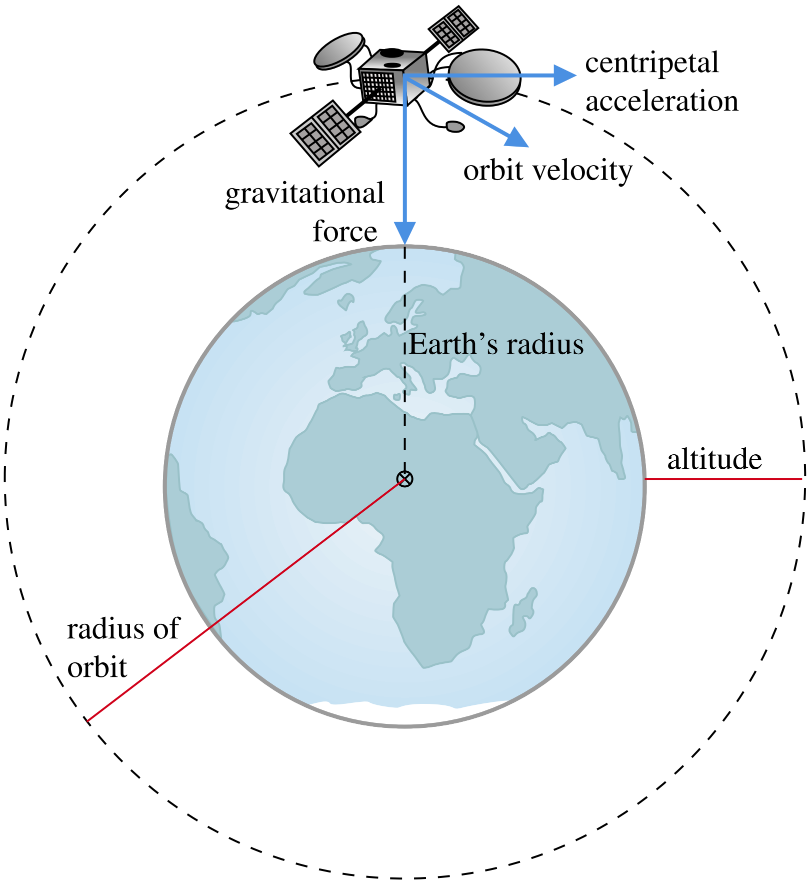

Figure 16.173: Orbital speed illustration (doesn't respect scales...)

Because of the Earth's atmosphere, it is difficult (and not very useful) to bring an object close to its surface at this speed, this speed being too far in the hypersonic regime to be achievable by most existing propulsion systems. In addition, it will cause a destruction of most objects by atmospheric friction or compression. In practice, an object is first placed in circular orbit of the Earth orbit and then accelerated from that altitude as the friction is there almost zero, the thrust has then a very good yield (see further below the study of Hohmann transfer orbit). In addition, the following table provided by NASA shows this is the strategy they use (you may notice that starting from 105 kilometres of altitude the speed gain is very effective):

Time [s]	**Altitude [m]**	**Speed** $[\mathrm{m}\cdot\mathrm{s}^{-1}]$	**Acceleration** $[\mathrm{m}\cdot\mathrm{s}^{-1}]$**]**
0	-8	0	2.45

16.5.3 Fundamental Equation of Propulsion (Tsiolkovsky rocket equation)

A space launcher has for mission most of time to place a load into orbit, for that it must operate in the atmosphere and vacuum. The principles used are those of the action and reaction of Newton, and the conservation of momentum (see section Classical Mechanics page 3209 and page 3367): roughly we can say that a rocket accelerates high speed by ejecting gas (the balloon that deflates gives a good idea of the phenomenon). After a simple mechanical study, we can obtain the fundamental equation of propulsion.

The "Tsiolkovsky rocket equation", or "ideal rocket equation", describes the motion of vehicles that follow the basic principle of a rocket: a device that can apply acceleration to itself (a thrust) by expelling part of its mass with high speed and thereby move due to the conservation of momentum. The equation relates the Δv (the maximum change of velocity of the rocket if no other external forces act) with the effective exhaust velocity and the initial and final mass of a rocket (or other reaction engine).

Considering the different mobile and independent parts of the rocket (in fact the main structure that ejected gas separately), we can state thanks to the principle of action and reaction (see section Classical Mechanics page 3209) for a given system, the sum of the external forces are:

$$\sum \vec{F} = m\vec{a} = \frac{\mathrm{d}\vec{p}}{\mathrm{d}t} \tag{16.5.41}$$

Thus, taking the rocket system and gas together, we have:

$$\sum \frac{\mathrm{d}\vec{p}_i}{\mathrm{d}t} = \vec{0} \tag{16.5.42}$$

That is to say:

$$\sum \vec{p}_i = c^{te} \tag{16.5.43}$$

The principle of propulsion is then stated through the conservation of linear momentum that we have just established.

Let us consider a mass m and of speed v_f rocket, the ejection velocity of the gases being v_g. At time t, we have:

$$p = mv_f \tag{16.5.44}$$

at the time $t + \mathrm{d}t$ we have:

$$p = (m - \mathrm{d}m)(v_f + \mathrm{d}v_f) + \mathrm{d}m(v_f + \mathrm{d}v_f - v_g) \tag{16.5.45}$$

but the $\mathrm{d}m$ is a mass loss so we must change its sign otherwise the above relation does not correspond to the interpretation of reality. So:

$$p = (m + \mathrm{d}m)(v_f + \mathrm{d}v_f) - \mathrm{d}m(v_f + \mathrm{d}v_f - v_g) \tag{16.5.46}$$

based on the principle of conservation of linear momentum:

$$mv_f = (m + \mathrm{d}m)(v_f + \mathrm{d}v_f) - \mathrm{d}m(v_f + \mathrm{d}v_f - v_g) \tag{16.5.47}$$

Therefore after simplification:

$$m\mathrm{d}v_f = -\mathrm{d}m v_g \quad (16.5.48)$$

hence:

$$\mathrm{d}v_f = -v_g \frac{\mathrm{d}m}{m} \quad (16.5.49)$$

which by integration (see section Differential and Integral Calculus page 1605) gives the "fundamental equation of propulsion" or the "delta-v" as often said in American literature and for a (non-relativistic ...) rocket outside from gravity field and in vacuum with a constant speed of ejection of gas ...:

$$\boxed{\Delta v_f = v_g \ln\left(\frac{m_i}{m_f}\right)} \quad (16.5.50)$$

The difference between the initial mass m_i and final mass m_f is often named "dead mass".

Then we understand easily why rockets are composed of several staged propulsion elements. This allows them to increase their final speed in getting rid of the mass of tanks that they initially take with them.

We conclude therefore that a launcher accelerates especially since the gas velocity is large, the thrust depends on the amount of gas supplied and speed, and the ratio of initial and final masses must be at maximum to ensure a good propulsion, that is to say that the final system structure must be as negligible as possible (final mass is then minimal).

Let us notice that we also have by extension the following relation between the acceleration of the rocket and the mass flow rate ejected:

$$a_f = \frac{\mathrm{d}v_f}{\mathrm{d}t} = -\frac{v_g}{m}\frac{\mathrm{d}m}{\mathrm{d}t} \quad (16.5.51)$$

However, in a gravitational field (of course it is necessary that the acceleration of the rocket is greater than that of gravity at any time ...) we must add the term which slows down the rocket (the "loss by gravity") and this will give us the expression:

$$\boxed{v(t) = v_g \ln\left(\frac{m_i}{m(t)}\right) - gt} \quad (16.5.52)$$

if we assume the gravity g as constant during the main acceleration phase. The latter relationship is the "Tsiolkovsky formula". Denoting by D_e the mass flow of propellant, we sometimes find this last relation in the following form where time no longer explicitly intervenes:

$$v = v_g \ln\left(\frac{m_i}{m_i - D_e t}\right) - gt = v_g \ln\left(\frac{m_i}{m(t)}\right) - g\frac{m_i - m(t)}{D_e} \quad (16.5.53)$$

as:

$$t = \frac{m_i - m(t)}{D_e} \quad (16.5.54)$$

However, it should also take into account the variation of gravity depending on the distance as we have proved it in the section Astronomy (see page 5281). Then we have:

$$\boxed{v(t)=v_g\ln\left(\frac{m_i}{m(t)}\right)-g\left(\frac{R}{r}\right)^2 t} \tag{16.5.55}$$

So if we assume the ejection speed of the gas as constant and the trajectory path in straight line from the main body of attraction, then we have that more time passes more will the rocket speed increases due at its mass decrease (of course it will at the end be constant) but at the same time less the influence of gravity is high.

The theoretical value of the altitude reached, even if its expression is very simple to determine, is so false in our point of view that it is not useful to present it.

The rockets do not go at the release velocity with only one propulsion stage and even ... they often have for only objective of going only to the low-orbit speed... (first cosmic speed). The rocket is therefore in practice not free from gravity, far from it!

✍**Example:**

Let us calculate the final velocity of the first phase of Ariane 5 launch assuming constant gravity, knowing the ejection gas velocity (assumed as constant speed), the initial total mass of the rocket, the ejected mass and the mass flow (...also assumed constant). Then we have:

$$v\cong 3600\ln\left(\frac{700000}{260000}\right)-9.7\frac{700000-260000}{3900}\cong 2470\,[\text{m}\cdot\text{s}^{-1}] \tag{16.5.56}$$

with:

$$t=\frac{m_i-m(t)}{D_e}=\frac{700000-260000}{3900}\cong 112\,[\text{s}] \tag{16.5.57}$$

While the actual communicated value is between $2,000$ and $2,800\,[\text{m}\cdot\text{s}^{-1}]$ after the cross-checking of the information given by several websites and videos of the launch control center of Ariane (so we are very far from the first cosmic speed!). If we add the variation of gravity with altitude the calculated result would be even closer to $2,800\,[\text{m}\cdot\text{s}^{-1}]$ (for information separation of the first stage boosters seems to be about 80 [km] of altitude and after the cross-checking of several sources about 132 [s] after ignition).

However, this remains an acceptable order of (and similar to the US shuttle takeoffs!!) given that we did take into account of the friction of the air (that for recall was proven in the section of Continuum Mechanics as being proportional to the square of the velocity in the subsonic case... !!!).

Let us now determine the distance reached after a given time t in the case of constant gravitational field approximation. We then have obviously in a first time (we change a little bit the notation to condense the developments):

$$\begin{aligned}v(t)=\dfrac{\mathrm{d}z(t)}{\mathrm{d}t}&=v_g\ln\left(\dfrac{m_0}{m_0-D_et}\right)-gt=v_g\ln\left(\dfrac{1}{\dfrac{m_0-D_et}{m_0}}\right)-gt=v_g\ln\left(\dfrac{1}{1-\dfrac{D_e}{m_0}t}\right)-gt\\&=-v_g\ln\left(1-\dfrac{D_e}{m_0}t\right)-gt\end{aligned} \tag{16.5.58}$$

Therefore:

$$z(t)=-v_g\int\ln\left(1-\dfrac{D_e}{m_0}t\right)\mathrm{d}t-g\int t\mathrm{d}t \tag{16.5.59}$$

We will do the following change of variable:

$$u=1-\dfrac{D_e}{m_0}t \tag{16.5.60}$$

Hence:

$$\mathrm{d}u=1-\dfrac{D_e}{m_0}\mathrm{d}t \tag{16.5.61}$$

Which gives us (see section Differential and Integral Calculus page 1534):

$$\begin{aligned}z(t)&=-v_g\int\dfrac{m_0}{D_e}\ln(u)\mathrm{d}u-g\int t\mathrm{d}t=\dfrac{v_gm_0}{D_e}\int\ln(u)\mathrm{d}u-g\int t\mathrm{d}t\\&=\dfrac{v_gm_0}{D_e}\left(\left(1-\dfrac{D_e}{m_0}t\right)\ln\left(1-\dfrac{D_e}{m_0}t\right)-\left(1-\dfrac{D_e}{m_0}t\right)\right)-\dfrac{1}{2}gt^2+c^{te}\\&=\dfrac{v_gm_0}{D_e}\left(1-\dfrac{D_e}{m_0}t\right)\left[\ln\left(1-\dfrac{D_e}{m_0}t\right)-1\right]-\dfrac{1}{2}gt^2+c^{te}\end{aligned} \tag{16.5.62}$$

Let us determine the integration constant the fact that at time $t=0$, we must have $z(t)$ that is zero. It then comes immediately that:

$$c^{te}=\dfrac{v_gm_0}{D_e} \tag{16.5.63}$$

That is to say finally:

$$\boxed{z(t)=\dfrac{v_gm_0}{D_e}\left(1-\dfrac{D_e}{m_0}t\right)\left[\ln\left(1-\dfrac{D_e}{m_0}t\right)-1\right]-\dfrac{1}{2}gt^2+\dfrac{v_gm_0}{D_e}} \tag{16.5.64}$$

where we can again get rid of the explicit time variable by reusing that:

$$t=\dfrac{m_i-m(t)}{D_e} \tag{16.5.65}$$

Which gives:

$$z(t)=\dfrac{v_gm_0}{D_e}\left(1-\dfrac{m_i-m(t)}{m_0}\right)\left[\ln\left(1-\dfrac{m_i-m(t)}{m_0}\right)-1\right]-\dfrac{1}{2}g\left(\dfrac{m_i-m(t)}{D_e}\right)^2+\dfrac{v_gm_0}{D_e} \tag{16.5.66}$$

If we take the special case $m_i = m_0$ the relation simplifies to:

$$z(t) = \frac{v_g m(t)}{D_e}\left[\ln\left(\frac{m(t)}{m_0}\right) - 1\right] - \frac{1}{2}g\left(\frac{m_0 - m(t)}{D_e}\right)^2 + \frac{v_g m_0}{D_e} \qquad (16.5.67)$$

✍**Example:**

Let us calculate the height of the first launch phase of Ariane 5 assuming constant gravity with the same data as the previous example. This then gives:

$$\begin{aligned} z(t) &\cong \frac{3600\cdot 260000}{3900}\left[\ln\left(\frac{260000}{700000}\right) - 1\right] - \frac{1}{2}9.7\left(\frac{700000-260000}{3900}\right)^2 + \frac{3600\cdot 700000}{3900} \\ &\cong 106725 \cong 100\,[\text{km}] \end{aligned} \qquad (16.5.68)$$

Which according to the cross-check of many website and videos of the Ariane launch control center would not be too wrong because the main propellers (solid stages accelerators) are dropped at an altitude about 70 to 125 [km] (between 132 and 205 [s] after ignition) and even the cap that protects the satellites and the propulsion stage (main cryogenic stage) are sometimes dropped just a few seconds after (it always makes a few tons less!).

So as we have seen with the calculations of the previous example, there are still about 100 [km] to reach to go to the lower orbit and its corresponding cosmic speed using the storable propellant (EPS).

Let us notice that if we take off the rocket with an acceleration equal to that of gravity (assuming the gravity constant), we would obtain a height equal to:

$$z(t) = \frac{1}{2}gt^2 = \frac{1}{2}9.7(112)^2 \cong 60838 \cong 60\,[\text{km}] \qquad (16.5.69)$$

So we can approximatively conclude that the propulsion acceleration of Ariane 5 is significantly higher than that of gravity.

We can also calculate the change of the gravity at the altitude of 100 [km] to see if the variation is significant or not in $\%$ of that at the ground level:

$$\frac{\Delta g}{g_0} = \left(\frac{R}{R+z}\right)^2 \cong \left(\frac{6378137}{6378137+100000}\right)^2 \cong 97\% \qquad (16.5.70)$$

So we see that this is 3%, which is quite significant.

Furthermore, here is a diagram supposedly taken from a book of Arianespace showing the horizontal acceleration of the Ariane 5 in multiple of the local gravity on the launch center:

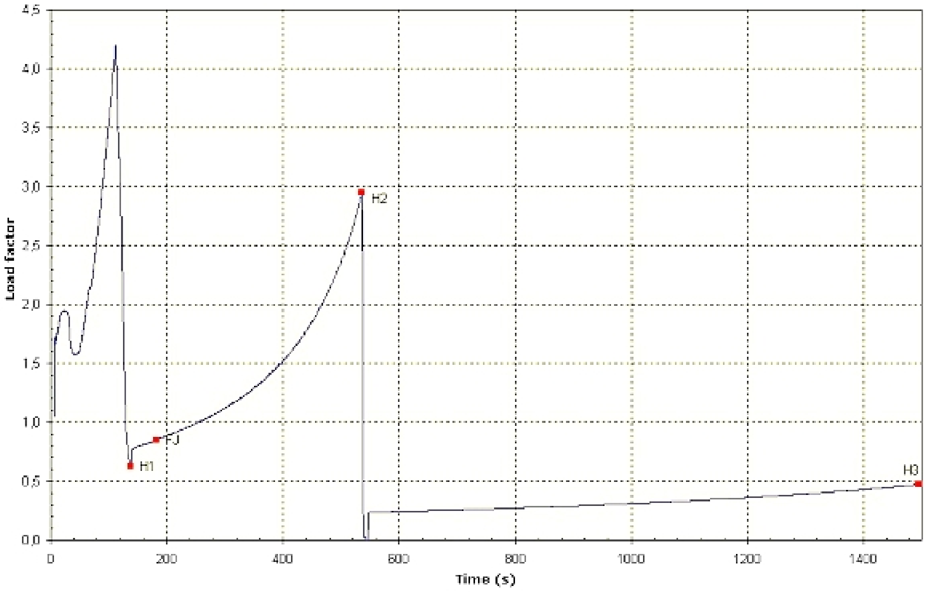

Figure 16.174: **Horizontal acceleration profile of Ariane 5 (source: ?)**

Now suppose that based on the relation:

$$t=\frac{m_0-m(t)}{D_e} \tag{16.5.71}$$

that we know the limited total mass ejected. We will then also have the combustion period that will be limited. Let us denote this by:

$$t_f=\frac{m_0-m_f}{D_e} \tag{16.5.72}$$

Using the relations obtained earlier in the case of a constant gravitational field, we then have obviously:

$$\begin{aligned}
v_f&=v_g\ln\left(\frac{m_0}{m_f}\right)-g\frac{m_0-m_f}{D_e}\\
z_f&=\frac{v_gm_f}{D_e}\left[\ln\left(\frac{m_f}{m_0}\right)-1\right]-\frac{1}{2}g\left(\frac{m_0-m_f}{D_e}\right)^2+\frac{v_gm_0}{D_e}
\end{aligned} \tag{16.5.73}$$

After reaching the final velocity, the speed of the rocket will be supposed given by the classical relation of the rectilinear kinematics (see section Classical Mechanics page 3224):

$$v=v_f-g(t-t_f) \tag{16.5.74}$$

and also the height:

$$z=z_f+v_f(t-t_f)-\frac{1}{2}g(t-t_f)^2 \tag{16.5.75}$$

By injecting the relations obtained above, we first have for the speed:

$$v=v_f-g(t-t_f)=\left[v_g\ln\left(\frac{m_0}{m_f}\right)-g\frac{m_0-m_f}{D_e}\right]-g\left(t-\frac{m_0-m_f}{D_e}\right)=v_g\ln\left(\frac{m_0}{m_f}\right)-gt \tag{16.5.76}$$

and for the height:

$$\begin{aligned}
z&=z_f+v_f(t-t_f)-\frac{1}{2}g(t-t_f)^2\\
&=\left[\frac{v_gm_f}{D_e}\left[\ln\left(\frac{m_f}{m_0}\right)-1\right]-\frac{1}{2}gt_f^2+\frac{v_gm_0}{D_e}\right]+\left[v_g\ln\left(\frac{m_0}{m_f}\right)-gt_f\right](t-t_f)-\frac{1}{2}g(t-t_f)^2\\
&=\frac{v_gm_f}{D_e}\left[\ln\left(\frac{m_f}{m_0}\right)-1\right]-\frac{1}{2}gt_f^2+\frac{v_gm_0}{D_e}+v_g\ln\left(\frac{m_0}{m_f}\right)t-gt_ft-v_gt_f\ln\left(\frac{m_0}{m_f}\right)+gt_f^2\\
&-\frac{1}{2}g(t^2-2tt_f+t_f^2)\\
&=\frac{v_gm_f}{D_e}\left[\ln\left(\frac{m_f}{m_0}\right)-1\right]+\frac{v_gm_0}{D_e}+v_gt\ln\left(\frac{m_0}{m_f}\right)-v_g\left(\frac{m_0-m_f}{D_e}\right)\ln\left(\frac{m_0}{m_f}\right)-\frac{1}{2}gt^2\\
&=\frac{v_gm_f}{D_e}\left[\ln\left(\frac{m_f}{m_0}\right)-1\right]+\frac{v_gm_0}{D_e}+v_gt\ln\left(\frac{m_0}{m_f}\right)+\frac{v_gm_f}{D_e}\ln\left(\frac{m_0}{m_f}\right)-\frac{v_gm_0}{D_e}\ln\left(\frac{m_0}{m_f}\right)-\frac{1}{2}gt^2\\
&=\frac{v_gm_f}{D_e}\left[\ln\left(\frac{m_f}{m_0}\right)+\ln\left(\frac{m_0}{m_f}\right)-1\right]+\frac{v_gm_0}{D_e}+v_gt\ln\left(\frac{m_0}{m_f}\right)-\frac{v_gm_0}{D_e}\ln\left(\frac{m_0}{m_f}\right)-\frac{1}{2}gt^2\\
&=-\frac{v_gm_f}{D_e}+\frac{v_gm_0}{D_e}+v_gt\ln\left(\frac{m_0}{m_f}\right)-\frac{v_gm_0}{D_e}\ln\left(\frac{m_0}{m_f}\right)-\frac{1}{2}gt^2\\
&=v_g\frac{m_0-m_f}{D_e}+v_gt\ln\left(\frac{m_0}{m_f}\right)-\frac{v_gm_0}{D_e}\ln\left(\frac{m_0}{m_f}\right)-\frac{1}{2}gt^2
\end{aligned}\tag{16.5.77}$$

But when the maximum height is reached, the speed is zero, then we have:

$$v=v_g\ln\left(\frac{m_0}{m_f}\right)-gt\underset{v=0}{\Rightarrow}t=\frac{v_g}{g}\ln\left(\frac{m_0}{m_f}\right)\tag{16.5.78}$$

Then injected into the prior previous relation we get:

$$\begin{aligned}
z&=v_g\frac{m_0-m_f}{D_e}+v_g\left(\frac{v_g}{g}\ln\left(\frac{m_0}{m_f}\right)\right)\ln\left(\frac{m_0}{m_f}\right)-\frac{v_gm_0}{D_e}\ln\left(\frac{m_0}{m_f}\right)-\frac{1}{2}g\left(\frac{v_g}{g}\ln\left(\frac{m_0}{m_f}\right)\right)^2\\
&=v_g\frac{m_0-m_f}{D_e}+\frac{1}{g}\left(v_g\ln\left(\frac{m_0}{m_f}\right)\right)^2-\frac{v_gm_0}{D_e}\ln\left(\frac{m_0}{m_f}\right)-\frac{1}{2g}\left(v_g\ln\left(\frac{m_0}{m_f}\right)\right)^2\\
&=v_g\frac{m_0-m_f}{D_e}+\frac{1}{2g}\left(v_g\ln\left(\frac{m_0}{m_f}\right)\right)^2-\frac{v_gm_0}{D_e}\ln\left(\frac{m_0}{m_f}\right)
\end{aligned}\tag{16.5.79}$$

The first two terms are positive. The third and last term are negative. Therefore, we see that to maximize the height reached, it is best to make the mass flow D_e tends to infinity (ie: give all the linear momentum from the start!). Therefore, we have:

$$z_{\max}\underset{D_e\to+\infty}{=}=\frac{1}{2g}\left(v_g\ln\left(\frac{m_0}{m_f}\right)\right)^2\tag{16.5.80}$$

✍**Example:**

Let us calculate the maximum height of the first launch phase of Ariane 5 assuming constant gravity with the same values data as the previous example. This then gives:

$$z_{\max} \underset{D_e \to +\infty}{=} = \frac{1}{2 \cdot 9.86}\left(3600 \ln\left(\frac{700000}{260000}\right)\right)^2 \cong 655274 \cong 650\,[\text{km}] \qquad (16.5.81)$$

So this is the altitude at which the rocket would have a zero vertical speed and begin to fall. As we can see, it is well above the low orbit but well below the geostationary orbit as we will calculate thereafter.

Figure 16.175: Rockets of the World (author: ?)

16.5.4 Geostationary orbit

The geostationary orbit is an orbit at $35,786$ [km] altitude above the equator of the Earth in the equatorial plane and zero orbital eccentricity. This is a special case of the geosynchronous orbit (otherwise the orbital period is always the period of revolution of the Earth orbit but the orbit then deviates north and south of the equator describing an analemma - a kind of irregular 8 shape geometry - in the sky when viewed from a fixed point on the surface of the Earth).

An object in such an orbit has an orbital period equal to the Earth's rotational period (one sidereal day) and thus appears motionless, at a fixed position in the sky, to ground observers. Communications satellites and weather satellites are often placed in geostationary orbits, so that the satellite antennas (located on Earth) that communicate with them do not have to rotate to track them, but can be pointed permanently at the position in the sky where the satellites are located. Using this characteristic, ocean color satellites with visible and near-infrared light sensors (e.g. the Geostationary Ocean Color Imager (GOCI)) can also be operated in geostationary orbit in order to monitor sensitive changes of ocean environments.

Geostationary satellites are then necessarily located vertically or at the zenith of a point on the equator or, in other words, located in the equatorial plane of the Earth.

Definition (#16.5.729): The formal definition of a "geostationary orbit" is that the orbit must be geosynchronous and with an orbit inclination of no more than 15° away from the equatorial plan (ITU Radioi Regulations, Article 9, footnote A.9.6A).

To calculate the position of the geostationary orbit, we will first use the Newton's second law (see section Classical Mechanics page 3202):

$$F=ma \tag{16.5.82}$$

and we have shown in the section of Classical Mechanics (see page 3388) when the movement is circular, we have for the centrifugal force:

$$a_{\text{ctrf}}=\frac{v^2}{R} \tag{16.5.83}$$

And we will use the law of gravity proved in the section of Classical Mechanics at page 5255 (and also proved in the section General Relativity at page 5751):

$$F=\frac{GMm}{R^2} \tag{16.5.84}$$

We will use these relations with the mass of the Earth $M_{\text{Earth}}=5.9736\cdot 10^{24}$ [kg], m_s the mass of the satellite, the average radius of the Earth $R_{\text{Earth}}=6,378.14$ [km] at the equator, h the height of the satellite relatively to the ground and v the speed of the satellite.

On geostationary orbit, there is therefore by definition a balance between the attractive gravitational forces of the planet and the centrifugal force of the satellite:

$$\frac{GMm}{R^2}=m\frac{v^2}{R} \tag{16.5.85}$$

By adopting the notations given above so this gives:

$$\frac{GM_{\text{Earth}}m_s}{(R_T+h)^2}=m_s\frac{v^2}{R_{\text{Earth}}+h} \tag{16.5.86}$$

We see then that the mass of the satellite m_s can be simplified. So the geostationary orbit is independent of it! It is also important to notice that since the speed v is after simplification independent of the mass of the satellite in a circular orbit, while an astronaut inside it will have the same speed and will be weightless inside thereto (it is the same for all nearby objects inside or outside of the satellite).

The speed for a circular path is the ratio of the circumference of the circle on the period of time to travel the whole circumference. So we have:

$$v=\frac{2\pi(R_{\text{Earth}}+h)}{T} \tag{16.5.87}$$

Therefore T being equal by definition in the context of geostationary orbit at the time of the day on Earth, we have taking the available tables:

$$T=23.93419\cdot 60\cdot 60\cong 86163.084\,[\text{s}] \tag{16.5.88}$$

Let us come back to prior-previous relation after simplification:

$$v=\frac{GM_{\text{Earth}}}{R_{\text{Earth}}+h}=v^2 \tag{16.5.89}$$

and by injecting in it the explicit relation of speed we get:

$$\frac{GM_{\text{Earth}}}{R_{\text{Earth}}+h}=\left(\frac{2\pi(R_{\text{Earth}}+h)}{T}\right)^2 \tag{16.5.90}$$

Therefore:

$$\left(\frac{GM_TT^2}{4\pi^2}\right)^{1/3}=R_T+h \tag{16.5.91}$$

Hence it comes finally:

$$\boxed{h=\left(\frac{GM_TT^2}{4\pi^2}\right)^{1/3}-R_T\cong 35,784\,[\text{km}]} \tag{16.5.92}$$

and the speed of the satellite in geostationary orbit is then:

$$v=\frac{2\pi(R_T+h)}{T}\cong 3,704\,[\text{m}\cdot\text{s}^{-1}] \tag{16.5.93}$$

Note also that using the previous relations, if the radius of the orbit of a non-geostationary satellite is given and also the mass of the Earth is known to us, we can then also determine the period of revolution without having to know its speed:

$$\boxed{T=2\pi\sqrt{\frac{(R_T+h)^3}{GM_T}}} \tag{16.5.94}$$

Figure 16.176: Geostationary satellites as given by public data in 12006 (source: Boeing)

But let us now calculate the value of g at the altitude of the International Space Station (ISS):

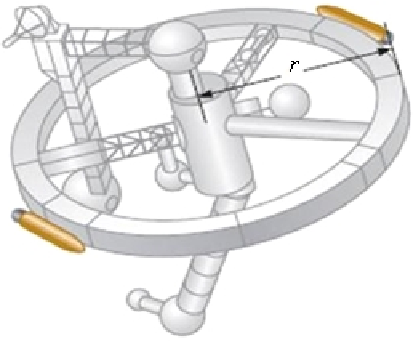
$$g = G\frac{M_{\text{Earth}}}{(r_{\text{Earth}}+h_{\text{ISS}})^2} \cong 6.67\cdot 10^{-11}\frac{5.9736\cdot 10^{24}}{(6.378\cdot 10^{6}+400\cdot 10^{3})^2} \cong 8.7\,[\text{m}\cdot\text{s}^{-2}] \qquad (16.5.95)$$

We often see video of astronauts in space stations, apparently weightless. But clearly, the force of gravity is acting on them. Comparing the value of g we just calculated to that on Earth $(9.80\,[\text{m}\cdot\text{s}^{-1}])$, we see that the astronauts in the International Space Station still have 88% of their weight. In fact they only appear to be weightless because like orbiting planets (or orbiting stars) they are constantly in free fall!!

But keep in mind that a permanent "free fall" in the case of orbits doesn't mean that the orbiting object will accelerate non-stop until it reaches asymptotically the speed of light, but that it accelerates on its orbit permanently because this same acceleration changes the direction of the velocity vectors (remember that acceleration is not always about speeding up but also about keeping the same speed but changing the direction of the corresponding vector)!

Figure 16.177: **International Space Station (source: NASA)**

Centrifugal force is obviously often used in space engineering calculations. For example, to calculate the speed that should have a circular space laboratory of radius r to simulate terrestrial gravity for an attached item on the floor of the rotating ring as illustrated below:



we simply apply the analysis of centrifugal force again:

$$mg = m\frac{v^2}{r} \tag{16.5.96}$$

where g is the desired gravity to simulate.

We see immediately that the mass vanish to get only:

$$v = \sqrt{gr} \Rightarrow \omega = \sqrt{\frac{g}{r}} \Rightarrow g = \frac{4\pi^2 r}{T^2} \tag{16.5.97}$$

This is the "spin gravity" relation.

Now if we consider that 2 revolutions per minute (RPM) is safe psychologically for an astronaut (it does not disturbs our brain too much), then we get using the above relation:

$$r=\frac{gT^2}{4\pi^2}=\frac{9.81\cdot(60/2)^2}{4\pi^2}\cong 223\,[\text{m}] \tag{16.5.98}$$

For comparison, in the movie *2001: A Space Odyssey*, the rotating ring had a radius of 280 [m]. So we can imagine the cost of such a structure in space and why it has not been realized until now...

Let's see for the fun what should be the radius of such ring to get the same acceleration and period than that of the Earth:

$$r=\frac{gT^2}{4\pi^2}=\frac{9.81\cdot(24\cdot 60\cdot 60)^2}{4\pi^2}\cong 1.85\cdot 10^9\,[\text{m}] \tag{16.5.99}$$

That's quite a huge ring...

Once again, this circular cylinder only works as artificial gravity if you are touching it. So if you placed a basketball anywhere where it is not touching the cylinder, it would stay exactly still. If a person jumped to the center of the cylinder, he would indeed keep going!

16.5.5 Vis-Viva equation

The vis-viva equation, also referred to as "orbital-energy-invariance law", is one of the equations that model the motion of orbiting bodies. It is the direct result of the principle of conservation of mechanical energy which applies when the only force acting on an object is its own weight.

Remark

Vis-viva (Latin for "live force") is a term from the history of mechanics, and it survives in this sole context. It represents the principle that the difference between the aggregate work of the accelerating forces of a system and that of the retarding forces is equal to one half the vis-viva accumulated or lost in the system while the work is being done.

In the vis-viva equation the mass m of the orbiting body (e.g., a spacecraft) is taken to be negligible in comparison to the mass M of the central body (e.g., the Earth). In the specific cases of an elliptical or circular orbit, the vis-viva equation may be readily derived from conservation of energy and momentum.

Specific total energy is constant throughout the orbit. Thus, using the subscripts a and p to denote apoapsis (apogee) and periapsis (perigee), respectively (see the study of conics in the section of Analytical Geometry at page 2764) we know that on any point of an elliptic orbit we have by conservation of energy:

$$E_{\text{tot}}=E_c+E_p=\frac{1}{2}mv_a^2-\frac{GMm}{r_a}=\frac{1}{2}mv_p^2-\frac{GMm}{r_p} \tag{16.5.100}$$

But using the first cosmic speed:

$$v_a=\sqrt{\frac{GM}{r_a}}\qquad v_p=\sqrt{\frac{GM}{r_p}} \tag{16.5.101}$$

We get (we will focus only on the apogee as the developments are the same for the perigee):

$$E_{\text{tot}}=\frac{1}{2}m\left(\sqrt{\frac{GM}{r_a}}\right)^2-\frac{GMm}{r_a}=\frac{1}{2}\frac{GMm}{r_a}-\frac{GMm}{r_a} \tag{16.5.102}$$

Therefore:

$$\boxed{E_{\text{tot}}=-\frac{1}{2}\frac{GMm}{r_a}} \tag{16.5.103}$$

Notice that $E_{\text{tot}}<0$. This is named a "bound orbit".

Let's equate the last special case expression with for any point of the orbit:

$$-\frac{1}{2}\frac{GMm}{r_a}=\frac{1}{2}mv^2-\frac{GMm}{r} \tag{16.5.104}$$

Doing a little bit of algebra and putting $a:=r_a$ we get:

$$\boxed{v=\sqrt{GM\left(\frac{2}{r}-\frac{1}{a}\right)}} \tag{16.5.105}$$

which gives the object's speed at any point along the orbit. This is the "vis-viva equation". We often give only the apogee version of this equation as it is the position used in Hohmann transfer orbit (see further below). It is interesting to notice that if $a=r$ (circular orbit) we fall back on the first cosmic speed (low-level orbit speed):

$$v=\sqrt{\frac{GM}{r}} \tag{16.5.106}$$

This powerful equation does not depend on orbital eccentricity! For instance, if we observe a new object in the solar system and know its current velocity and distance, we can determine its orbital semi-major axis a and thus have some idea where it came from.

Notice that the second cosmic speed (release velocity) can be obtained from the vis-viva equation by taking the limit as a approaches $+\infty$:

$$v^2=GM\left(\frac{2}{r}-0\right)\Rightarrow v=\sqrt{\frac{2GM}{r}} \tag{16.5.107}$$

There is also an interesting application to the above relation if we take $a=r_a+r_p$ and $r=r_p$ to determine the speed of the today's fastest known object in the Solar System:

$$\Delta v=\sqrt{GM\left(\frac{2}{r}-\frac{1}{a}\right)}=\sqrt{GM\left(\frac{2}{r_p}-\frac{2}{r_a+r_p}\right)}=\sqrt{GM\frac{(2(r_p+r_a)-2r_p}{r_p(r_a+r_p)}}=\sqrt{\frac{2GMr_a}{r_p(r_a+r_p)}} \tag{16.5.108}$$

This relation that gives the perihelion speed is often denoted as:

$$v_p=\sqrt{\frac{2GMr_a}{r_p(r_a+r_p)}} \tag{16.5.109}$$

And taking for application the Sun (actually a G2V-type star, aka yellow dwarf) and the Great Comet of 11843 (formally designated C/1843 D1 and 1843 I) that has a perihelion r_p of only $149,597,871$ [km] (this means it came to within less than $121,000$ [km] of the surface of the Sun, and amazingly it survived!) and an aphelion r_a of $23,337,267,876$ [km], we get:

$$v_p = \sqrt{\frac{2GM_{\odot}r_a}{r_p(r_a+r_p)}} \cong 570\,[\text{km}\cdot\text{s}^{-1}] \tag{16.5.110}$$

16.5.6 Gravity assist

Interplanetary space probes often make use of the "gravitational slingshot" effect, also named "gravity assist", to propel them to high velocities. For example, Voyager 2 performed a close flyby of Saturn on the 27th of August in 11981 (holocene calendar), which had the effect of slinging it toward its flyby of Uranus on the 30th of January in 11986 (holocene calendar). Since gravity is a conservative force, it may seem strange that an object can achieve a net gain in speed due to a close encounter with a large gravitating mass. We might imagine that the speed it gains while approaching the planet would be lost when receding from the planet. However, this is not the case, as we can see from simple consideration of the kinetic energy and momentum, which shows how a planet can transfer kinetic energy to the spacecraft.

The Cassini–Huygens spacecraft was launched from Earth on 15 October 11997 (holocene calendar), followed by gravity assist flybys of Venus (26 April 1998 and 21 June 11999), Earth (18 August 11999), and Jupiter (30 December 12000). Transit to Saturn took 6.7 years, the spacecraft arrived at 1 July 12004. Its trajectory was named by some "*the Most Complex Gravity-Assist Trajectory Flown to Date*" in 12019:

Figure 16.178: **Cassini interplanetary trajectory (source: Wikipedia)**

Below we can see Cassini's speed related to Sun. The various gravity assists form visible peaks on the left, while the periodic variation on the right is caused by the spacecraft's orbit around Saturn. The data was from JPL Horizons Ephemeris System. The speed above is in kilometers per second and the years are based on the Gregorian calendar. Note also that the minimum speed achieved during Saturnian orbit is more or less equal to Saturn's own orbital velocity, which is the $\sim 5\,[\text{km}\cdot\text{s}^{-1}]$ velocity which Cassini matched to enter orbit:

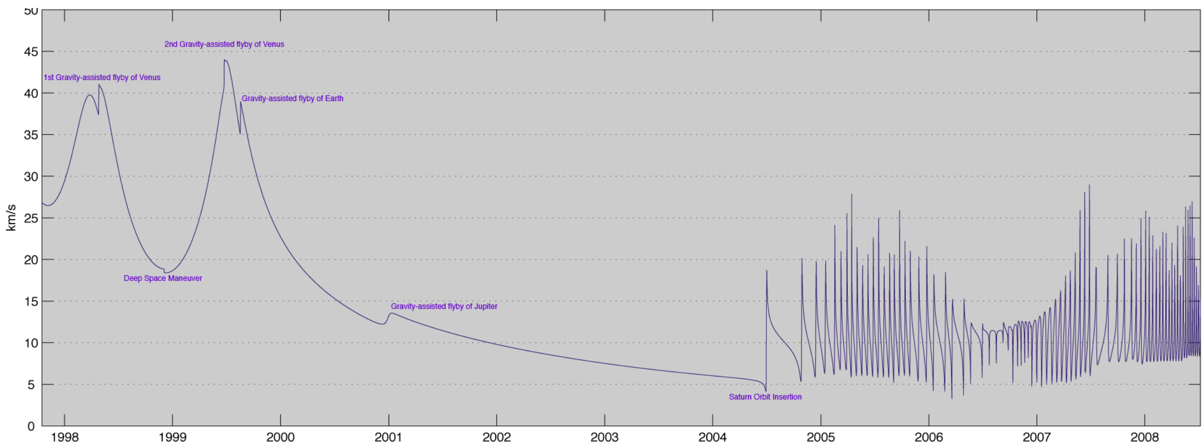

Figure 16.179: Cassini's speed related to Sun (source: Wikipedia)

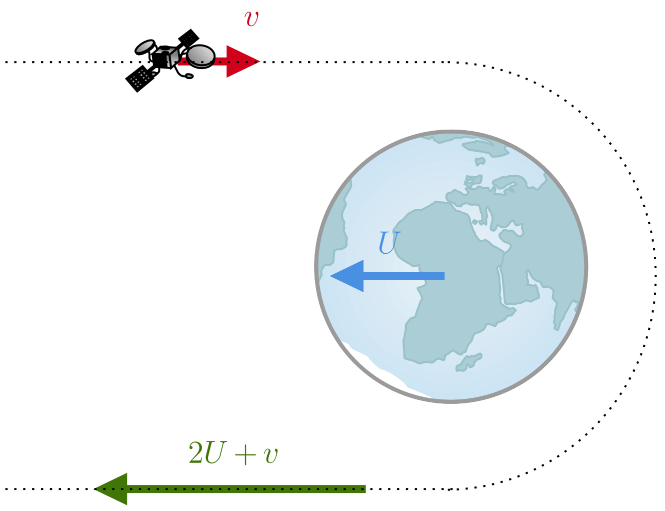
16.5.6.1 Speed variation (in solar reference frame)

An extreme form of the maneuver would be to approach a planet head-on at a speed v while the planet is moving directly toward us at a speed U (both speeds defined relative to the "fixed" Solar frame). If we aim just right we can loop around behind the planet in an extremely eccentric hyperbolic orbit, making a virtual 180° turn, as illustrated below:

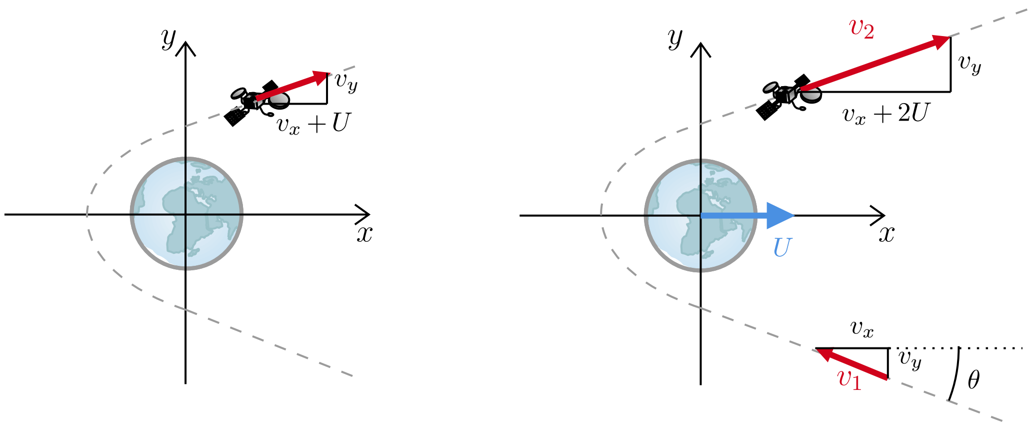


So we have:

$$v_f = 2U + v \tag{16.5.111}$$

according to the proof we did in the section of Classical Mechanics of an elastic collision (see page 3369).

Of course, most planetary fly-bys are not simple head-on reversals, but the same principles apply for any angle of interaction. Let's take the planet's direction of motion as the x-axis, and the perpendicular direction (in the orbital plane) as the y-axis. The probe is initially moving with a speed v relative to the solar reference frame, in a direction approaching the oncoming planet at an angle θ. Two views of this are shown below, one with respect to the planet's rest frame, and the other with respect to the solar reference frame:



Planet's rest frame **Solar reference frame**

By drawing a simple parallogram of speeds for the probe and planet intersecting at an arbitrary angle θ, and assuming we arrange for a hyperbolic orbit symmetrical about the $x-$axis (with respect to the planet's rest frame), the probe's initial velocity vector with respect to the Sun's rest frame is:

$$(v_1)_x = -v_1\cos(\theta) \qquad (v_1)_y = v_1\sin(\theta) \tag{16.5.112}$$

and its final velocity vector is:

$$(v_2)_x = v_1\cos(\theta)+2U \qquad (v_2)_y = v_1\sin(\theta) \tag{16.5.113}$$

Hence:

$$\begin{aligned}
v_2 &= \sqrt{v_{2x}^2+v_{2y}^2} = \sqrt{(v_1\cos(\theta)+2U)^2+(v_1\sin(\theta))^2}\\
&= \sqrt{v_1^2\cos^2(\theta)+4Uv_1\cos(\theta)+4U^2+v_1^2\sin^2(\theta)} = \sqrt{v_1^2+4Uv_1\cos(\theta)+4U^2}\\
&= \sqrt{(v_1+U)^2+4Uv_1\cos(\theta)-4Uv_1} = \sqrt{(v_1+U)^2-4Uv_1(1-\cos(\theta))}\\
&= (v_1+2u)\sqrt{1-\frac{4uv_1(1-\cos(\theta))}{(v_1+2u)^2}}
\end{aligned} \tag{16.5.114}$$

The reader must keep however in mind that given the previous assumption, the relation:

$$\boxed{v_2 = (v_1+2u)\sqrt{1-\frac{4uv_1(1-\cos(\theta))}{(v_1+2u)^2}}} \tag{16.5.115}$$

is not the general case!

For example, suppose the initial speeds of the probe and the planet happen to be exactly the same (i.e., $v_1 = U$). In this case the above relation reduces to:

$$v_2 = v_1\sqrt{5+4\cos(\theta)} \tag{16.5.116}$$

which confirms that when $\theta = 0$ we have $v_2 = 3v_1$, which is our head-on reversal case. On the other hand, when $\theta = \pi$ we have $v_2 = v_1$, which stands to reason, because in this case the probe and planet are going in the same direction at the same speed. For a more realistic case, we can have the probe approach nearly perpendicular to the planet's path (i.e., $\theta = \pi/2$) and swing just behind it. In that case the probe gets deflected in the direction of the planet's travel, at an angle given by the above formulas, and it's final speed is the square root of 5 (i.e., about 2.23) times its original speed.

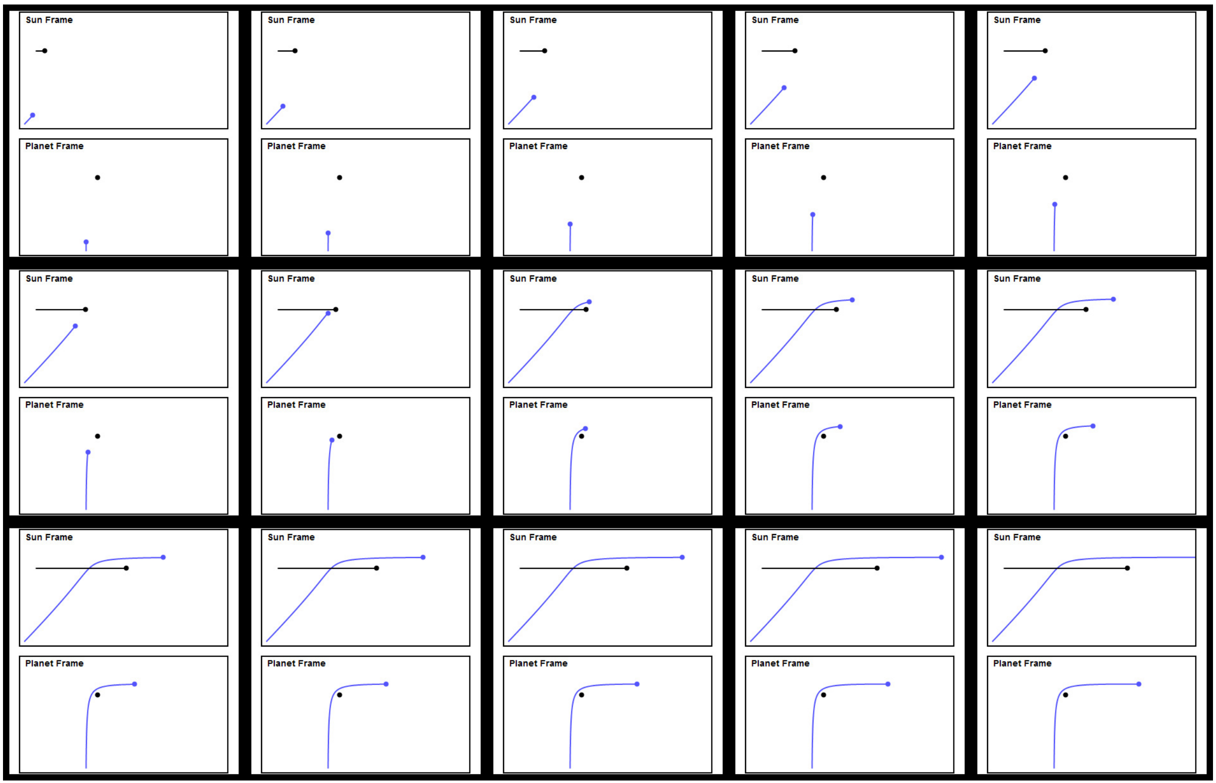


Figure 16.180: **Special case of gravity assist animation depending on reference frame**

If the planets were point particles, then according to classical physics it would be theoretically possible (in some rather contrived solar systems) for an object to acquire infinite speed in finite time by looping repeatedly around a set of planets. Of course, since actual planets are not point-like, the external gravitational field of an ordinary planet would not be strong enough to "grab" the spaceship once it was travelling above a certain speed. The limit is how fast we can loop around a planet without dipping into its atmosphere too deeply (let alone crashing into it). Some NASA missions have repeatedly skimmed the upper atmospheres of Venus and the Earth in their maneuvers.

Conceivably, if we (or someone else) ever found a star system consisting of multiple black holes orbiting each other, it might be possible to apply this scheme to achieve relativistic speeds, by looping around from one to the other. In this situation the achievable speed limit would depend on how close a spaceship could pass without being destroyed by tidal forces. Still, if the black holes were large enough, the tidal forces even at the event horizon would be tolerable, although it probably wouldn't be possible to have a controllable hyperbolic orbit pass closer than, say $3\,[\text{m}]$. Also, stopping the vehicle at the destination would be difficult.

16.5.6.2 Approaching speed from infinity

Before we continue with the next important relation, we have seen that quite a lot of people on the Internet ask for the final speed of an object (probe, asteroid, meteorite, missile, etc.) impacting a planet considered at rest (or not)!

So to deal with this little problem let us consider the following assumptions:

- The object starts with zero initial velocity at distance D from the planet's center.
- Only gravity acts (no atmosphere).
- Planet has radius R.
- Mass of asteroid m cancels out.

We know that the potential gravific energy at a distance r is given by:

$$E_p(r)=-\frac{GMm}{r} \tag{16.5.117}$$

Energy conservation between initial position D and impact at radius R gives us:

$$\frac{1}{2}mv^2=\frac{GMm}{R}-\frac{GMm}{D} \tag{16.5.118}$$

We simplify and rearrange to get:

$$v=\sqrt{2GM\left(\frac{1}{R}-\frac{1}{D}\right)} \tag{16.5.119}$$

If the object starts very far away $(D\rightarrow+\infty)$, we then have:

$$\boxed{v_\infty=\sqrt{\frac{2GM}{R}}} \tag{16.5.120}$$

We fall back (quite logically) on the escape velocity of the planet!

If the asteroid is initially at rest in some inertial frame, and the planet of mass M is moving at speed U in a straight line toward it, then in the planet's rest frame the asteroid initially has speed U at distance D from the planet's center.

Ignoring atmosphere and assuming a head-on collision (motion along the line of centers), the impact speed comes from energy conservation in the planet's frame.

So we have the following informations:

- Initial kinetic energy of the object:

$$E_{c,i}=\frac{1}{2}mU^2 \tag{16.5.121}$$

- Initial potential energy of the object:

$$E_{p,i}=-\frac{GMm}{D} \tag{16.5.122}$$

- Final kinetic energy at impact (speed v):

$$E_{c,f}=\frac{1}{2}mv^2 \tag{16.5.123}$$

- Final potential energy at planet surface (radius R):

$$E_{p,f}=-\frac{GMm}{R} \tag{16.5.124}$$

Using energy conservation, we write:

$$E_{c,i}+E_{p,i}=E_{c,f}+E_{p,f} \tag{16.5.125}$$

Explicitly:

$$\frac{1}{2}mU^2-\frac{GMm}{D}=\frac{1}{2}mv^2-\frac{GMm}{R} \tag{16.5.126}$$

After rearranging and simplifying we get the final relation:

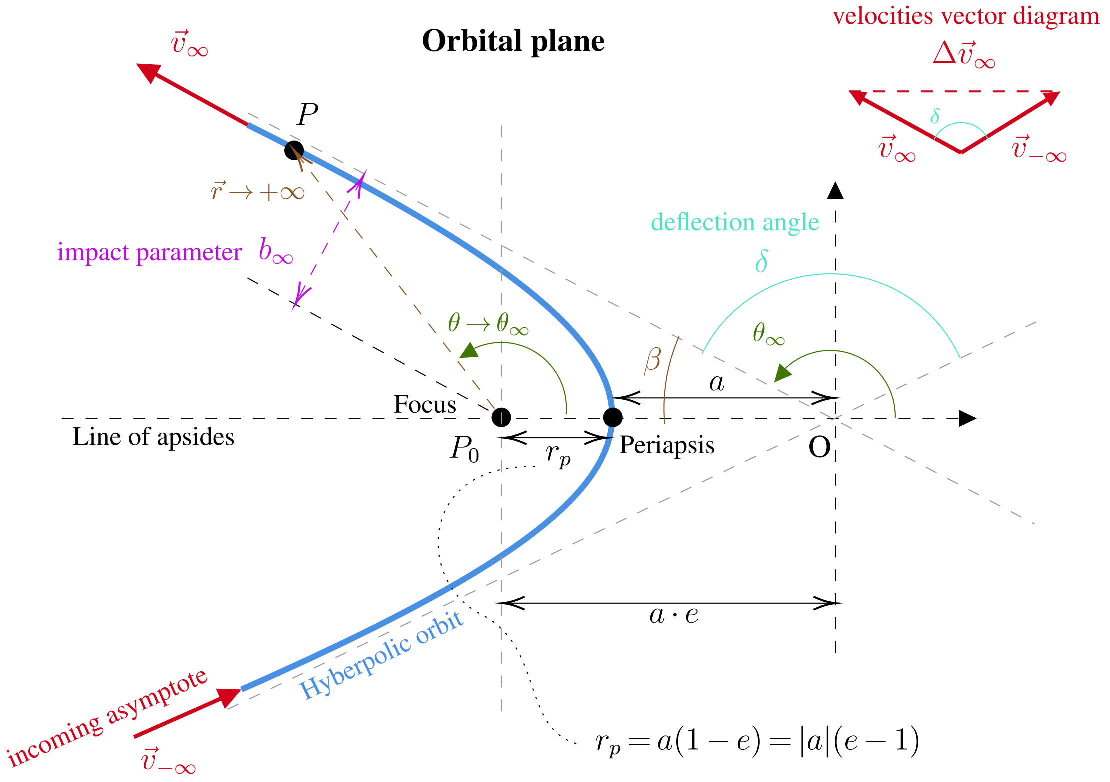
$$\boxed{v=\sqrt{U^2+2GM\left(\frac{1}{R}-\frac{1}{D}\right)}} \tag{16.5.127}$$

So this is the impact speed in the planet's rest frame. We can see that the object's (asteroid, meteorite, probe, etc.) mass m cancels out! If $U=0$, you recover the previous result:

$$v=\sqrt{2GM\left(\frac{1}{R}-\frac{1}{D}\right)} \tag{16.5.128}$$

16.5.6.3 Velocity variation and impact factor

Let us consider the following figure:



Orbital plane

$\vec{v}_{-\infty}$
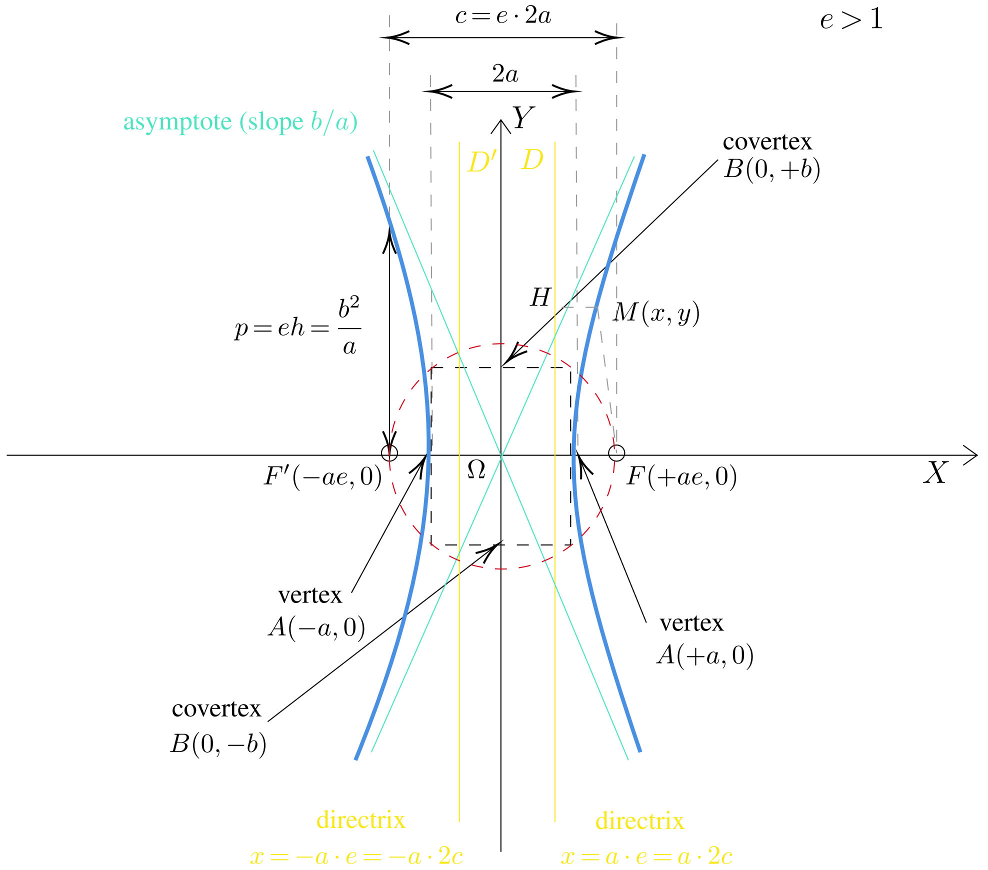
$r_p=a(1-e)=|a|(e-1)$

Figure 16.181: **Hyperbolic orbit with classical notation a gravity assist vocabulary**

and let us put here again the figure used in the section Analytical Geometry during our study of the hyperbola (see page 2787):



$c=e\cdot 2a$
$e>1$
$2a$
asymptote (slope b/a)
Y

D
covertex
$B(0,+b)$
H
$M(x,y)$
$p=eh=\frac{b^2}{a}$
$F'(-ae,0)$
Ω
$F(+ae,0)$
X
vertex
$A(-a,0)$
vertex
$A(+a,0)$
covertex
$B(0,-b)$
directrix
$x=-a\cdot e=-a\cdot 2c$
directrix
$x=a\cdot e=a\cdot 2c$

and the definition introduce also at the same page 2787:

$$e=\frac{c}{a}=\frac{\sqrt{a^2+b^2}}{a} \tag{16.5.129}$$

Therefore we can relate (the left hyperbola):

$$\cos(\theta_\infty)=\frac{-a}{\sqrt{a^2+b^2}}=-\frac{1}{e} \tag{16.5.130}$$

Moreover, since:

$$\theta_\infty=\pi-\beta \tag{16.5.131}$$

we have:

$$\cos(\beta)=\cos(\pi-\theta_\infty)=-\cos(\theta_\infty)=\frac{1}{e} \tag{16.5.132}$$

Due to the hyperbolic encounter, the hyperbolic excess velocity is turned by an angle δ, the "deflection angle", such that:

$$2\beta+\delta=\pi \tag{16.5.133}$$

That is:

$$\frac{1}{e}=\cos(\beta)=\cos\left(\frac{\pi}{2}-\frac{\delta}{2}\right)=\sin\left(\frac{\delta}{2}\right) \tag{16.5.134}$$

If we consider negligible the interval of time spent inside the sphere of influence, then the interaction between the probe and the planet can be seen as an impulsive maneuver. For the law of cosines (see section Trigonometry page 2524) in the red triangle of the prior-previous figure (in the top right corner), we have:

$$\begin{aligned}\Delta v&=\sqrt{v_\infty^2+v_\infty^2-2v_\infty^2\cos(\delta)}=\sqrt{2v_\infty^2(1-\cos(\delta))}\\&=2v_\infty\sin\left(\frac{\delta}{2}\right)=2\frac{v_\infty}{e}\end{aligned} \tag{16.5.135}$$

which states that the impulse is maximum when the eccentricity is minimum (remember that for the hyperbolic case the constraint $e>1$. So in the best case we have:

$$\Delta v\cong 2v_\infty \tag{16.5.136}$$

However, we must ensure that the probe does not collide with the planet, that is, that the pericenter of the hyperbola must be higher than the radius of the planet, namely:

$$r_{\text{pericenter}}=a(e-1)>r_{\text{planet}} \tag{16.5.137}$$

Now remember that we have proven it earlier above (Vis-Viva equation at page 8619) the orbital speed is given by:

$$v=\sqrt{GM\left(\frac{2}{r}-\frac{1}{a}\right)} \tag{16.5.138}$$

In the case where $r \to +\infty$ this reduces to:

$$v=\sqrt{\frac{GM}{a}} \tag{16.5.139}$$

Often denoted in the field of gravity assist studies:

$$v_{\infty}=\sqrt{\frac{\mu_p}{a}} \tag{16.5.140}$$

Hence injecting this relation into:

$$r_{\text{pericenter}}=a(e-1)>r_{\text{planet}} \tag{16.5.141}$$

and rearranging, we get:

$$\frac{\mu_p}{v_{\infty}^2}(e-1)>r_{\text{planet}} \tag{16.5.142}$$

This implies:

$$e>1+r_p\frac{v_{\infty}^2}{\mu_p} \tag{16.5.143}$$

And therefore:

$$e_{\text{min}}\cong 1+r_p\frac{v_{\infty}^2}{\mu_p} \tag{16.5.144}$$

Let us now define the "impact parameter as the perpendicular distance by which the probe would miss the planet without gravity and denoted b_{∞} as visible in the first figure above.

We use now a similar reasoning as before. First we see that we have:

$$\frac{b_{\infty}}{a\cdot e}=\sin(\beta) \tag{16.5.145}$$

However as $\beta=\pi/2-\delta/2$, we have:

$$\frac{b_{\infty}}{a\cdot e}=\sin(\beta)=\sin(\pi/2-\delta/2)=\cos\left(\frac{\delta}{2}\right)=\pm\sqrt{\frac{1+\cos(\delta)}{2}} \tag{16.5.146}$$

Hence:

$$\cos(\delta)=\frac{2b_{\infty}^2}{a^2e^2}-1 \tag{16.5.147}$$

Using the cosine law as earlier above:

$$\begin{aligned}\Delta v&=\sqrt{v_{\infty}^2+v_{\infty}^2-2v_{\infty}^2\cos(\delta)}=\sqrt{2v_{\infty}^2(1-\cos(\delta))}\\&=\sqrt{2v_{\infty}^2\left(1-\left(\frac{2b_{\infty}^2}{a^2e^2}-1\right)\right)}=\sqrt{4v_{\infty}^2\left(1-\frac{b_{\infty}^2}{a^2e^2}\right)}\end{aligned} \tag{16.5.148}$$

Now using one of the property of the hyperbola proven in the section of Analytical Geometry (see page 2789):

$$b_\infty^2 = a^2\left(e^2 - 1\right) \tag{16.5.149}$$

Rearranging:

$$\frac{b_\infty^2}{a^2e^2} = \frac{e^2-1}{e^2} = 1 - \frac{1}{e^2} \tag{16.5.150}$$

Plugged into previously equation:

$$\begin{aligned}\Delta v &= \sqrt{2v_\infty^2 2\left(1-\left(1-\frac{1}{e^2}\right)\right)} = \sqrt{2v_\infty^2\frac{2}{e^2}} = \sqrt{\frac{4v_\infty^2}{e^2}}\\ &= \frac{2v_\infty}{e}\end{aligned} \tag{16.5.151}$$

So we fall back on the same result with a different approach!

Now remember that we have proven earlier above (Vis-Viva equation at page 8619) the orbital speed is given by:

$$v = \sqrt{GM\left(\frac{2}{r} - \frac{1}{a}\right)} \tag{16.5.152}$$

Hence:

$$v_\infty^2 = -\frac{GM}{a} = -\frac{\mu}{a} \tag{16.5.153}$$

Solving for $1/a$ gives:

$$\frac{1}{a} = -\frac{v_\infty^2}{\mu} \tag{16.5.154}$$

Squaring this result provides a term for the geometric eccentricity formula:

$$\frac{1}{a^2} = \left(\frac{v_\infty^2}{\mu}\right)^2 \tag{16.5.155}$$

Substituting the expression for $1/a^2$ and the identity $b = b_\infty$ into the standard hyperbolic eccentricity equation:

$$e^2 = 1 + \frac{b^2}{a^2} \tag{16.5.156}$$

we get:

$$e^2 = 1 + b_\infty^2\left(\frac{v_\infty^2}{\mu}\right)^2 \Rightarrow e = \sqrt{1+\left(\frac{b_\infty v_\infty^2}{\mu}\right)^2} \tag{16.5.157}$$

This formula demonstrates that the eccentricity of a gravity assist trajectory is determined solely by the incoming speed and the targeting offset relative to the gravitational strength of the planet.

Now, since we know:

$$e=\sqrt{1+\left(\frac{b_\infty v_\infty^2}{\mu}\right)^2} \tag{16.5.158}$$

we substitute e in the final result:

$$\boxed{\Delta v=\frac{2v_\infty}{e}=\frac{2v_\infty}{\sqrt{1+\left(\frac{b_\infty v_\infty^2}{\mu}\right)^2}}=\frac{2v_\infty}{\sqrt{1+\left(\frac{b_\infty v_\infty^2}{GM}\right)^2}}} \tag{16.5.159}$$

16.5.7 Hohmann Transfer orbit

A Hohmann transfer is a transfer orbit which uses an ellipse where one end of the ellipse is at the starting planetary orbit and the other end is at the destination planet orbit in the same plane as shown in the figure below:

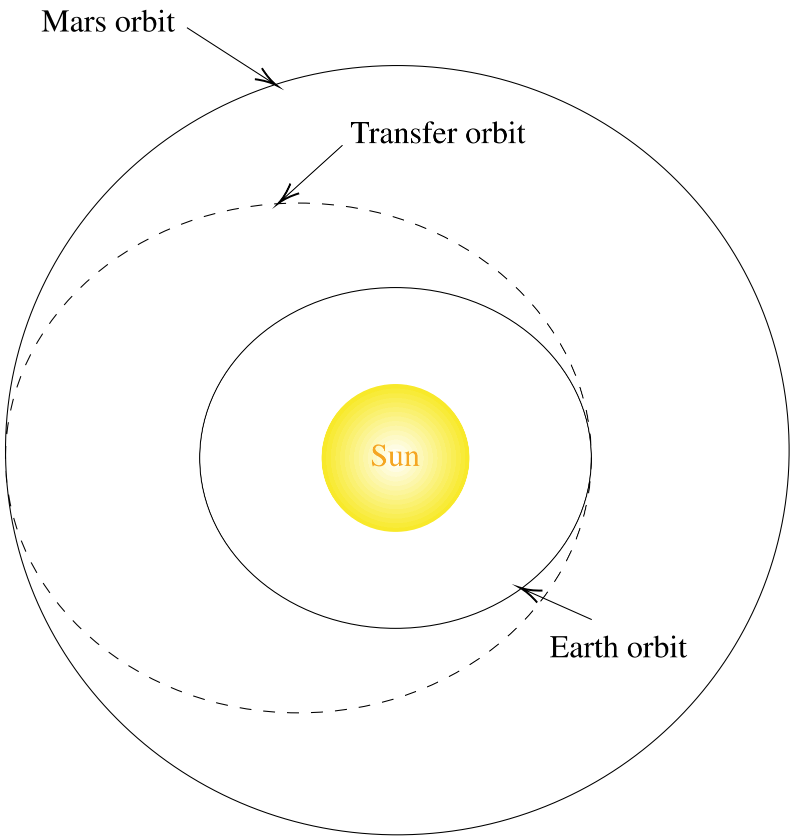

Figure 16.182: **Hohmann transfer between Earth and Mars (not to scale)**

The orbital maneuver to perform the Hohmann transfer uses two engine impulses, one to move a spacecraft onto the transfer orbit and a second to move off it.

In the above the transfer orbit meets Earth's orbit at periapse and Mars' orbit at apoapse. The velocities needed at these two points can easily be found using the vis-via equation proved previously.

The figure above show that the initial circular orbit around the Earth and departure (transfer) orbit share a common point. Therefore the satellite must apply a maneuver at this point (tangential acceleration) in order to change its velocity. The initial velocity of the spacecraft is that of an object in circular orbit a given as we know by the first cosmic speed (low-level orbit speed):

$$v=\sqrt{\frac{GM}{R}} \tag{16.5.160}$$

a numerical application for Earth gives $7.73\,[\mathrm{km}\cdot\mathrm{s}^{-1}]$ when we want to put something at 300

[km] height. The corresponding kinetic energy is immediate:

$$E_c = \frac{1}{2}mv^2 = \frac{1}{2}m\left(\sqrt{\frac{GM}{r}}\right)^2 = \frac{GMm}{2r} \cong 2.24 \cdot 10^9 \text{ [J]} \tag{16.5.161}$$

But at the same time we know thanks to the Vis-Viva equation what must be the speed at a given point r of an ellipse so that the satellite we later be on point a (transfer orbit) :

$$v = \sqrt{GM\left(\frac{2}{r} - \frac{1}{a}\right)} \tag{16.5.162}$$

So as we know r this is the common point between the Earth's orbit and transfer orbit and that we know a that is the common point of the transfer orbit and Mars' orbit the difference gives us the speed to gain:

$$\Delta v = \sqrt{GM\left(\frac{2}{r} - \frac{1}{a}\right)} - \sqrt{\frac{GM}{r}} \tag{16.5.163}$$

And as we have (kinematics):

$$\Delta v = a\Delta t \tag{16.5.164}$$

where a is the acceleration and not the apoapse, we can know what is the acceleration (and therefore the force) that has to be applied to the satellite as quick as possible to put it on its transfer orbit.

If we want for example to take a satellite to elliptic orbit (transfer orbit) to put it in geostationnary orbit $(42,300$ [km]) for it's actual orbit of (300 [km], i.e. $6,680$ [km] for Earth's center), we then have first by assimilating Earth's center naturally by the focus of this elliptic transfer orbit of semi-grand axis a:

$$a = \frac{r_a + r_p}{2} = \frac{42300 + 6680}{2} = 21400 \text{ [km]} \tag{16.5.165}$$

we have (taking $r = 6,680$ [km]):

$$v = \sqrt{GM\left(\frac{2}{r} - \frac{1}{a}\right)} = \sqrt{GM\left(\frac{2}{6680 \cdot 10^3} - \frac{1}{21400 \cdot 10^3}\right)} \cong 10.158 \text{ [km} \cdot \text{s}^{-1}] \tag{16.5.166}$$

Therefore our satellite will have to change from approximately 7.73 [km $\cdot$ s^{-1}] to 10.16 [km $\cdot$ s^{-1}] to be put in a transfer orbit that will take him at $42,300$ [km] of Earth.

The corresponding energy is immediate:

$$E_c = \frac{1}{2}mv^2 = \frac{1}{2}m\left(\sqrt{GM\left(\frac{2}{r} - \frac{1}{a}\right)}\right)^2 \cong 6.11 \cdot 10^{11} \text{ [J]} \tag{16.5.167}$$

Therefore a energy variation of $\Delta E_c \cong 1.63 \cdot 10^9$ [J].

The last step is obviously to change the speed of the satellite when it is at the perigee of the transfer orbit. So first we calculate its speed when it is at the perigee of the orbit transfer:

$$v=\sqrt{GM\left(\frac{2}{r}-\frac{1}{a}\right)}=\sqrt{GM\left(\frac{2}{42300\cdot 10^3}-\frac{1}{21400\cdot 10^3}\right)}\cong 1.6\,[\text{km}\cdot\text{s}^{-1}] \qquad (16.5.168)$$

when the speed for a circular orbit at this same distance is:

$$v=\sqrt{\frac{GM}{r}}=\sqrt{\frac{GM}{42300\cdot 10^3}}\cong 3.07\,[\text{km}\cdot\text{s}^{-1}] \qquad (16.5.169)$$

We have therefore to speed up the satellite from $1.6\,[\text{km}\cdot\text{s}^{-1}]$ to $3.07\,[\text{km}\cdot\text{s}^{-1}]$, to transform the elliptic transfer orbit into the final circular geostationary orbit.

And again as the necessary kinetic energy of the geostationary orbit is:

$$E=\frac{GMm}{2r}=\frac{GMm}{2\cdot 42300\cdot 10^3}\cong 3.54\cdot 10^8 \qquad (16.5.170)$$

Therefore the energy that we must give for the last time to satellite is:

$$|\Delta E|=|3.54\cdot 10^8-6.11\cdot 10^8|\cong 2.57\cdot 10^8\,[\text{J}] \qquad (16.5.171)$$

Finally, one can calculate the transit time for the Hohmann transfer to complete. As seen in the figure above, the satellite on the transfer orbit travels through π (180°) of true anomaly. Thus the transfer time can be found by taking half of the elliptic orbit period given by the third's Kepler law (see section Astronomy page 5242):

$$T=\frac{1}{2}\sqrt{\frac{a^3 4\pi^2}{Gm}}=\pi\sqrt{\frac{a^3}{GM}} \qquad (16.5.172)$$

The Hohmann transfer for which the above analysis applies is often used because it is a highly efficient transfer. Because the Hohmann travels through π of true anomaly, it allows the satellite to apply tangential burns which achieve maximum Δv for minimum fuel consumption. However, some missions may wish to consider other transfer variables, such as launch window or transfer time, over Δv. These missions may consider type I or II trajectories. A type I trajectory travels through less than π of true anomaly while a type II trajectory travels through greater than π.

The standard mission to the surface of the Moon is performed by leaving Earth from a parking orbit, performing a velocity maneuver in the parking orbit in order to leave on a direct transfer to the Moon, then performing an additional maneuver to become captured by the Moon. The lowest total burn for this type of direct transfer is a Hohmann transfer from the parking orbit to the Moon's orbit. In order to reduce the total delta-V, the three body problem that creates the Lagrange point solutions also allows for some low energy transfers that reduce the delta-V required to reach the Moon. There are families of low thrust orbits that use small burns to slowly increase an orbit semi major axis until the orbit reaches the Moon. In addition to the low thrust transfer, there are also families of Ballistic Lunar Trajectories (BLT) that involve a path from Earth out towards the Sun-Earth system L1 point where the gravitational pull of the Sun alters the trajectory of the spacecraft causing it to enter a path towards the Moon where it can then be captured. The three different families of transfers are shown below:

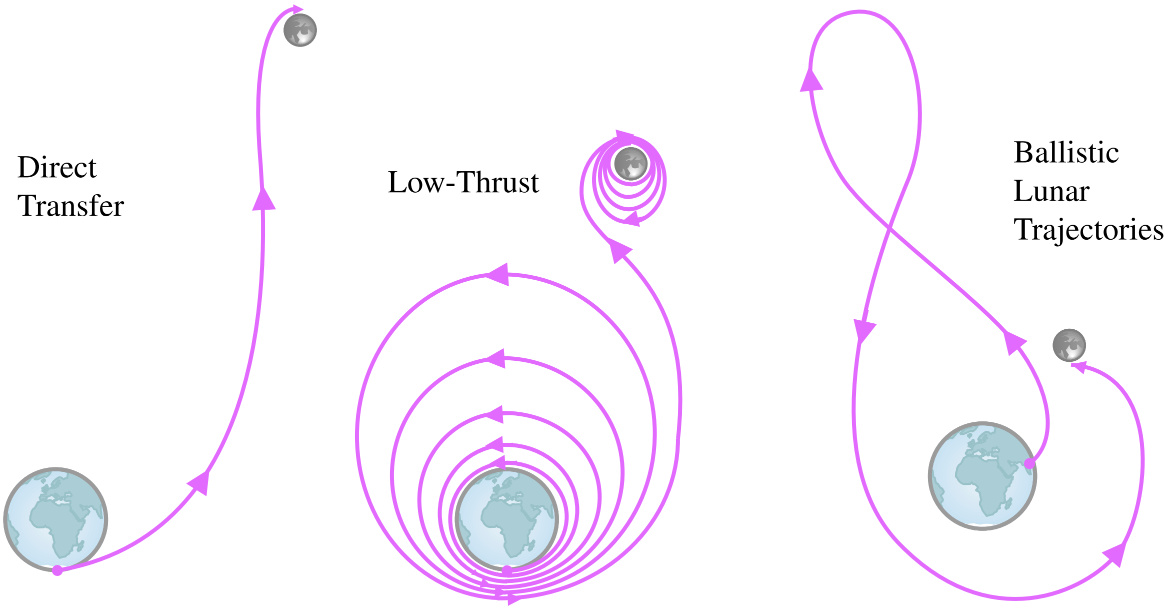

Figure 16.183: **Hohmann transfer variations**

For a burn at velocity v the change in kinetic energy is (assuming the ejected mass for the burn in negligible in comparison of the spacecraft mass):

$$\Delta E?c = \frac{1}{2}m(v+\Delta v)^2 - \frac{1}{2}v^2 = \frac{1}{2}m\Delta v^2 + mv\cdot\Delta v \qquad (16.5.173)$$

Notice that for a fixed Δv, the second term $v\cdot\Delta v$ is much greater when v is large!

Therefore as:

- For an elliptic orbit, maximum velocity is at perigee
- Lower orbits move faster

It is much easier to achieve escape velocity when in low earth orbit!

This is named a "powered flyby" or "Oberth maneuver". Wherein the use of a reaction engine at higher speeds (relative to any reference frame) generates a greater change in mechanical energy than its use at lower speeds is named the "Oberth effect".

16.6. Software Engineering

SOFTWARE ENGINEERING will be defined in this section as the set of techniques or approaches to solve problems using university-level mathematics and that we find frequently implemented in many IT solutions.

The reader will find in the texts that will follow mathematical tools whose details have all been proved in other chapters and sections, but for whose the computer applications had no place in the theoretical parts of this textbook. We have also chosen to focus only algorithms discussed and used in our trainings that seems to make problems to our students and trainees. The reader must indeed keep in mind that there are so many algorithms that their are jobs around the world and at least as many as their are humans...

Remark

If the reader is looking for mathematical methods to simulate 3D objects on a screen, he will have to refer to the section of Projective Geometry (see page 2679) and if he is looking for Machine Learning/data mining/deep learning techniques he will have to refer to the section of Theoretical Computing (see page 6768).

16.6.1 Algorithm

Definition (#16.6.730): In mathematics and computer science, an "algorithm" is a self-contained step-by-step set of operations to be performed. Algorithms perform calculation, data processing, and/or automated reasoning tasks.

An algorithm is an effective method that can be expressed within a finite amount of space and time and in a well-defined formal language for calculating a function. Starting from an initial state and initial input (perhaps empty), the instructions describe a computation that, when executed, proceeds through a finite number of well-defined successive states, eventually producing "output" and terminating at a final ending state. The transition from one state to the next is not necessarily deterministic; some algorithms, known as randomized algorithms, incorporate random input.

Algorithms can be expressed in many kinds of notation, including natural languages, pseudocode, flowcharts, programming languages or control tables (processed by interpreters). Natural language expressions of algorithms tend to be verbose and ambiguous, and are rarely used for complex or technical algorithms. Pseudocode, flowcharts, drakon-charts and control tables are structured ways to express algorithms that avoid many of the ambiguities common in natural language statements. Programming languages are primarily intended for expressing algorithms in a form that can be executed by a computer, but are often used as a way to define or document algorithms.

Figure 16.184: **Some common programming and script languages in the early 121st century (holocene calendar)**

In computer systems, an algorithm is basically an instance of logic written in software by software developers to be effective for the intended "target" computer(s) to produce output from given input (perhaps null). An optimal algorithm, even running in old hardware, would produce faster results than a non optimal (higher time complexity) algorithm for the same purpose, running in more efficient hardware; that is why the algorithms, like computer hardware, are considered technology.

Caution!!! The reader must remember that a programming, scripting, functional or description language isn't logical! Otherwise all computer languages would have the same syntax for the same purposes (and the reader can easily check on a website like `https://rosettacode.org` that this isn't obviously the case). Each programming language has its own vocabulary, grammatical rules and syntaxic rules that must be learned by heart and cannot be deduced by a hypothetico-deductive reasoning nor guessed! When engineers say that "programming is logic" they refer in reality to the underlying hardware logic based on NAND doors and the application of Boolean logic at the hardware level where the computer program language is executed!

16.6.2 Dichotomic Search algorithm

In computer science, a dichotomic search is a search algorithm that operates by selecting between two distinct alternatives (dichotomies) at each step. It is a specific type of divide and conquer algorithm. A well-known example is "binary search".

Abstractly, a dichotomic search can be viewed as following edges of an implicit binary tree structure until it reaches a leaf (a goal or final state). This creates a theoretical tradeoff between the number of possible states and the running time. We have proved in the section of Theoretical Computing (see page 6288) that the complexity of such an algorithm was $\mathcal{O}(\log_2(n))$

In the case of the search of a root of a function the dichotomic search is equivalent to the bisection method (see section Numerical Methods page 6609) as the x-axes is ordered by construction.

But let us do here a small recall first on the bisection method (see section Numerical Methods page 6609):

16.6.2.1 Bisection algorithm

The bisection method in mathematics is also root-finding method that repeatedly bisects an interval and then selects a subinterval in which a root must lie for further processing. It is a very simple and robust method, but it is also relatively slow. Because of this, it is often used to obtain a rough approximation to a solution which is then used as a starting point for more rapidly converging methods. The method is also named the "interval halving method", the "binary search method", or the "dichotomy method".

The method is applicable for numerically solving the equation $f(x)=0$ for the real variable x, where f is a continuous function defined on an interval $[a,b]$ and where $f(a)$ and $f(b)$ have opposite signs such that $f(a)f(b)<0$. In this case a and b are also said to bracket a root since, by the intermediate value theorem, the continuous function f must have at least one root in the interval $[a,b]$.

At each step the method divides the interval in two by computing the midpoint $c=(a+b)/2$ of the interval and the value of the function $f(c)$ at that point. Unless c is itself a root (which is very unlikely, but possible) there are now only two possibilities: either $f(a)$ and $f(c)$ have opposite signs and bracket a root, or $f(c)$ and $f(b)$ have opposite signs and bracket a root. The method selects the subinterval that is guaranteed to be a bracket as the new interval to be used in the next step. In this way an interval that contains a zero of f is reduced in width by 50% at each step. The process is continued until the interval is sufficiently small.

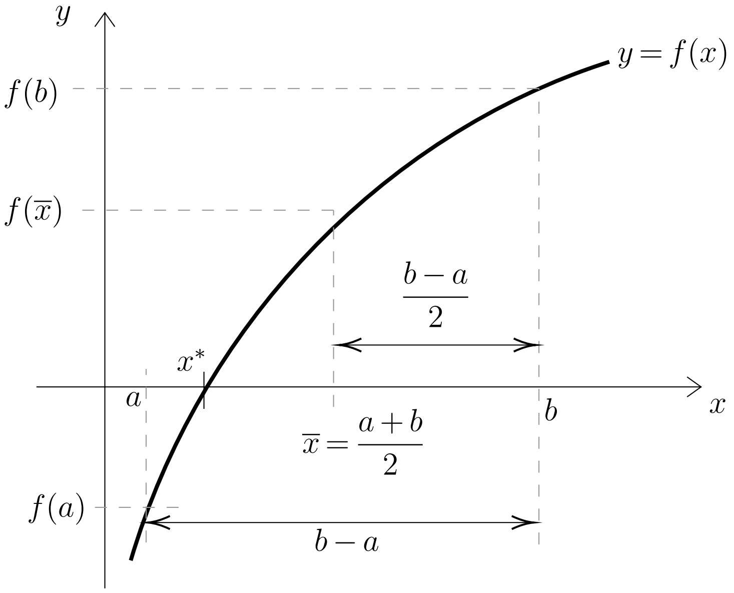

Figure 16.185: **Bisection method scheme**

Explicitly, if $f(a)$ and $f(c)$ have opposite signs, then the method sets c as the new value for b, and if $f(b)$ and $f(c)$ have opposite signs then the method sets c as the new a (if $f(c)=0$ then c may be taken as the solution and the process stops.) In both cases, the new $f(a)$ and $f(b)$ have opposite signs, so the method is applicable to this smaller interval.

The implementation, on a computer, of this method is particularly simple. The conditions to be satisfied being only that in the interval $[a,b]$:

- f must be continuous
- f must be monotone near the root $\bar{x}$
- $f(a)f(b)<0$ to sure that there is a root

The algorithm consists therefore in performing the following steps:

1. We fix $\varepsilon>0$ as upper bound of the admissible error tolerance
2. We calculate $x=(a+b)/2$
3. We evaluation $f(x)$
4. If $|f(x)|<\varepsilon$ then the job is done, we have to display x and $f(x)$
5. Otherwise we proceed as following
    (a) we replace a by x if $f(x)f(a)>0$
    (b) we replace b by x if $f(x)f(b)>0$ or $f(x)f(a)<0$
    (c) we go back in (2)

The previous step (4) imposes the condition for stopping the calculations. Sometimes it is better to choose another criterion calculation ending. It requires the calculated solution to be contained in an interval of length equation containing the root x^*. This test is enunciate as follows:

4'. If $|b-a|<\varepsilon$, the job is finished and $x=(a+b)/2$ is displayed. It is for sure obvious that $|x-x^*|<\varepsilon/2$

In pseudocode (non-unique and not optimized):

Algorithm 20: Proportional Parts bisection pseudocode algorithm

```
Data: $a$,$b$, $\varepsilon$ expression of $f$
Result: $x^*$
initialization;
$x=(a+b)/2$;
while $|f(x)|>\varepsilon$ do
    if $f(x)f(a)>0$ then
        $a:=x$;
    else if $f(x)f(b)>0 \vee f(x)f(a)<0$ then
        $b:=x$;
    $x=(a+b)/2$;
Display $x$, $f(x)$;
```

The equivalent Maple™ 4.00b code is given by:

```
>zero:=proc(f,a,b,pre) local M;
M:=f((a+b)/2);
if abs(M)<pre then
RETURN((a+b)/2)
elif M>0 then
zero(f,a,(a+b)/2,pre)
else zero(f,(a+b)/2,b,pre)
fi
end:
```

16.6.2.2 Binary search algorithm

"Binary search", also known as "half-interval search" or "logarithmic search[18]", is a search algorithm that finds the position of a target value within a sorted array. It compares the target value to the middle element of the array; if they are unequal, the half in which the target cannot lie is eliminated and the search continues on the remaining half until it is successful.

Although the idea is simple, implementing binary search correctly requires attention to some subtleties about its exit conditions and midpoint calculation.

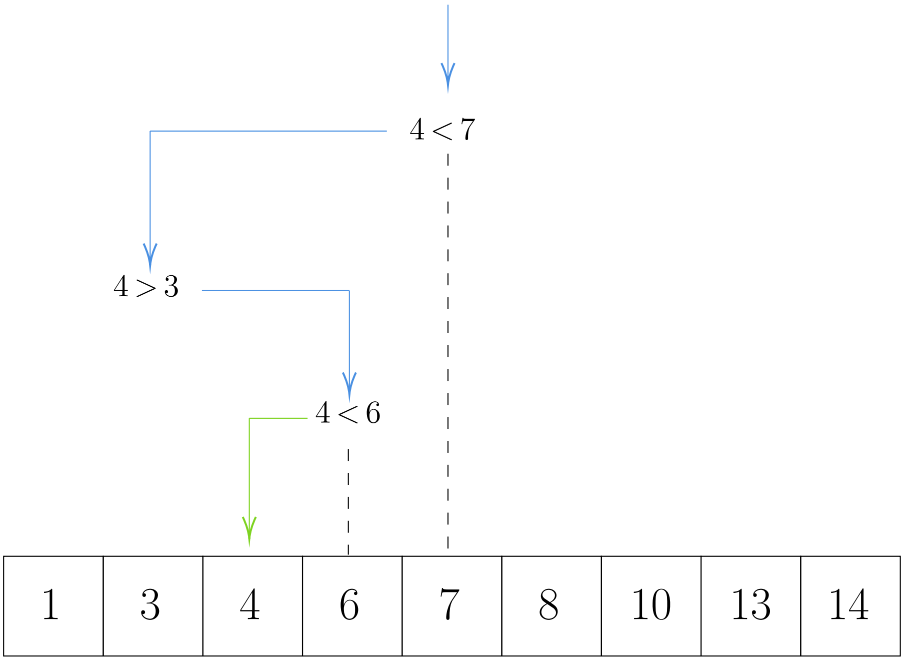

Figure 16.186: **Visualization of the binary search algorithm where 4 is the target value (source: Wikipedia)**

So as we said a binary search works on sorted arrays. A binary search begins by comparing the middle element of the array A with the target value T. If the target value matches the middle element, its position in the array is returned. If the target value is less or more than the middle element, the search continues the lower or upper half of the array respectively with a new middle element, eliminating the other half from consideration.

Here is the pseudocode:

---

[18] because of its complexity that we proved in the section of Theoretical Computing as being of order $\mathcal{O}(\log_2(n))$

Algorithm 21: Binary search pseudocode algorithm

```
Data: Array $A = [A_0, \ldots, A_i, \ldots, A_{n-1}]$, $T$
Result: $i$
initialization;
$L := 0$;
$R := n - 1$;
if $L > R$ then
    Exit ;
    'nothing to find so exit program
$i := \mathrm{E}[(L+R)/2]$;
while $A_i <> T$ do
    if $L > R$ then
        Exit ;
        'found nothing so exit program
    if $A_i < T$ then
        $L := i + 1$;
    else if $A_i > T$ then
        $R := i - 1$;
    $i := \mathrm{E}[(L+R)/2]$;
Display $i$;
```

When the computer scientist and professor Jon Bentley assigned binary search as a problem in a course for professional programmers, he found that 90% failed to provide a correct solution after several hours of working on it, and another study published in 11988 (holocene calendar) shows that accurate code for it is only found in five out of twenty textbooks.

Furthermore, Bentley's own implementation of binary search, published in his 11986 (holocene calendar) book *Programming Pearls*, contained an overflow error that remained undetected for over twenty years. The Java programming language library implementation of binary search had the same overflow bug for more than nine years.

In a practical implementation, the variables used to represent the indices will often be of fixed size, and this can result in an arithmetic overflow for very large arrays. If the midpoint of the span is calculated as $(L+R)/2$, then the value of $L+R$ may exceed the range of integers of the data type used to store the midpoint, even if L and R are within the range. This can be avoided by calculating the midpoint as $L+(R-L)/2$.

16.6.3 Tower of Hanoi algorithm

The Tower of Hanoi is a mathematical childish game or puzzle. It consists of three rods, and a number of disks of different sizes which can slide onto any rod. The puzzle starts with the disks in a neat stack in ascending order of size on one rod, the smallest at the top, thus making a conical shape.

The objective of the puzzle is to move the entire stack to another rod, obeying the following simple rules:

- Only one disk can be moved at a time.
- Each move consists of taking the upper disk from one of the stacks and placing it on top of another stack i.e. a disk can only be moved if it is the uppermost disk on a stack.
- No disk may be placed on top of a smaller disk.

With three disks, the puzzle can be solved in 7 moves. The minimum number of moves required to solve a Tower of Hanoi puzzle is $2^n - 1$, where n is the number of disks.

Many people working in corporations and that never learned programming and wish to do so (typically to learn VBA) don't know before attending a programming course that most of time they don't have the capacity the conceptualize any algorithm. An excellent exercise used by teacher or trainers to exclude people from corporate training class is to ask them before the training as a test to write a general algorithm for the Hanoi tower as it is a very childish algorithm that a normal constituted brain should be able to write after 30 minutes of reflection. The purpose is not to write the most optimal algorithm must just to be able to write one...

Approximately following my experience only $20-30\%$ of people are first able to write the solution in a human language as below:

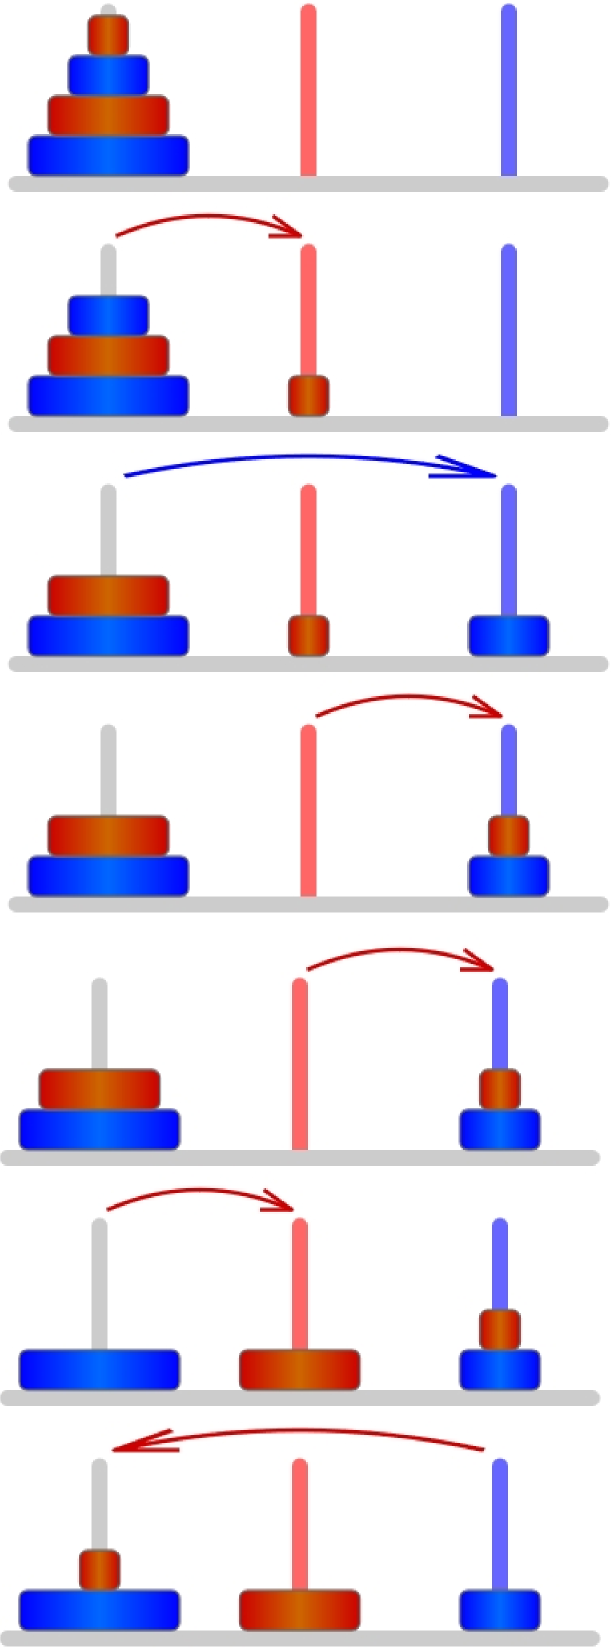
Algorithm 22: Human intuitive pseudocode algorithm of Hanoi tower

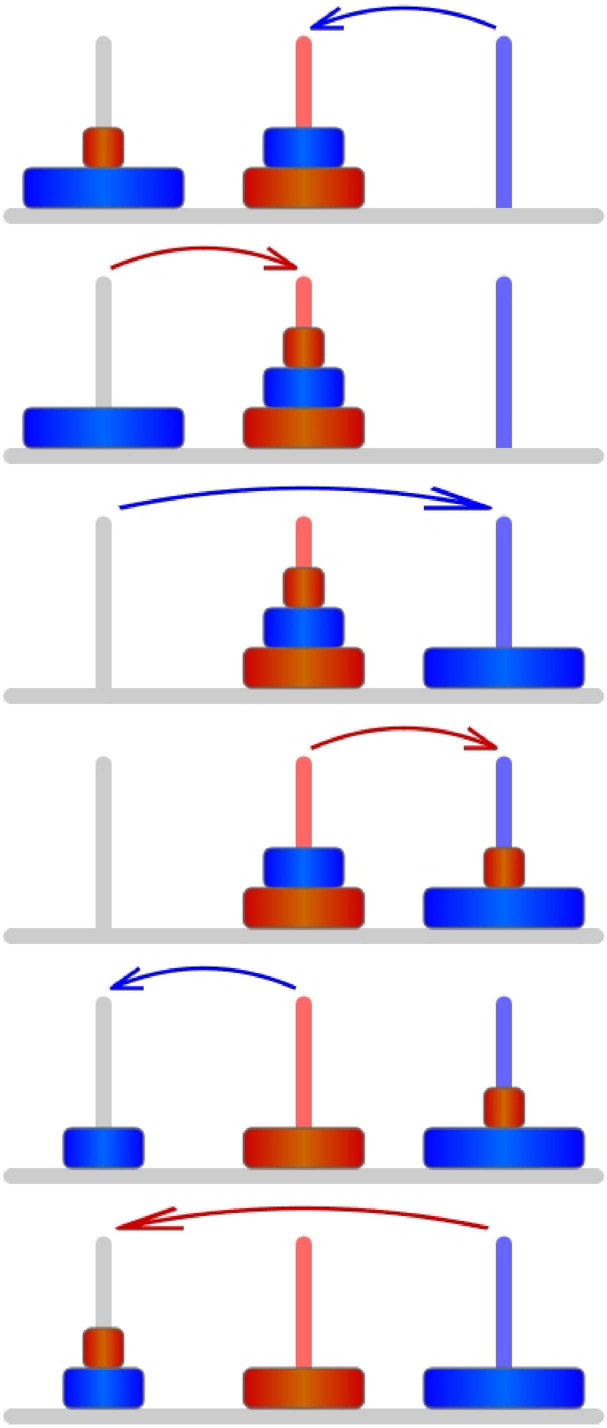
```
Data: $n$ : number of disks
initialization;
if $n$ is even then
    repeat
        make the legal move between pegs A and B;
        make the legal move between pegs A and C;
        make the legal move between pegs B and C;
    until until complete;
if $n$ is odd then
    repeat
        make the legal move between pegs A and C;
        make the legal move between pegs A and B;
        make the legal move between pegs C and B;
    until until complete;
```

Or a little bit better:

```
Data: $n$ : number of disks
initialization;
if $n$ is even then
    repeat
        make the legal move between pegs A and B;
        make the legal move between pegs A and C;
        make the legal move between pegs B and C;
    until until complete;
else
    repeat
        make the legal move between pegs A and C;
        make the legal move between pegs A and B;
        make the legal move between pegs C and B;
    until until complete;
```

That is to say:





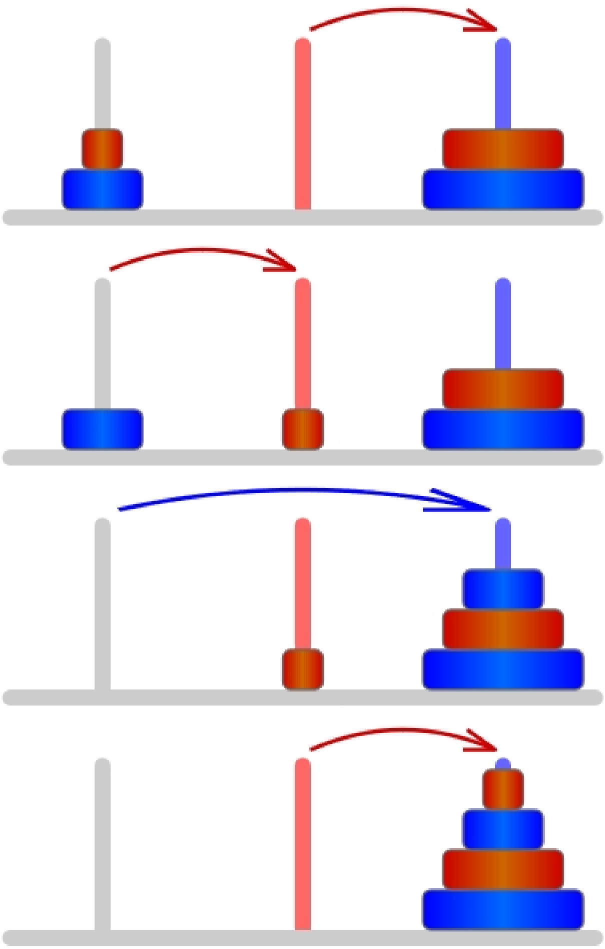


Figure 16.187: **Hanoi Tower $n = 4$ algorithm illustration (source: Wikipedia)**

But this is not a computer oriented pseudocode!! If we request to the students or trainees to write a pseudocode that is "computer oriented" that is to say to use arrays, instead of "pegs"... and use numbers instead of "disks" and write in a mathematical form the "is even" as computers don't know what is an even or odd number, then such a constraint decrease the number of people that successfully pass the test to almost 10% and this shows an inability to have a structured reasoning in the huge majority of the population.

For example to move n disks we will use numbers to identify uniquely each disk (as when first humans invented numbers to identify uniquely items in a collection):

Algorithm 23: Hanoi Tower computer pseudocode algorithm

```
Data: $n$ : number of disks
$A$ = dim([ ],$n$);
$B$ = dim([ ],$n-1$);
$C$ = dim([ ],$n$);
initialization;
for $i=1$ to $n$ do
    $A[i]=(n+1)-i$
if $n>0$ then
    if $n \equiv 0 \mod (2)$ then
        repeat
            if $A[\text{count}[A]] > B[\text{count}[B]]$ then
                $B[\text{count}[B]] = A[\text{count}[A]]$
            else
                $A[\text{count}[A]] = B[\text{count}[B]]$
            if $A[\text{count}[A]] > C[\text{count}[C]]$ then
                $C[\text{count}[C]] = A[\text{count}[A]]$
            else
                $A[\text{count}[A]] = C[\text{count}[C]]$
            if $B[\text{count}[B]] > C[\text{count}[C]]$ then
                $C[\text{count}[C]] = B[\text{count}[B]]$
            else
                $B[\text{count}[B]] = C[\text{count}[C]]$
        until $C$=$A$;
    else
        repeat
            if $A[\text{count}[A]] > C[\text{count}[B]]$ then
                $C[\text{count}[C]] = A[\text{count}[A]]$;
            else
                $A[\text{count}[A]] = C[\text{count}[C]]$;
            if $A[\text{count}[A]] > B[\text{count}[B]]$ then
                $B[\text{count}[B]] = A[\text{count}[A]]$;
            else
                $A[\text{count}[A]] = B[\text{count}[B]]$;
            if $C[\text{count}[C]] > B[\text{count}[B]]$ then
                $B[\text{count}[B]] = C[\text{count}[C]]$;
            else
                $C[\text{count}[C]] = B[\text{count}[B]]$;
        until $C$=$A$;
```

This is obviously not optimal but a minimum we can expect from a human being.

16.6.4 Sorting algorithms

A sorting algorithm is an algorithm that puts elements of a list in a certain order. The most-used orders are numerical order and lexicographical order. Efficient sorting is important for optimizing the use of other algorithms (such as search and merge algorithms) which require input data to be in sorted lists; it is also often useful for canonicalizing data and for producing human-readable output.

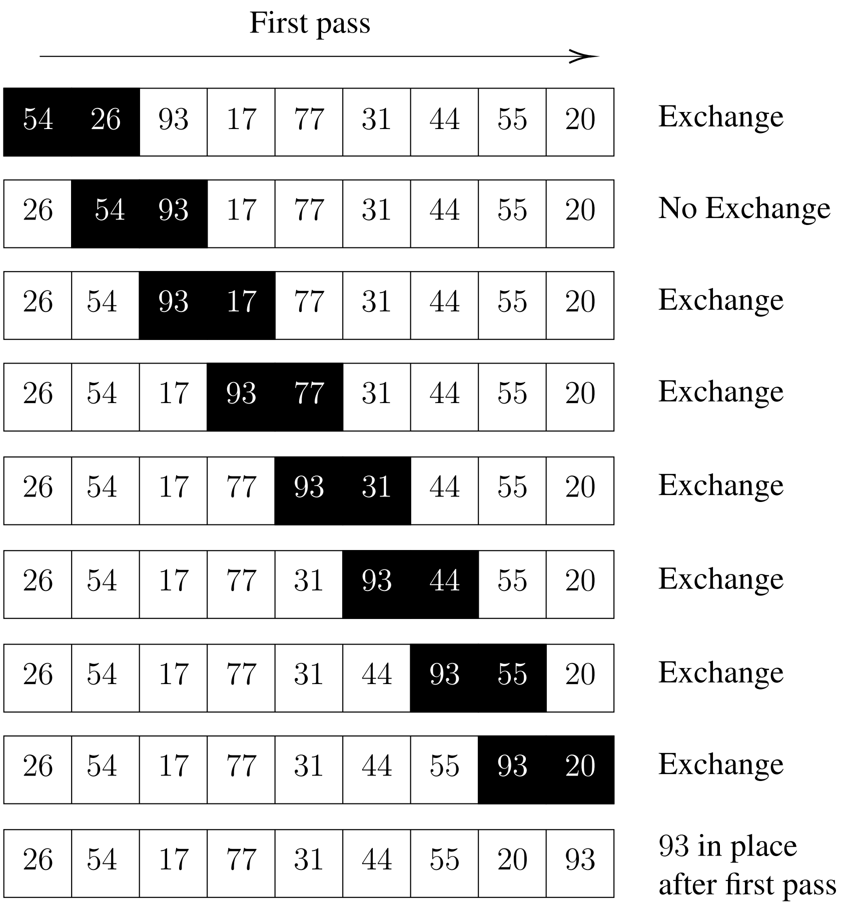
There is a consequent list of sorting algorithms (see Wikipedia for an exhaustive list of almost 20 of them). As already mentioned at the beginning of this section we will focus only on the algorithms used by the redactor of this section when he teach computer science in schools or organizations.

16.6.4.1 Bubble sort

The "Bubble sort", sometimes referred to as "sinking sort", is a simple sorting algorithm that repeatedly steps through the list to be sorted, compares each pair of adjacent items and swaps them if they are in the wrong order. The pass through the list is repeated until no swaps are needed, which indicates that the list is sorted. The algorithm, which is a comparison sort, is named for the way smaller elements "bubble" to the top of the list. Although the algorithm is simple, it is too slow and impractical for most problems.

Bubble sort can operate in-place on an array, requiring small additional amounts of memory to perform the sorting.

So let us see the idea behind the Bubble sort:



54	26	93	17	77	31	44	55	20	Exchange
26	54	93	17	77	31	44	55	20	No Exchange
26	54	93	17	77	31	44	55	20	Exchange
26	54	17	93	77	31	44	55	20	Exchange
26	54	17	77	93	31	44	55	20	Exchange
26	54	17	77	31	93	44	55	20	Exchange
26	54	17	77	31	44	93	55	20	Exchange
26	54	17	77	31	44	55	93	20	Exchange
26	54	17	77	31	44	55	20	93	93 in place after first pass

Figure 16.188: **Schematic principle of the Bubble Sort algorithm**

Here is the pseudocode of this algorithm:

Algorithm 24: Bubble sort pseudocode algorithm

```
Data: $A$ : list of sortable items
Result: $x_1$
initialization;
$n :=$ length($A$);
repeat
    swapped: = false;
    for $i = 1$ to $n - 1$ do
        if $A[i-1] > A[i]$ then
            swap($A[i-1]$,$A[i]$);
            swapped := true;
until not swapped;
display $A$ : list of sorted items;
```

The bubble sort algorithm can be easily optimized by observing that the n-th pass finds the n-th largest element and puts it into its final place. So, the inner loop can avoid looking at the last $n-1$ items when running for the n-th time:

Algorithm 25: Alternative optimized Bubble sort pseudocode algorithm

```
Data: $A$ : list of sortable items
Result: $x_1$
initialization;
$n = \text{length}(A)$;
repeat
    swapped := false;
    for $i = 1$ to $n-1$ do
        if $A[i-1] > A[i]$ then
            swap($A[i-1]$,$A[i]$);
            swapped := true;
    $n := n-1$;
until not swapped;
Display $A$ : list of sorted items;
```

As the bubble sort has two nested loops, the worst-case and average complexity both $\mathcal{O}(n^2)$, where n is the number of items being sorted (obviously when the list is already sorted (best-case), the complexity of bubble sort is only $\mathcal{O}(n^2)$). There exist many sorting algorithms with substantially better worst-case or average complexity of $\mathcal{O}(n\log(n))$. Even other $\mathcal{O}(n^2)$) sorting algorithms, such as insertion sort, tend to have better performance than bubble sort. Therefore, bubble sort is not a practical sorting algorithm when n is large.

16.6.4.2 QuickSort algorithm

"Quicksort" (sometimes named "partition-exchange sort") is an efficient sorting algorithm, serving as a systematic method for placing the elements of an array in order. Developed by Tony Hoare in 11959 (holocene calendar), with his work published in 11961 (holocene calendar), it is still a commonly used algorithm for sorting.

Quicksort can as bubble sort operate "in-place" on an array, requiring small additional amounts of memory to perform the sorting.

Quicksort is a divide and conquer algorithm. Quicksort first divides a large array into two smaller sub-arrays: the low elements and the high elements. Quicksort can then recursively sort the sub-arrays.

The steps are:

1. Pick an element, named a pivot, from the array.
2. Partitioning: reorder the array so that all elements with values less than the pivot come before the pivot, while all elements with values greater than the pivot come after it (equal values can go either way). After this partitioning, the pivot is in its final position. This is named the "partition operation".
3. Recursively apply the above steps to the sub-array of elements with smaller values and separately to the sub-array of elements with greater values.

Here is an illustration of the concept:

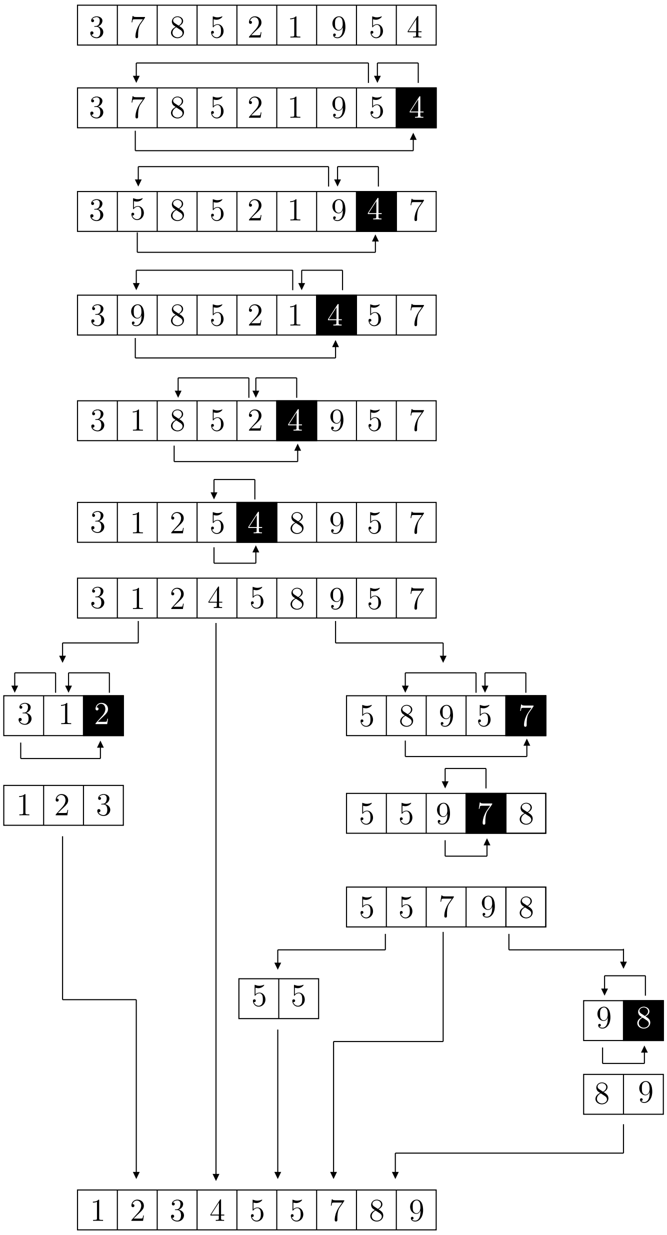


Figure 16.189: **Schematic principle of the QuickSort algorithm**

In pseudocode, a quicksort that sorts elements `lo` through `hi` (inclusive) of an array A can be expressed as (Lomuto partition scheme[19]):

Algorithm 26: QuickSort pseudocode algorithm with function

```
Data: Global $A$ : list of sortable items
Algorithm quicksort($A$, lo, hi)()
    if $lo<hi$ then
        p:=partition($A$, lo, hi)
        quicksort($A$, lo, $p-1$)
        quicksort($A$, $p+1$, hi)
    end
    return
Procedure proc()
    pivot:=A[$hi$]
    for $j=lo$ to $hi-1$ do
        if $A[i-1] \leq pivot$ then
            swap($A[i]$,$A[j]$)
            $i := i+1$
        end
    end
    swap($A[i]$,$A[hi]$)
    return $i$
```

16.6.5 Dijkstra's algorithm

The "Dijkstra's algorithm" is an algorithm for finding the shortest paths between nodes in a graph, which may represent, for example, road networks. It was conceived by computer scientist Edsger W. Dijkstra in 11956 (holocene calendar) and published three years later.

The algorithm exists in many variants; Dijkstra's original variant found the shortest path between two nodes, but a more common variant fixes a single node as the "source" node and finds shortest paths from the source to all other nodes in the graph, producing a shortest-path tree.

For a given source node in the graph, the algorithm finds the shortest path between that node and every other. It can also be used for finding the shortest paths from a single node to a single destination node by stopping the algorithm once the shortest path to the destination node has been determined. For example, if the nodes of the graph represent cities and edge path costs represent driving distances between pairs of cities connected by a direct road, Dijkstra's algorithm can be used to find the shortest route between one city and all other cities. As a result, the shortest path algorithm is widely used in network routing protocols, most notably IS-IS and Open Shortest Path First (OSPF). It is also employed as a subroutine in other algorithms.

So how does a Dijkstra Algorithm work? We will explain this using four simple steps:

1. Assign to every node a tentative distance value: set it to zero for our initial node and to

---

[19] This scheme is attributed to Nico Lomuto and popularized by Bentley in his book *Programming Pearls* and Cormen et al. in their book *Introduction to Algorithms*.

infinity for all other nodes.

2. Set the initial node as current. Mark all other nodes unvisited. Create a set of all the unvisited nodes named the "unvisited set".
3. For the current node, consider all of its neighbours and calculate their tentative distances. Compare the newly calculated tentative distance to the current assigned value and assign the smaller one.
4. When we are done considering all of the neighbours of the current node, mark the current node as visited and remove it from the unvisited set. A visited node will never be checked again.
5. If the destination node has been marked visited (when planning a route between two specific nodes) or if the smallest tentative distance among the nodes in the unvisited set is infinity (when planning a complete traversal; occurs when there is no connection between the initial node and remaining unvisited nodes), then stop. The algorithm has finished.
6. Otherwise, select the unvisited node that is marked with the smallest tentative distance, set it as the new "current node", and go back to step 3.

Suppose you would like to find the shortest path between two intersections on a city map: a starting point and a destination. Dijkstra's algorithm initially marks the distance (from the starting point) to every other intersection on the map with infinity. This is done not to imply there is an infinite distance, but to note that those intersections have not yet been visited; some variants of this method simply leave the intersections' distances unlabelled. Now, at each iteration, select the current intersection. For the first iteration, the current intersection will be the starting point, and the distance to it (the intersection's label) will be zero. For subsequent iterations (after the first), the current intersection will be a closest unvisited intersection to the starting point (this will be easy to find).

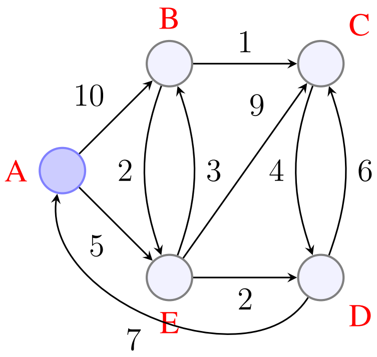
From the current intersection, update the distance to every unvisited intersection that is directly connected to it. This is done by determining the sum of the distance between an unvisited intersection and the value of the current intersection, and relabelling the unvisited intersection with this value (the sum), if it is less than its current value. In effect, the intersection is relabelled if the path to it through the current intersection is shorter than the previously known paths. To facilitate shortest path identification, in pencil, mark the road with an arrow pointing to the relabelled intersection if you label/relabel it, and erase all others pointing to it. After you have updated the distances to each neighbouring intersection, mark the current intersection as visited, and select an unvisited intersection with minimal distance (from the starting point) – or the lowest label—as the current intersection. Nodes marked as visited are labelled with the shortest path from the starting point to it and will not be revisited or returned to.

Continue this process of updating the neighbouring intersections with the shortest distances, then marking the current intersection as visited and moving onto a closest unvisited intersection until you have marked the destination as visited. Once you have marked the destination as visited (as is the case with any visited intersection) you have determined the shortest path to it, from the starting point, and can trace your way back, following the arrows in reverse; in the algorithm's implementations, this is usually done (after the algorithm has reached the destination node) by following the nodes' parents from the destination node up to the starting node; that's why we also keep track of each node's parent.

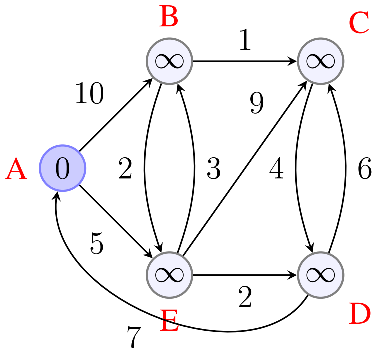
This algorithm makes no attempt to direct "exploration" towards the destination as one might expect. Rather, the sole consideration in determining the next "current" intersection is its distance from the starting point. This algorithm therefore expands outward from the starting point, interactively considering every node that is closer in terms of shortest path distance until it reaches the destination. When understood in this way, it is clear how the algorithm necessarily finds the shortest path. However, it may also reveal one of the algorithm's weaknesses: its relative slowness in some topologies.

Now aim of this is to make the Dijkstra algorithm work on a small concrete example!

Let us look for the shortest paths of origin A in this graph to node C:



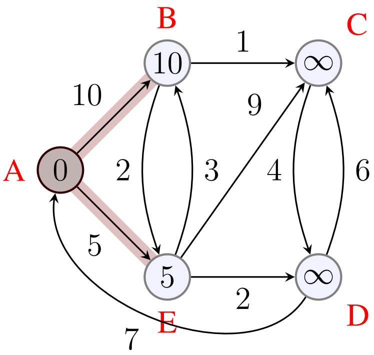
We place ourselves on A and we put the infinites values:



We initialize the following table according to the algorithm:

A	B	C	D	E
$\boxed{0}$	∞	∞	∞	∞
•				
•				
•				
•				
•				

Each of the edges starting from the selected nodes are studied:

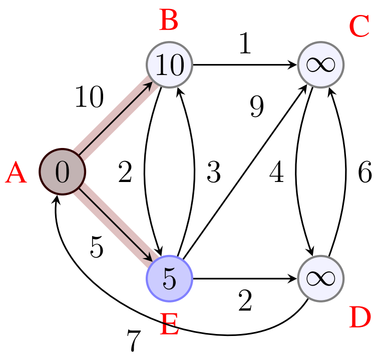


We report the distance to the adjacent node (keeping also the source as we must never use it anymore later!):

A	B	C	D	E
$\boxed{0}$	∞	∞	∞	∞
•	10_A	∞	∞	5_A
•				
•				
•				
•				

In the columns, we put the distance to A, and the node from which we come from.

We put ourselves on the node with the smallest weight, here E (the corresponding node color has been darken in the graph below to put it in evidence):

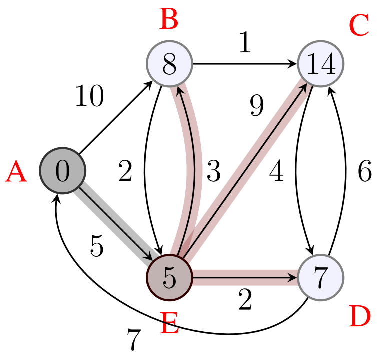


B
C
A
D
E
0
10
∞
5
∞
10
1
9
2
3
4
6
5
2
7

And we highlight in the table our new starting point having the minimal weight:

A	B	C	D	E
0	∞	∞	∞	∞
●	10_A	∞	∞	$\boxed{5_A}$
●				●
●				●
●				●
●				●

And we iterate again the procedure:

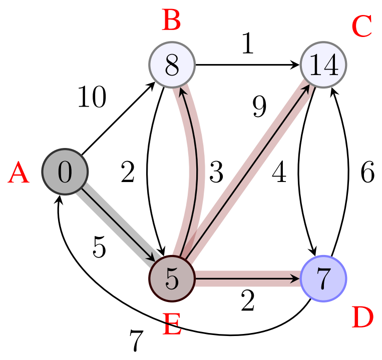


B
C
A
D
E
0
8
14
5
7
10
1
9
2
3
4
6
5
2
7

And we get:

A	B	C	D	E
0	∞	∞	∞	∞
●	10_A	∞	∞	$\boxed{5_A}$
●	8_E	14_E	7_E	●
●				●
●				●

And we put ourselves on node D (highlighted in the figure below):

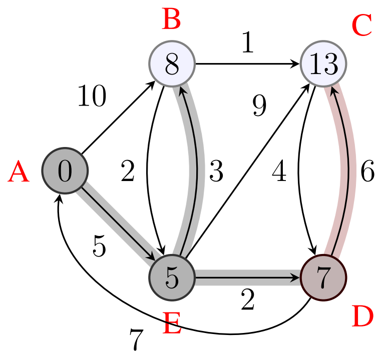


B
C
8
1
14
10
9
A
0
2
3
4
6
5
5
7
2
E
D
7

So we put the new starting point and corresponding node in evidence in the table:

A	B	C	D	E
0	∞	∞	∞	∞
•	10_A	∞	∞	5_A
•	8_E	14_E	$\boxed{7_E}$	•
•			•	•
•			•	•

Now starting from node D it remains only one possible path:

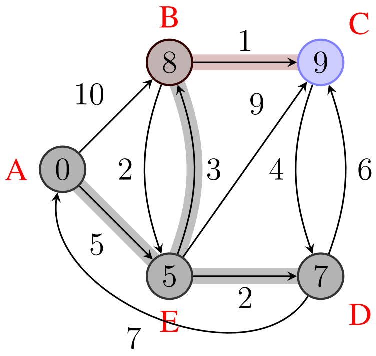


B
C
8
1
13
10
9
A
0
2
3
4
6
5
5
7
2
E
D
7

A	B	C	D	E
0	∞	∞	∞	∞
•	10_A	∞	∞	5_A
•	8_E	14_E	$\boxed{7_E}$	•
•	8_E	13_D	•	•
•			•	•
•			•	•

So we have arrived to our destination! Now we go backward to check if we really have the shortest path. Starting from C we see that by going backward the shortest path is to go through B that itself comes from E:

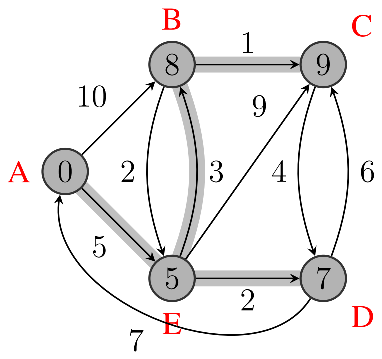
A	B	C	D	E
0	∞	∞	∞	∞
•	10_A	∞	∞	5_A
•	8_E	14_E	7_E	•
•	$\boxed{8_E}$	13_D	•	•
•	•		•	•
•	•		•	•



And as 8_E joins our initial forward path, we stop here and therefore the shortest path has a weight equal to 9.

A	B	C	D	E
0	∞	∞	∞	∞
•	10_A	∞	∞	5_A
•	8_E	14_E	7_E	•
•	8_E	13_D	•	•
•	•	$\boxed{9_B}$	•	•
•	•	•	•	•

Hence the final path:



Ok the example may help to understand the human way... but what about the computer implementation that may seem quite not obvious (indeed... it's not obvious!). Here is the corresponding pseudocode for a computer implementation:

```
function Dijkstra(Graph, source):
    for each vertex v in Graph: // Initializations
        dist[v] := infinity
    // Unknown distance function from source to v
        previous[v] := undefined
    // Previous node in optimal path from source
    dist[source] := 0
    // Distance from source to source
    Q := the set of all nodes in Graph
    // All nodes in the graph are unoptimized - thus are in Q
    while Q is not empty:       // The main loop
        u := vertex in Q with smallest dist[]
        if dist[u] = infinity:
            break
    // all remaining vertices are inaccessible
        remove u from Q
        for each neighbor v of u:
    // where v has not yet been removed from Q.
            alt := dist[u] + dist_between(u, v)
            if alt < dist[v]:    // Relax (u,v,a)
                dist[v] := alt
                previous[v] := u
    return previous[]
```

As we can see above, this Dijkstra simple algorithm has a complexity of order $\mathcal{O}(v^2)$ as two loops depending on v (the number of vertices) are inside each other. Some algorithms are faster using various empirical techniques (adjacency lists or quantum computing).

16.6.6 Google PageRank algorithm

At its creation in 11998 (holocene calendar), Google (search engine currently well known by many Internet users) has dominated in 12011 (holocene calendar) and still dominates the market for Internet search engines. His initial strength is based on the simple idea to sort the results by relevance, what did not make the other major search engines before it.

The main idea behind the initial Google algorithm is interesting to present in this textbook because it is a practical example of purely mathematical concepts we have presented so far (graph theory and Markov chains in the respective sections of Graph Theory and Probability) and created one of the largest international companies in new technologies in the years 12000's according to holocene calendar (Google earns billions thanks to linear algebra ...) and even since the beginning of worldwide economy! As it is often the case in a market economy, it is primarily theoretical research (mathematical or physics) that helped to develop new tools!

Remarks

R1. Obviously the basic algorithm has changed since 11998 (holocene calendar) because you can add many mathematical parameters (weighting by a distance for example) or empirical (visits, clicks, advertising, design, etc.).

R2. This algorithm is not only used in the field of Internet. Indeed, it can be used to highlight any object in a multiple relation with other objects (e.g. variables in a project that influence each other by having direct or indirect relations: a structural analysis) or also to determiner influencers in a social network.

To find an information in the amorphous and not really structured content that is the Internet (given the few developers who properly comply with the standards set by the W3C...), the user will search by keywords. This obviously requires for sure some preparation to be effective: the search engine copy first in the local memory all web pages and sorts extracted words (or combination of words) in alphabetical order using traditional empirical algorithms index of the IT domain (b trees, b+ trees or even others...). The result is a directory of keywords with their associated web pages.

To analyse how Google identifies the most relevant web pages, we will ignore the content of pages and only count the links between them. What we get then is the structure of a graph (not necessarily connected!).

The following image shows a miniature example (there would $25\cdot 10^9$ websites from Google in the early 12007 according to holocene calendar):

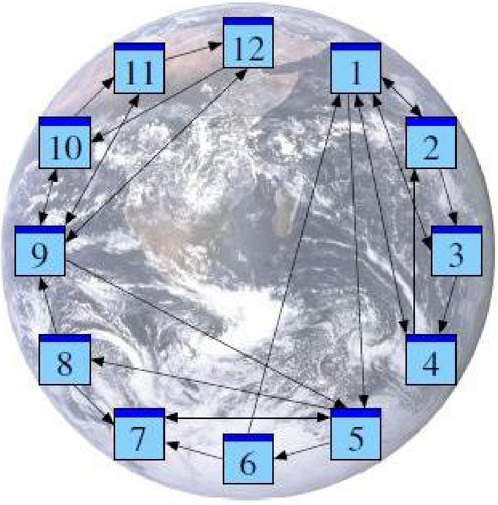


Figure 16.190: Schematic principle of the graph to study

For what follow, we will denote the web pages by:

$$P_1, P_2, \ldots, P_n \tag{16.6.1}$$

and we will write:

$$j \longrightarrow i \tag{16.6.2}$$

if the page P_j directly quotes the page P_i (directly related citation or link). Thus, in the previous image, we have a link $1 \longrightarrow 5$, for example, but no link $5 \longrightarrow 1$.

Obviously, a link $j \longrightarrow i$ is a recommendation of the page P_j to go read the page P_i. Thus it is a vote of P_j in favour of the of the page P_i (we then understand easily then easily why exchanging links between two websites with no contextual relation was somehow banned by Google).

Let us analyse the previous image in a more consistent aspect of graph theory (see corresponding section in this textbook), which hierarchy will have to be justified to be as following:

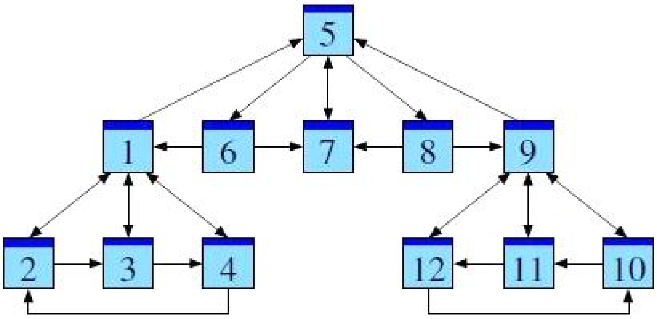

Figure 16.191: Preceding figure into more mathematical aspect

For purely educational reasons, we will introduce three theoretical models of ranking web pages. The latest model is say to be the closest to that implemented by Google in 11998 (holocene calendar) and the first two models were just here to prepare the basis.

16.6.6.1 Weighted Count

It is highly possible that if a page is important, it gets a lot of links. With a bit of naivety, we can assume that the reverse is true (that is to say: if a page gets a lot of links, it means it is important). Thus, we could define the importance μ_i of a page P_i as the number of directly related links $j \rightarrow i$. In mathematical form, we write it in this way: In other words, μ_i is equal to the number of votes for the page P_i, where each vote contributes for the same value 1. This is certainly easy to calculate, but often do not match with the importance felt by the user.

Therefore in our above example we have:

$$\mu_1 = \mu_9 = 4 \tag{16.6.3}$$

that is in front of (in terms of ranking):

$$\mu_5 = \mu_7 = 3 \tag{16.6.4}$$

what is worse, is that this naive count can be too easily manipulated by adding pages (another Internet domain name for example) without interest recommending any other page.

> **Remark**
>
> So the maximum weight is verbatim equal to $n-1$.

Some pages emit a lot of (hyper)links. They therefore seem less specific (specialized) and their weight will (must) therefore be lower. We therefore share the vote of the page P_j in l_j equal parts, where l_j denotes the number of emitted links. So we can define a finer measurement:

$$\mu_i = \sum_{j \rightarrow i} \frac{1}{l_j} \tag{16.6.5}$$

In other words, μ_i counts now the number of weighted votes for the page P_i. It is easy to calculate, but we always still remain with the above problem.

In our example, we have therefore:

$$\begin{aligned}
\mu_1 &= \sum_{j \rightarrow 1} \frac{1}{l_j} = \frac{1}{l_2} + \frac{1}{l_3} + \frac{1}{l_4} + \frac{1}{l_6} = \frac{1}{2} + \frac{1}{2} + \frac{1}{2} + \frac{1}{2} = 2 \\
\mu_9 &= \sum_{j \rightarrow 9} \frac{1}{l_j} = \frac{1}{l_8} + \frac{1}{l_{10}} + \frac{1}{l_{11}} + \frac{1}{l_{12}} = \frac{1}{2} + \frac{1}{2} + \frac{1}{2} + \frac{1}{2} = 2
\end{aligned} \tag{16.6.6}$$

and:

$$\mu_5 = \sum_{j \rightarrow 5} \frac{1}{l_j} = \frac{1}{l_1} + \frac{1}{l_7} + \frac{1}{l_9} = \frac{1}{4} + \frac{1}{1} + \frac{1}{4} = 1.5 \tag{16.6.7}$$

and:

$$\mu_7 = \sum_{j \rightarrow 7} \frac{1}{l_j} = \frac{1}{l_5} + \frac{1}{l_6} + \frac{1}{l_7} = \frac{1}{3} + \frac{1}{2} + \frac{1}{2} = \frac{4}{3} \tag{16.6.8}$$

Remark

If all the pages were directly related (conner), then we would have $\mu_i = 1$ for all i.

16.6.6.2 Recursive counting

Heuristically, a page P_1 seems important if many important pages cite it. This leads us to define the μ_i recursively as follows:

$$\mu_i = \sum_{j \to} \frac{1}{l_j} \mu_j \tag{16.6.9}$$

It is therefore a system of homogeneous linear equations with n unknowns, where in the chosen example $n = 12$. More traditionally, the system may be denoted:

$$\left(\sum_{j \to i} \frac{1}{l_j} \mu_j \right) - \mu_i = 0 \tag{16.6.10}$$

or more explicitly (see section Linear Algebra page 1924):

$$\begin{bmatrix}
-1 & l_2^{-1} & l_3^{-1} & l_4^{-1} & l_5^{-1} & l_6^{-1} & l_7^{-1} & l_8^{-1} & l_9^{-1} & l_{10}^{-1} & l_{11}^{-1} & l_{12}^{-1} \\
l_1^{-1} & -1 & l_3^{-1} & l_4^{-1} & l_5^{-1} & l_6^{-1} & l_7^{-1} & l_8^{-1} & l_9^{-1} & l_{10}^{-1} & l_{11}^{-1} & l_{12}^{-1} \\
l_1^{-1} & l_2^{-1} & -1 & l_4^{-1} & l_5^{-1} & l_6^{-1} & l_7^{-1} & l_8^{-1} & l_9^{-1} & l_{10}^{-1} & l_{11}^{-1} & l_{12}^{-1} \\
l_1^{-1} & l_2^{-1} & l_3^{-1} & -1 & l_5^{-1} & l_6^{-1} & l_7^{-1} & l_8^{-1} & l_9^{-1} & l_{10}^{-1} & l_{11}^{-1} & l_{12}^{-1} \\
\vdots & \ddots & & & -1 & & & & & & & \vdots \\
 & & & & & -1 & & & & & & \\
 & & & & & & -1 & & & & & \\
\vdots & & & & & & & -1 & & & \ddots & \vdots \\
l_1^{-1} & l_2^{-1} & l_3^{-1} & l_4^{-1} & l_5^{-1} & l_6^{-1} & l_7^{-1} & l_8^{-1} & -1 & l_{10}^{-1} & l_{11}^{-1} & l_{12}^{-1} \\
l_1^{-1} & l_2^{-1} & l_3^{-1} & l_4^{-1} & l_5^{-1} & l_6^{-1} & l_7^{-1} & l_8^{-1} & l_9^{-1} & -1 & l_{11}^{-1} & l_{12}^{-1} \\
l_1^{-1} & l_2^{-1} & l_3^{-1} & l_4^{-1} & l_5^{-1} & l_6^{-1} & l_7^{-1} & l_8^{-1} & l_9^{-1} & l_{10}^{-1} & -1 & l_{12}^{-1} \\
l_1^{-1} & l_2^{-1} & l_3^{-1} & l_4^{-1} & l_5^{-1} & l_6^{-1} & l_7^{-1} & l_8^{-1} & l_9^{-1} & l_{10}^{-1} & l_{11}^{-1} & 1
\end{bmatrix}
=
\begin{pmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \\ \mu_4 \\ \mu_4 \\ \mu_4 \\ \mu_5 \\ \mu_6 \\ \mu_7 \\ \mu_8 \\ \mu_9 \\ \mu_{10} \\ \mu_{11} \\ \mu_{12} \end{pmatrix}
\begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix}
\tag{16.6.11}$$

Which gives with our example:

$$\begin{bmatrix} -1 & 2^{-1} & 2^{-1} & 2^{-1} & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 \\ 4^{-1} & -1 & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 4^{-1} & 2^{-1} & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 4^{-1} & 0 & 2^{-1} & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 4^{-1} & 0 & 0 & 0 & -1 & 0 & 1^{-1} & 0 & 4^{-1} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3^{-1} & -1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3^{-1} & 2^{-1} & -1 & 2^{-1} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3^{-1} & 0 & 0 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 2^{-1} & -1 & 2^{-1} & 2^{-1} & 2^{-1} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4^{-1} & -1 & 0 & 2^{-1} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4^{-1} & 2^{-1} & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4^{-1} & 0 & 2^{-1} & -1 \end{bmatrix} \begin{pmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \\ \mu_4 \\ \mu_4 \\ \mu_4 \\ \mu_5 \\ \mu_6 \\ \mu_7 \\ \mu_8 \\ \mu_9 \\ \mu_{10} \\ \mu_{11} \\ \mu_{12} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix} \tag{16.6.12}$$

In addition to the trivial solution (null vector), this system has an infinity of solutions because its determinant is zero (see section Linear Algebra page 1980), which can easily be verified with the `MDETERM( )` function of Microsoft® Excel® 11.8346.

Let us now write the previous system in the following equivalent form:

$$\begin{bmatrix} 0 & 2^{-1} & 2^{-1} & 2^{-1} & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 \\ 4^{-1} & 0 & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 4^{-1} & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 4^{-1} & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 4^{-1} & 0 & 0 & 0 & 0 & 0 & 1^{-1} & 0 & 4^{-1} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3^{-1} & 2^{-1} & 0 & 2^{-1} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 2^{-1} & 0 & 2^{-1} & 2^{-1} & 2^{-1} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4^{-1} & 0 & 0 & 2^{-1} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4^{-1} & 2^{-1} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4^{-1} & 0 & 2^{-1} & 0 \end{bmatrix} \begin{pmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \\ \mu_4 \\ \mu_4 \\ \mu_4 \\ \mu_5 \\ \mu_6 \\ \mu_7 \\ \mu_8 \\ \mu_9 \\ \mu_{10} \\ \mu_{11} \\ \mu_{12} \end{pmatrix} = \begin{pmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \\ \mu_4 \\ \mu_4 \\ \mu_4 \\ \mu_5 \\ \mu_6 \\ \mu_7 \\ \mu_8 \\ \mu_9 \\ \mu_{10} \\ \mu_{11} \\ \mu_{12} \end{pmatrix} \tag{16.6.13}$$

We notice two things before continuing:

1. In the above matrix, each column is such that the sum of its values equals unity. It is therefore the transpose of a stochastic matrix of a Markov chain (see section Probabilities page 537).

2. The importance μ_i is positive or zero. So the vector $\vec{\mu}$ is strictly positive and it is the stochastic vector of the Markov chain (see section Probabilities page 537) whose sum of the components must be equal to unity.

We will write this system in condensed form:

$$P^T\mu=\mu \tag{16.6.14}$$

Thus, 1 is the eigenvalue and μ is the eigenvector of the application P. We know from our study of Markov chains that this relation is verified only for the invariant measure denoted traditionally π in the domain of study of Markov chains:

$$P^T\pi=\pi \tag{16.6.15}$$

To determine the measure, it is necessary to first rewrite the network in the format of a matrix application of a Markov chain (see section Probabilities page 537):

$$p(n+1)=P^Tp(n) \tag{16.6.16}$$

With Microsoft® Excel® 11.8346, the modelling is quite simple enough to reproduce to determine the invariant measure with any starting point (any distribution) in the graph:

27	0.05	0.05	0.051	0.052	0.052	0.053	0.054	0.054	0.054	0.055	0.055	0.055

Figure 16.194: **Convergence at the 35th iteration**

So finally the invariant measure is:

$$\pi=\mu=\begin{pmatrix}0.12\\0.06\\0.06\\0.06\\0.18\\0.11\\0.06\\0.12\\0.06\\0.11\\0.06\\0.06\\0.06\end{pmatrix} \tag{16.6.17}$$

This gives us the convergent distribution per page of a cohort of 17 Internet users (sums of values of the stochastic vector).

The pages where μ_i is large are the most popular in terms of equilibrium probabilities. In the quest to classify web pages, it is still an argument to use the measure μ as an empirical indicator.

Remark

The reader will be able to find in the `R` companion book how we plot the above network and calculate the invariant measure in a more efficient way that in Microsoft® Excel®...

16.6.6.3 Absorbing states

However, if our graph contains a page (or group of pages) without issue then this one absorbs all the probability, because our cohort will fall sooner or later on this page and will not be able to leave it ("absorbing state" as defined In the Probabilities section). We represent this in the following graphical form if, for example, we add a page P_{13} that is an absorbing page:

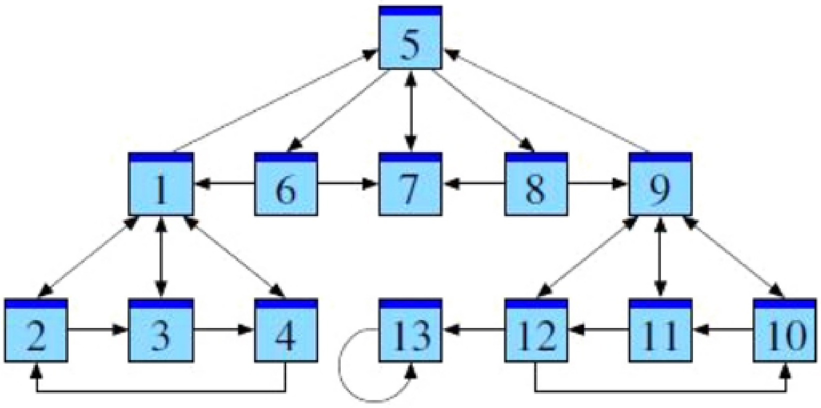

Figure 16.195: **Graph with an absorbent state**

With the associated transition matrix:

$$\begin{bmatrix} 0 & 2^{-1} & 2^{-1} & 2^{-1} & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 4^{-1} & 0 & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 4^{-1} & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 4^{-1} & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 4^{-1} & 0 & 0 & 0 & 0 & 0 & 1^{-1} & 0 & 4^{-1} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3^{-1} & 2^{-1} & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 2^{-1} & 0 & 2^{-1} & 2^{-1} & 3^{-1} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4^{-1} & 0 & 0 & 3^{-1} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4^{-1} & 2^{-1} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4^{-1} & 0 & 2^{-1} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 3^{-1} & 1 \end{bmatrix} \tag{16.6.18}$$

Our model is not yet satisfactory. We could then construct a matrix that allows to escape the absorbent states by putting that any column that contains only one 1 with only elsewhere 0 teleport the visitor on all pages with an equal weight. Which would give us since we have 13 pages:

$$\begin{bmatrix} 0 & 2^{-1} & 2^{-1} & 2^{-1} & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 13^{-1} \\ 4^{-1} & 0 & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 13^{-1} \\ 4^{-1} & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 13^{-1} \\ 4^{-1} & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 13^{-1} \\ 4^{-1} & 0 & 0 & 0 & 0 & 0 & 1^{-1} & 0 & 4^{-1} & 0 & 0 & 0 & 0 & 13^{-1} \\ 0 & 0 & 0 & 0 & 3^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 13^{-1} \\ 0 & 0 & 0 & 0 & 3^{-1} & 2^{-1} & 0 & 2^{-1} & 0 & 0 & 0 & 0 & 0 & 13^{-1} \\ 0 & 0 & 0 & 0 & 3^{-1} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 13^{-1} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 2^{-1} & 0 & 2^{-1} & 2^{-1} & 3^{-1} & 0 & 13^{-1} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4^{-1} & 0 & 0 & 3^{-1} & 0 & 13^{-1} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4^{-1} & 2^{-1} & 0 & 0 & 0 & 13^{-1} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4^{-1} & 0 & 2^{-1} & 0 & 0 & 13^{-1} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 3^{-1} & 1 & 13^{-1} \end{bmatrix} \tag{16.6.19}$$

But this is not very optimal, because it loads the matrix so it is very greedy in terms of memories and calculations.

To escape the absorbing states, Google uses a more refined empirical model.

We take the initial application which is a linear mapping:

$$f:\mathbb{R}^n \mapsto \mathbb{R}^n \qquad \mu \mapsto P^T\mu \tag{16.6.20}$$

Where for reminder the sum of the components of μ is always 1. We rewrite this in the form:

$$f:\mathbb{R}^n \mapsto \mathbb{R}^n \qquad \mu \mapsto 1\cdot P^T\mu \tag{16.6.21}$$

where the 1 represents the fact that there is a 100% probability of having the state $P^T\mu$. Now the trick is to write:

$$f:\mathbb{R}^n \mapsto \mathbb{R}^n \qquad \mu \mapsto \varepsilon c+(1-c)P^T\mu \tag{16.6.22}$$

with:

$$\varepsilon=\begin{pmatrix}\dfrac{1}{n}\\ \vdots\\ \dfrac{1}{n}\\ \vdots\\ \dfrac{1}{n}\end{pmatrix} \tag{16.6.23}$$

which means that the Internet user has at all times a probability $(1-c)$ of being in the state $P^T\mu$ and a probability c of being in the state ε, that is to say to find ourselves with an equiprobable probability in any point of the graph. Finally, we sum up the two to obtain a stochastic vector (whose sum of the components is equal to 1).

Indeed, if we take for example 10% for the value of c, we have the sum of the components of the vector:

$$(1-c)P^T\mu \tag{16.6.24}$$

which will be equal to 0.9 and respectively the sum of the components of the vector εc that will be equal to 0.1 (since the sum of the components of ε equals 1 by construction).

So to summarize, with a fixed probability c the indexing engine (or the Internet user) abandons the current page P_i and starts again on one of the n pages of the web, this one being chosen, in order not to privilege anyone! Otherwise, with a probability $1-c$ the crawl engine follows one of the links of the page P_j, chosen equally. The only delicate point that remains is to calibrate the value of c which is therefore between 0 and 1. If it is 0 we fall back on the initial model with the problem of the absorbing states, if it is 1 we have a model that gives an equal note to each page. It is therefore necessary to choose c with low values close to 0.

This teleportation tip avoids being trapped by an absorbing page and guarantees to arrive anywhere in the graph, regardless of connectivity issues.

We must put the whole back in the form of components, so we have the notation (whose second term converges):

$$\boxed{\mu_1=\frac{1}{n}c+\sum_{j\rightarrow i}\frac{1-c}{l_j}\mu_j} \tag{16.6.25}$$

which has the enormous advantage of being able to calculate the value of any component μ_i of the stochastic vector of any step of a random walk on the graph and this without necessitating at any moment the manipulation of an immense matrix that would be too greedy in terms of memory capacity !!

To close this section about the PageRank algorithm let us quote the coinventor of the World Wide Web Robert Cailliau when speaking in the documentary *Made In Switzerland* (released in 12026 according to holocene calendar) produced by the RTS (Swiss Radio Television) at the timestamp 57m05s while sitting in one of the CERN office:

quote
16.6:8671.#91

> *The Internet wasn't public; only universities and research centers had access to it. Then, the Internet opened to the general public, and that's when parasites developed on the same infrastructure that have nothing to do with the web at all. These are all the social networks!*

16.7. Industrial Engineering

INDUSTRIAL ENGINEERING involves the design, improvement and installation of systems. It uses the knowledge from the mathematical, physical and social sciences as well as the principles and methods specific to the art of engineering in order to specify, predict and evaluate the results arising from these systems.

We can summarize all areas affecting the industrial engineering (and not only... industrial this can apply with ad hoc adaptation to the administration) with the objective to optimize and monitor the overall performance of the business (costs , deadlines, quality) because:

Only what is measured can be improved!

Note that some industrial engineering techniques have been discussed in other sections and subsections as: quantitative management techniques, optimization (operations research), financial analysis, queues analysis, etc. and that this section also includes "Quality Engineering".

In this chapter we will only deal with the minimum theoretical aspects of SQC (Statistical Quality Control) relating to statistical quality control (that's the job of the "quality controller") in the manufacturing environment and into production of goods or services and which is the minimum-minimorum knowledge of any quality engineer in any organization (industrial or administrative) under penalty of having no credibility! Also beware of companies - especially multinationals - who are looking for quality specialists mastering Microsoft® Excel® or Microsoft Access. Because it means that they use non-professional tools to do a job which should be done with appropriate tools (and Microsoft® Excel® or Microsoft Access are not appropriate tools) !!! So in terms of internal organization, you can ensure that these companies organize and analyse anything, anyhow, with an unsuitable tools and therefore that internally the organization is a general mess.

Depending on the use we distinguish three main areas of application of Industrial Engineering that are in the conventional order:

1. "Statistical Process Control" (S.P.C.), production monitoring and quality settings. This is the monitoring of a manufacturing process for the mass production of products to discover the differences in quality and to be able to step in and drive directly corrective actions.

   The engineers must absolutely consult the standard ISO/TR 13425:2006 *Guidelines for the selection of statistical methods in standardization and specification* as well as the standard ISO/TR 8258 *Shewhart control cards* and finally the ISO/TR 18532 *Guidelines for the application of statistical methods to quality and to industrial standardization* before implementing S.P.C. tools within their company.

Remark

Most mathematical techniques related to this field are univariate models. There are some bivariate models also but above it starts to become a nightmare (some unique pieces in the industry have more that ten or twenty specifications). I complicated situations production is managed by Machine Learning techniques that corrects production parameters using neural networks. This is what we name "Automated Process Control" (A.P.C.).

2. "Delivery check or receipt sample test (Acceptance Sampling)". This is an input control, a control during production and a final product inspection in a company (or factory) without direct influence on the production. Thus, the amount of product is measured. The initial inspection is also used to reject the incoming goods. It therefore influences the production only indirectly.

   The engineers must absolutely consult the family of norms ISO 3591 *Sampling procedures for inspection by variables and attributes* before setting up reception control tools within their company.

3. Preventive maintenance and control of aging and failure and critical impacts best known as "Failure Mode Analysis, Effects and Criticality Analysis (FMEA)". This is mainly to calculate the lifespan of components or machines to provide replacements in advance and actions related thereto to be taken to avoid human or financial emergencies.

   The engineer must absolutely consult the norm IEC 61649 *Weibull Analysis* and the norm NF EN 13306 *Terminology for maintenance* before putting in place preventive maintenance tools within their company.

These three areas using statistics in general, the engineer should always refer to the family of norms ISO 3534 *Vocabulary and symbols*, ISO 3534-1 *Probability and general statistical terms*, ISO 3534-2 *Statistical Quality Control*, ISO 3534- 3 *Design of experiments*.

For information, since the late 120th century (holocene calendar), it is fashionable to combine the first two points in a working methodology named "Six Sigma" that we will study immediately. Finally, note that in practice, to get an interest of chiefs executives the engineer must always find a quantitative relations between non-quality and costs in order to make things change...

16.7.1 Six Sigma

Two objects are never perfectly identical. Whatever the techniques used to manufacture these objects or precise are the tools, there is variability in any production process. The aim of any industrial is that this natural variability remains within acceptable limits. This is a major concern in the improvement of industrial quality.

One of the tools used to work towards this quality is the "Statistical Process Control " (S.P.C.). If you produce a certain type of object, and if you want to keep your customers to sustain your business, you must ensure that the lots that you deliver them are consistent with what has been agreed between you, usually by contract. Any serious industrial performs checks on produced lots to check the quality, that he is the manufacturer of the goods or that he receives them. Various statistical techniques related to sampling are then used to avoid, in most cases, to check one by one all the objects in a batch. The samples control taken in batches is essential if the controls at destroying the artefact, as in an analysis of the active ingredient dose contained in a tablet. However, there are cases where it is preferred to check all objects (for example it is desirable that the brakes of a vehicle works and a control of the braking function on a sample of produced cars does not guarantee that all vehicles have good braking...).

Control
Define
LEAN
6σ
Measure
Analyze
Improve

When a batch is controlled, it is conform or it is not. If it is conform, we deliver it (we are the supplier) or we accept it (we are the customer). If it is not conform, we can destroy it, check one by one all the elements and destroy only those who do not comply, etc. All solutions to handle non-conforming lots are expensive. If the batch does not comply, the damage is done. The S.P.C. methods aim to avoid producing non-conforming goods by monitoring production and intervening whenever anomalies are found. A good S.P.C. implementation eliminates a significant number of controls of conformity by setting up statistical tools for monitoring manufacturing processes.

To resume, the S.P.C. is therefore to control the process during manufacturing and to act on the process rather than on the product if problems are detected. This approach tries to go up at the highest possible level of the production line to prevent the occurrence of defective product and goods. We discuss in this special case of "process control".

This is a useful working methodology to satisfy customers and the idea of this methodology is to deliver products/services of quality, knowing that quality is inversely proportional to the variability. Moreover, the introduction of quality should be optimized so as not to overly increase costs. The subtle interplay between these two parameters (quality/costs) and their joint optimization is often associated with the term "lean management". If we integrate Six Sigma, then we speak of "Lean Six Sigma".

Six Sigma integrates all aspects of the control of variability in business whether at the level of manufacturing, services, organization, marketing or management. Hence why it is such interesting! Moreover, in Six Sigma a defect must be paradoxically welcome, because it is a source of progress of an initially hidden problem. Then you have to ask several times the question "Why?" (traditionally 5 times) to better trace the source of it.

We distinguish two types of variability in practice:

1. The "inherent variability" in the process (and difficult to change) that induces the concept

of measures distribution (usually accepted by businesses as a Normal distribution).

2. The "external variability" which induces most often a bias (deviation) in the distributions over time.

Manufacturing processes in the high tech industry having a strong tendency to become terribly complex, it should be noted that the basic components used for each product are not always of equal quality or performance. And if in addition, production procedures are difficult to establish, the drifts will inevitably exists.

Whether for one reason or another, ultimately many products will be outside of the normality and will deviate of the range corresponding to the acceptable quality for the customer. This drift is very costly for the company. The management of waste, rework or customer returns for nonconformity generate substantial costs seriously amputating the expected benefits.

As we shall see in the texts, a pretty fair possible definition of Six Sigma is: solving problems based on the exploitation of data. Thus it is a scientific method of management!

16.7.1.1 Quality Control

In the situation of quality studies in a business, we often give up a 100% control because of the price it would generate. We then do a sampling. These must obviously be representative, that is to say, representatives and with equal probabilities (i.e. the mixture is good).

The purpose of sampling is obviously the real probability of failure of the whole lot on the basis of observed failures in the sampling.

Let us recall before going further that we have seen in the section of Statistics the hypergeometric distribution (and its interpretation) given by (see section Statistics page 672):

$$H(k)=\frac{C_k^m C_{p-k}^{n-m}}{C_p^n} \tag{16.7.1}$$

where the notation of the binomial coefficient is consistent with that defined and chosen in the section of Probabilities (therefore non-compliant with ISO 31-11).

During a sampling, we normally have a pack of n elements which we draw p of them. Instead of taking m (remember it is an integer!) as the number of defective parts, we will implicitly defined it as being equal to:

$$m=p_d\cdot n \tag{16.7.2}$$

where p_d is the probability (assumed known or imposed...) that a part is defective. Thus, we have for probability to find k defective parts in a sample of p among n:

$$H(k)=\frac{C_k^{p_d n} C_{p-k}^{n-p_d n}}{C_p^n}=\frac{C_k^{p_d n} C_{p-k}^{n(1-p_d)}}{C_p^n} \tag{16.7.3}$$

The cumulative probability of finding k defective parts (between 0 and k defectives in other words) is then simply calculated with the cumulative hypergeometric distribution:

$$\sum_{x=0}^{k} H(x)=H(0)+H(1)+\ldots+H(k)=\sum_{x=0}^{k}\frac{C_k^{p_d n} C_{p-k}^{n(1-p_d)}}{C_p^n} \tag{16.7.4}$$

✍**Example:**

In a batch of 100 machines, we assume that a maximum of 3 are defective (i.e. that is to say $p_d=3\%$). We conduct a control sampling p at each output order of 20 machines.

We want to know at first what is the probability that in this sample of size p, 3 machines are defective and secondly what is the maximum number of defective machines allowed in this sample of size p that says us with 90% confidence that the batch of n machines contain only 3 defective.

x	$H(x)$	$\sum_{x=0}^{k} H(x)$
0	0.508	0.508
1	0.391	0.899
2	0.094	0.993
3	0.007	1.000

Table 16.12: **Application of the hypergeometric distribution**

Thus, the probability of sampling in one series three defective machines in the sample of 20 is $0.7\%(0.007)$ and the maximum number of defective machines allowed in this sample of 20 that allows us with at least 90% of confidence to have 3 defectives is 1 defective machine found in the sample (cumulative probability: 0.899)!

$H(x)$ values can be calculated easily with the English version of Microsoft® Excel® 11.8346. For example, the first value is obtained by the function:

```
=HYPGEOM.DIST(0,20,3,100,FALSE)
=COMBIN(30,0)*COMBIN(97,20-0)/COMBIN(100,20)=0.508
```

16.7.1.2 Defaults/Errors

Let us now exhibit for the general culture a practical and special example of what is only a simple application of the theory of statistics and probabilities. To understand the importance of quality and the concept of "zero defects", let us consider the following general example of the inventor of the method:

For example, consider that the installation of a tourism car includes $2,500$ operations (pieces) and each operation is perfect 99 times out of 100. A priori, a having a successful operation in 99% of cases is a sign of an almost perfect mastery of the quality. But in fact, the perfection of the whole assumes that $2,500$ times, the operations are fully perfectly realized! If the daily production is of $2,000$ units, one the 5 million operations that are done daily in our factory, there is $100\%-99\%=1\%$ of defects assemblies that is to say $50,000$, and an average of 25 defects per car, which is hardly acceptable. Also, let us imagine this imaginary factory is equipped with a control service sampling systematically at the end of the assemblies line. This represents a considerable cost in working hours for control. If the defects can be corrected, this will require rework, replace perhaps some parts and work in unexpected conditions to correct the defects. If the defects are too important, these defects makes the final product unusable, and scrap are extremely expensive depending on the product. Even worse: if the control service sees 99% of defects it remains about 500 of them daily and this requires costly repairs and returns and a significant deterioration of the image depending on the performance of competitors.

This example serving as a school case study, imagine now a company manufacturing 3 copies of a same product coming out of the same production line, each copy being composed of 8 elements.

Remark

We can just as easily imagine a services company developing (manufacturing) 3 copies of a software (product) out of the same development team (production line), each composed of an equal number of modules (elements).

Suppose that the product $P1$ has 1 defects in average, the product $P2$ has 0 defects $P3$ has 2 defects and that each product is composed of 8 items.

Here Six Sigma implicitly assumes that defects are independent variables, which is relatively rare in machinery production lines but more common in chains in which humans are involved. However, we can consider in the application of the S.P.C. on machines that a sampling in time in the measurement process is equivalent to having a random independent variable!!

Remarks

R1. As part of the example above with the software, independence is unlikely if we do not take an example in which the programming modules are customized according to customer needs.

R2. The inconstancy of production results of certain machines whose settings move during operation... (which is common!), and also where raw material quality changes during production (which is also common!) generates major issues in S.P.C. methods and is this inconstancy problem is the heart of Six Sigma.

The arithmetic average of the defects is named in the Six Sigma methodology "Defects Per Unit (D.P.U.)" and is defined by:

$$\text{DPU}=\frac{\text{\# of defects in sample}}{\text{\# of units in sample}}=\frac{D}{N} \tag{16.7.5}$$

And this will give with our small example above:

$$\text{DPU}=\frac{1+0+2}{3}=\frac{3}{3}=1 \tag{16.7.6}$$

which means that on average each product has a design or manufacturing defect.

Many quality softwares also reports the cumulative DPU over a population of sample and obviously defined for a period j by:

$$\text{Cumulative DPU}_j=\frac{\sum_{i=1}^{j} D_i}{\sum_{i=1}^{j} N_i} \tag{16.7.7}$$

Remark

Warning! This value is not a probability for the simple reasons that it may initially be higher than 1 and that it has the dimension of [defects]/[products].

Similarly, the analysis can be done with the total number of possible defective elements that make up the product so that we are led naturally to define following the Six Sigma methodology the "Defects per Unit Opportunity (D.P.O.)":

$$\text{DPO}=\frac{\text{DPU}}{\text{\# of potential defects in a unit}} \tag{16.7.8}$$

And this will give with our small example:

$$\text{DPO}=\frac{\text{DPU}}{m}=\frac{1}{8}=0.125 \tag{16.7.9}$$

and this can be seen as the probability of a default product element since it is a dimensionless value and the value is always less than or equal 1:

$$\text{DPO}=\frac{\text{DPU}}{m}=\frac{\left[\dfrac{\text{defaults}}{\text{unit}}\right]}{\text{total potential}\left[\dfrac{\text{defaults}}{\text{unit}}\right]} \tag{16.7.10}$$

By extension, we can argue that 87.5% of the components of a unit does not have defects and because Six Sigma enjoys working with examples of the order of a million (it's more awesome...) we then define the "Defects per Million Opportunities (D.P.M.O.)" as:

$$\text{DPMO}=\text{DPO}\cdot 1,000,000=\frac{\text{DPU}}{m}\cdot 10^6 \tag{16.7.11}$$

And this will give with our small example:

$$\text{DPMO}=\frac{\text{DPU}}{m}\cdot 10^6=\frac{1}{8}\cdot 10^6=125,000 \tag{16.7.12}$$

To summarize:

$$\boxed{\begin{aligned}\text{DPMO}&=\frac{\text{\# of defects in sample}}{\text{\# of units in sample}\cdot\text{\# of potential defects in a unit}}\cdot 10^6\\&=\frac{\text{DPU}}{\text{\# of potential defects in a unit}}\cdot 10^6=\text{DPO}\cdot 10^6\end{aligned}} \tag{16.7.13}$$

As D_i is the probability that an element i is not defective is 87.5% (that is to say 12.5% of scrap) then, by the axiom of joint probabilities (see section Probabilities page 480), the probability that a product as a whole is not defective if all elements are serial is:

$$P\left(\bigcap_{i=1}^{8} D_i\right)=\prod_{i=1}^{8}(1-\text{DPO})=(1-\text{DPO})^8=0.875^8\cong 0.3436=34.36\% \tag{16.7.14}$$

This is not good...

In Six Sigma, the joint probabilities are also naturally used to calculate the joint probability of non-defective products in a production process connected in series or to calculate the defect probability of an administrative serial workflow. This joint probability is named in Six Sigma the "Rolled throughput Yield (R.T.Y.)" and is denoted by:

$$\boxed{P\left(\bigcap_{i} P_i\right)=\prod_{i} P_i} \tag{16.7.15}$$

✍**Example:**

Consider the following serial process/workflow or production line with its given yields (non-default rates):

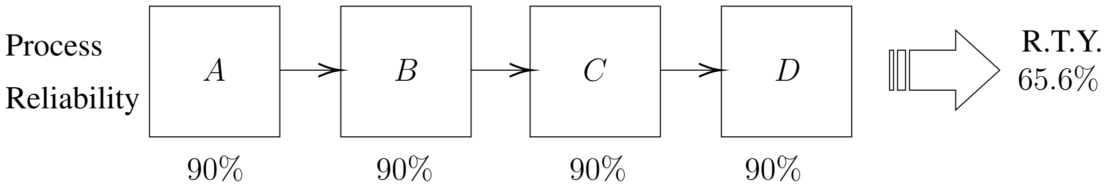

Figure 16.196: Serial process/workflow

We find ourselves in final with a 65.6% reliability that is to say a cumulative probability of default for the entire process/workflow of 34.4% (you can also imagine that these are four tasks in sequence of a project!).

Remark

The reader that is attentive will have noticed that the serial system is always less reliable than its least reliable component!!

This type of calculation is widely used by supply chain manager and the result is named "availability rate" as well as by project managers for the duration of a phase of a project when they consider durations as independent tasks (for more complex structures, remember that we sometimes talk about "weighted probability trees" or "topological systems").

Thus, in an industrial production line based on the previous example to have a well-defined amount Q of products (supposed to use only one component of each stage) at the end of the production line, it will be necessary at the step A to bring:

$$A=\frac{Q}{\text{RTY}}=\frac{Q}{\prod\limits_i P_i}=\frac{Q}{65.6\%}=152.42\% \qquad (16.7.16)$$

That is to say 52.42% of components of type A more than expected. At stage B:

$$B=\frac{Q}{\text{RTY}}=\frac{Q}{\prod\limits_i^{n-1} P_i}=\frac{Q}{0.9\cdot 0.9\cdot 0.9}=\frac{Q}{72.9\%}=137.17\% \qquad (16.7.17)$$

Recall now that the probability density of having k times the event p and $N-k$ times the event q in any arrangement (or order) is given by (see section Statistics page 658):

$$P(n,k)=C_k^n P=\frac{n!}{k!(n-k)!}p^k q^{n-k} \qquad (16.7.18)$$

and is nothing less than the binomial law whose expected mean and standard deviation are (see section Statistics page 658):

$$\mu=np \qquad \sigma=\sqrt{npq} \qquad (16.7.19)$$

Thus, in the Six Sigma methodology, we would apply the binomial distribution (to make things simple because in facts we should use the Hypergeometric law for small samples) to determine what is the probability of having zero defective items and 8 others working well on a product of the production line of our example (if all elements have the same probability to fail for sure...):

$$P(8,0)=\frac{8!}{0!(8-0)!}0.125^0 0.875^8=1\cdot 0.875^8\cong 0.3436=34.36\% \tag{16.7.20}$$

and we obviously fall back on the value obtained with the joint probabilities:

$$\begin{aligned}\mu&=8\cdot 0.125=1=\text{DPU}\\ \sigma&=\sqrt{8\cdot 0.125\cdot 0.875}=0.935\end{aligned} \tag{16.7.21}$$

Or the probability to have one defective item and seven working others on a product of the production line:

$$P(8,1)=\frac{8!}{1!(8-1)!}0.125^1 0.875^7=\frac{8!}{1!7!}0.125^1 0.875^7\cong 0.3926=39.26\% \tag{16.7.22}$$

we see that the binomial distribution gives us 39.26% probability to have one defective item on 8 in a product.

Moreover, in the section of Statistics, we have shown that when the probability p is very small and tends to zero but however the average value $n\cdot p$ tends to a fixed value when n approaches infinity, the binomial law of average $\mu=np$ with k trials was then given by a Poisson law:

$$P_k=P(X=k)=p(k)=\frac{\mu^k}{k!}e^{-\mu} \tag{16.7.23}$$

with (see section Statistics page 686):

$$\mu=np \qquad \sigma=\sqrt{\mu} \tag{16.7.24}$$

Remark

In a practical context, it is made use of the maximum likelihood estimators of the exponential law to determine the mean and standard deviation above (see section Statistics page 825).

What in Six Sigma methodology is naturally written:

$$p(k)=\frac{\text{DPU}^k}{k!}e^{-\text{DPU}} \tag{16.7.25}$$

with:

$$\mu=\text{DPU} \qquad \sigma=\sqrt{\text{DPU}} \tag{16.7.26}$$

Thus, in our example, it is interesting to see the value obtained (which will necessarily be different since we are far from having an infinity of individuals and p is far from being small):

$$p(k)=\frac{\mu^k}{k!}e^{-\mu}=\frac{np^k}{k!}e^{-np}=\frac{np^0}{0!}e^{-0.125\cdot 8}=\frac{1}{1}e^{-1}\cong 36.97\% \tag{16.7.27}$$

with:

$$\mu = 1 \qquad \sigma = 1 \tag{16.7.28}$$

that is a result even worst than with the binomial law for our products.

However, if p is fixed and small, the average $\mu = np$ also tends to infinity in theory with the Binomial Law, moreover the standard deviation $\sigma = \sqrt{npq}$ also tends to infinity.

If we want to calculate the limit of the binomial distribution, we will therefore need to make a change of origin which stabilizes the average at 0 for example and a change of unit that stabilizes the standard deviation for example to 1. This calculation has already been done in the Statistics section (see page 692), we know that the result is the Normal distribution:

$$P(k) = \frac{1}{\sigma\sqrt{2\pi}} e^{\frac{(k-\mu)^2}{2\sigma^2}} \tag{16.7.29}$$

For our example we know we have to take $k = 0, \sigma = 0, \mu = 0$:

$$P(0) = \frac{1}{1 \cdot \sqrt{2\pi}} e^{\frac{(0-1)^2}{2 \cdot 1^2}} = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}} \cong 24.19\% \tag{16.7.30}$$

Thus, applying the Normal distribution, we have 24.19% chance to sample the first time a defective product. This difference compared to other methods is simply explained by the assumptions (finite number of individuals, significant probability of defect, etc.).

16.7.1.3 Capability Indices

The Six Sigma methodology (and also the series of norms ISO 22514) defines several indexes that permits to quantify during the manufacturing process the capability of control in the case of a large amount of defects measures distributed as Gaussian-Laplace law (Normal law).

In the case where the measures do not follow a Normal law we have therefore to transform the data using various empirical techniques (Johnson transformations typically that Minitab and `R` can easily manage) or Kernel Smoothing techniques (see section Statistics page 1143) that softwares like SAS JMP can easily manage.

Basically, if we imagine ourselves working in a company, in charge of the manufacturing quality of a new machine of a new series of pieces, we will be faced with two major situations:

1. At the beginning of production, there may be big quality differences due to defects in the machine or poorly initialization of important settings of the machine. These are defects that will often be rapidly corrected (on the short-term) thanks to a systematic control (destructive or not) of small samples.
2. Once the big anomalies corrected, we will have in theory only minimal issues that will be very difficult to control and even on the long term. Therefore systematic control is not necessary anymore and once this period of large corrections passed, we make checks per batch (between each correction) and each will be considered an independent and identically distributed random variable (according to a Normal law), but obviously with a different average and standard deviation.

These two scenarios show that we do not then logically perform the same tests at the beginning of the production and then on the long term. This is why we define in S.P.C. several indices (whose symbols are unique to this textbook because they change according the used standards) whose two most important are:

D1. We name "short-term process potential capability" or "short-term dispersion index" the ratio of the range of control E of the distribution of values tolerated by the customer and the Six Sigma quality (6σ) when the process is almost under control as:

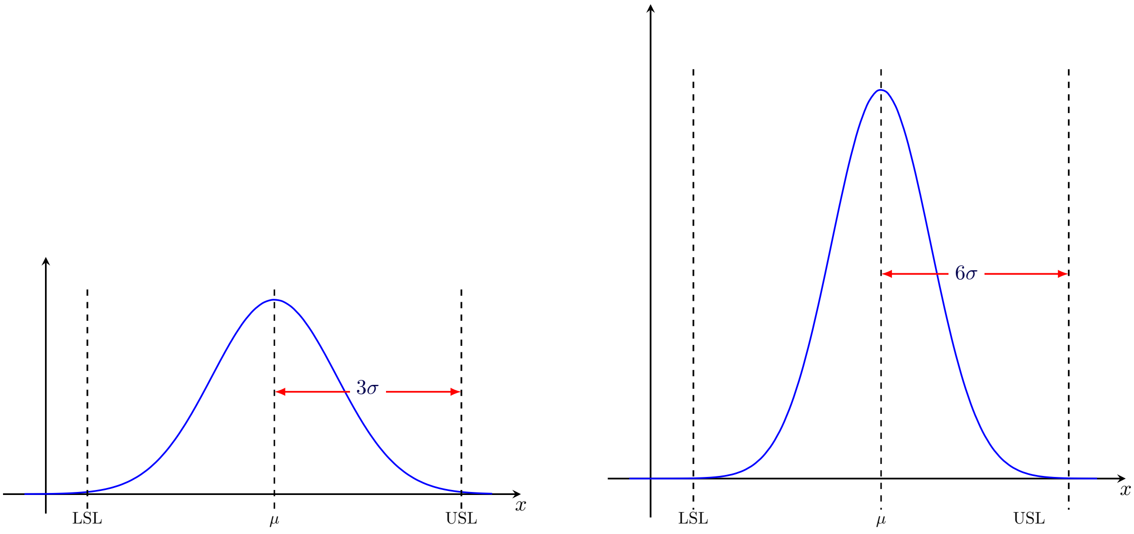
$$\boxed{C_p=\frac{E}{6\sigma}=\frac{\text{USL}-\text{LSL}}{6\sigma_{\text{ST}}}} \qquad (16.7.31)$$

More generally given by:

$$C_p=\frac{E}{6\sigma}=\frac{\text{USL}-\text{LSL}}{L\sigma_{\text{ST}}} \qquad (16.7.32)$$

Where USL is the "Upper Specification Level" of the distribution and LSL the "Lower Specification Level" that we often impose (but not always!) in the industry as at equal distances to the desired theoretical mean μ. The term L (often equal to 6 in the Six Sigma methodology) is named the "study variation".

Normally within manufactures, the range of control is fixed (the numerator) and so when the value of the standard deviation is large (more variations, not enough controls) the value of the index is low and when the standard deviation is low (less variation, lot of controls) the value of the index is high as shown by the two examples below:



(a) $C_p=1$ (b) $C_p=2$

Figure 16.197: **Illustration of C_p index**

The above capability is therefore an indication that we will seek to maximize (since the standard deviation in the denominator should be minimized!).

This ratio is useful in the industry in the sense that the range E (which is important because it represents the tolerated dispersion/process variation) is considered as the "voice of the customer" (his request) and the 6 sigma denominator the actual behaviour of the process/process meant to include virtually all possible outcomes. It is better to hope that this report is at worst equal to unity!

Here is a typical example in project management where, when the customer does not pay for a fine tuning risk modelling (the customer therefore accepts by contract a change in time and costs that can exceed 50%), we come across with this type of chart:

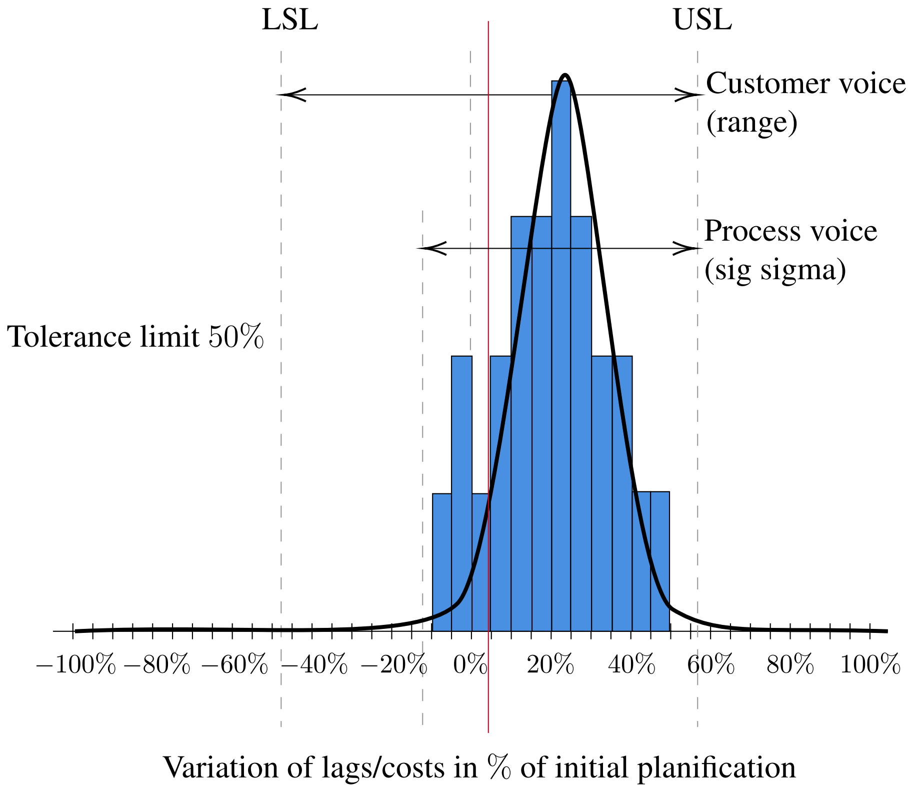


Figure 16.198: **Typical plot of a control histogram with tolerances and limits**

Remark

In S.P.C., the range E is sometimes denoted TI, meaning "tolerance interval" (but this is wrong... instead it should be named "fluctuation interval").

The standard deviation in the denominator is simply defined as the average of the variances in the case of k independent random variables:

$$\boxed{\sigma_{\text{ST}}=\sqrt{\frac{\displaystyle\sum_{i=1}^{k}\sigma_i^2}{k}}} \tag{16.7.33}$$

where it is useful perhaps to remember that ST is the abbreviation for "Short Term" (abbreviation often unspecified in the practice as assumed known in the context). The standard deviations σ_{ST} is obviously the easiest to apply for the first scenario which we have mentioned above. Because between each big correction, batches are considered independent and can not be analysed as a single lot (it would be an aberration!).

Remark

According to the type of industry some use the standard deviation based on the range for σ_{ST} and that is given as we proved it in the section Statistics during our study of extreme values by the ratio of the average of ranges of all measurements made by different operators and divided by the Hartley's constant such that:

$$\sigma_{\text{ST}}=\frac{\bar{R}}{d_2(k)} \tag{16.7.34}$$

Be careful! As it is often the situation in short term processes (during the correction of the big sources of error), tested batches are small - even very small - and this in the purpose to reduce costs. Then the standard deviation below the root is for sure not really a correct value... This is why it is important to calculate a confidence interval! So let us see that it is possible to easily construct a hypothesis test for the C_p indicator under the assumption that each sample is identically distributed following a Normal law. Indeed, remembering that we proved in the section Statistics (see page 863) that:

$$\frac{(n-1)S^2}{\chi^2_{\alpha/2,n-1}}\leq\sigma^2\leq\frac{(n-1)S^2}{\chi^2_{1-\alpha/2,n-1}} \tag{16.7.35}$$

It is immediate that:

$$\frac{\chi^2_{1-\alpha/2,n-1}}{(n-1)S^2}\leq\frac{1}{\sigma^2}\leq\frac{\chi^2_{\alpha/2,n-1}}{(n-1)S^2} \tag{16.7.36}$$

Thus:

$$\frac{1}{S}\sqrt{\frac{\chi^2_{1-\alpha/2,n-1}}{n-1}}\leq\frac{1}{\sigma}\leq\frac{1}{S}\sqrt{\frac{\chi^2_{\alpha/2,n-1}}{n-1}} \tag{16.7.37}$$

Therefore:

$$\frac{E}{\hat{\sigma}_{\text{ST}}}\sqrt{\frac{\chi^2_{1-\alpha/2,n-1}}{n-1}}\leq\frac{E}{\sigma_{\text{ST}}}\leq\frac{E}{\hat{\sigma}_{\text{ST}}}\sqrt{\frac{\chi^2_{\alpha/2,n-1}}{n-1}} \tag{16.7.38}$$

or:

$$\boxed{\hat{C}_p\sqrt{\frac{\chi^2_{1-\alpha/2,n-1}}{n-1}}\leq C_p\leq\hat{C}_p\sqrt{\frac{\chi^2_{\alpha/2,n-1}}{n-1}}} \tag{16.7.39}$$

and we can apply the same reasoning for all types of indicators of the same kind that we will see later!

Remark

As part of our study later of control charts, we will see that it is possible to use special expressions for the standard deviation when working with samples of measures. These expressions will be based for one on the chi-square law and the other on order statistics.

D2. We name "Overall performance of long-term process" the ratio of the range of control E of the distribution of values tolerated by the customer and the Six Sigma quality (6σ) when the process is centered that is to say under statistical control (product manufacturing parameters vary only a little bit) as:

$$\boxed{P_p=\frac{E}{6\sigma}=\frac{\text{USL}-\text{LSL}}{6\sigma_{\text{LT}}}} \tag{16.7.40}$$

But where the standard deviation in the denominator is given this time by the fact we consider all the big issues corrected and the process as stable such that we can consider all manufactured pieces in the long term as a single controlled batch:

$$\boxed{\sigma_{\text{LT}}=\sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(x_i-\overline{x})^2}} \tag{16.7.41}$$

where it is useful perhaps to remember that LT is the abbreviation for "Long Term" (abbreviation often unspecified in the practice as assumed known in the context). This standard deviation is obviously the simplest for the second scenario which we have mentioned above. Because the variations are now, by hypothesis, very small, the entire production can be assumed as a single lot of control over the long term (this does not avoid that sometimes it is necessary to clean the extreme values that may occur).

Tolerancing the characteristics is therefore important for obtaining the desired quality and reliability of assembled products. Traditionally, a tolerance is expressed in the form of a bi-point $[\text{Min},\text{Max}]$. A characteristics is then accepted as conform if it is within tolerance.

The problem of the art of tolerancing is to try to conciliate the fixation of the acceptable variability limits to reduce production costs and ensure the highest level of quality in the finished assembled product.

Two approaches attempt to solve this problem:

1. "Worst Tolerancing" ensures the assembly in all situations from the time the basic characteristics are within tolerance. This is the far the best method when the production is very small (and in the extreme case when there is only one unit...).

2. "Statistical Tolerancing" takes into account the low probability of extreme assemblies and enables to significantly expand the tolerances to reduce costs and so it is to this that we will look further below. For sure this can be apply only for large production sets.

A process is said to "limit capable" if the ratios C_p, P_p given above (choosing six times the standard deviation) is almost equal to 1. But in the industry, we actually prefer to take the value 1.33 in the case of a Normal distribution that is not perfectly centered (we will see later where this last value comes from).

Obviously, the value of the standard deviation σ can be calculated by using the maximum likelihood estimators with and without bias seen in the Statistics (see page 822) and in practice you must never forget that this is just an estimator and not the real theoretical value! Furthermore, we will see later that depending on the standard deviation used, the notations change!

Remark

In manufacture, one must be careful because the measuring instrument adds its own standard deviation (error) on these of the production process.

As we have proved it in the section on Statistics (see page 611), the standard error (standard deviation of the mean) is:

$$\sigma_{\overline{X}}=\frac{\sigma}{\sqrt{n}} \tag{16.7.42}$$

In the Six Sigma methodology, we then often have for long term process and under statistical control:

$$\boxed{\begin{aligned}\text{LCL}&=\mu-3\frac{\sigma}{\sqrt{n}}\\ \text{UCL}&=\mu+3\frac{\sigma}{\sqrt{n}}\end{aligned}} \tag{16.7.43}$$

when we analyse control charts (see further below at page 8934) whose random variables is a sample of n independent and identically Normally distributed random variables and that the limits were not imposed by a customer or an internal policy or technical constraints! Obviously, we must be aware that UCL and LCL are not the same mathematical expression in more complex cases and therefore for distributions other than the Normal distribution!

Remark

Keep in mind that UCL is the "Upper Control Limit" and LCL "Lower Control Limit" and that at the opposite of the USL (Upper Specification Limit) and LSL (Lower Specification Limit) their are calculated by more or less complex mathematical relations.

Instead of specification limits, a process may have "boundaries". The difference is that when there are boundaries we assume that it is not possible for data to exceed the specification limits and therefore the C_p (among others) has no sense to be calculated (some softwares - like Minitab - ask the user if he wants change his specification limits as boundaries for example...).

Furthermore, the above expression differs for short-term process because the example given above is for a case of measures over the long term for reminder!

As we know C_p requires that the average (target) is centered between USL and LSL. Therefore, the average is confounded with what we name the "target T" of the process.

But the average μ in reality can be offset from the original target T which must always (in common use) be equidistant between USL and LSL as shown in the figure below in the special case a Normal distribution:

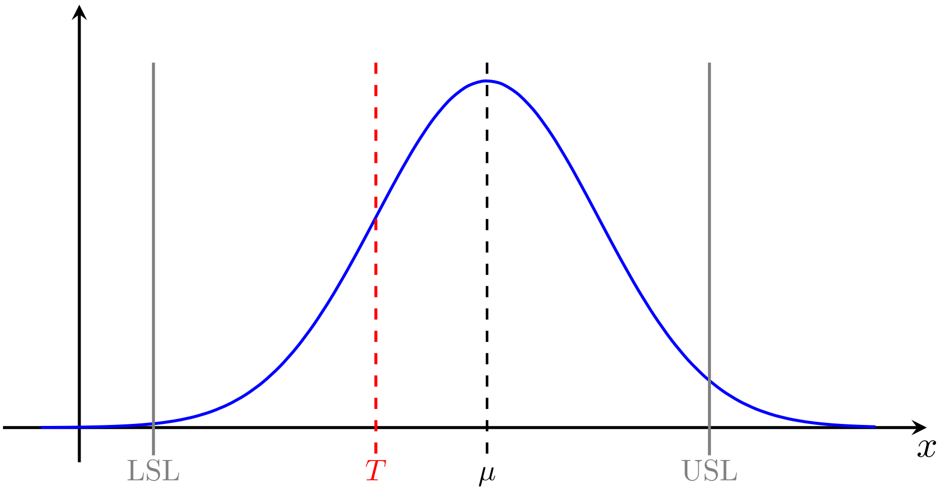

Figure 16.199: Measures under statistical control offset from the target (typical with index C_p)

But this is not necessarily the case in reality where engineers (whatever their application field) can choose asymmetrical LSL and USL with respect to the average and this only because the distribution is not always following a Normal law (typically the case in project management...)! Hence the following definition:

Definition (#16.7.731): We name "short term non-centered potential Capability for the process" (in the biased case) or more frequently "Process Capability Index (Within)" the relation:

$$\boxed{C_{pk}=C_p(1-k)} \tag{16.7.44}$$

with (in the special case of a 6σ process):

$$k=\frac{|T-\mu|}{\dfrac{1}{2}(\text{USL}-\text{LSL})}=\frac{|T-\mu|}{3\sigma C_p} \tag{16.7.45}$$

where $k\geq 0$ is named the "degree of bias" or "index position" and T is as we know the "target" naturally given most of the time (so not always!) by:

$$T=\frac{\text{USL}-\text{LSL}}{2} \tag{16.7.46}$$

which gives the middle of the distribution relative to the bi-point $[\text{LSL},\text{USL}]$ requested by the customer (remember that the standard deviation in the denominator of the prior-previous relation is the standard deviation short term!).

In fact this control capability indicator C_{pk} may seem very artificial, but it is not completely... Indeed, there are some outstanding values (those that interest the engineer) that can help to get a good idea of what happens with it:

1. If the average and the target are confused, then we have:

   $$T=\mu \tag{16.7.47}$$

   We find ourselves with $k=0$ and therefore $C_{pk}=C_p$ and judgement criterion of the value of the index will then be based on the short-term capability index.

2. If because of a poor control of the process we have:

$$|T-\mu|>0.5(\text{USL}-\text{LSL}) \tag{16.7.48}$$

Then the mean μ is either above USL or below LSL which has the consequence of having $k>1$ and therefore $C_{pk}<0$.

3. If we have:

$$0<|T-\mu|<0.5(\text{USL}-\text{LSL}) \tag{16.7.49}$$

Then the average μ is between the values USL and LSL which has the consequence of having $0<k<1$ and therefore $0<C_{pk}<C_p$.

4. If we have:

$$|T-\mu|=0.5(\text{USL}-\text{LSL}) \tag{16.7.50}$$

Then it simply means that the average is aligned with USL or LSL and we therefore have $k=1$ and $C_{pk}=0$. As the interpretation remains sometimes delicate and difficult, we build unilateral capability indices "Upper Capability Index CPU" and "Lower Capability Index CPL" given by:

$$\boxed{\text{CPU}=\frac{\text{USL}-\mu}{3\sigma}\qquad \text{CPL}=\frac{\mu-\text{LSL}}{3\sigma}} \tag{16.7.51}$$

That we will obviously also seek to maximize. Let's see where these two definitions comes from and how to use them:

Proof 16.2.2. First, we need two specific formulations of the degree of bias k.

(a) If:

$$\frac{\text{USL}+\text{LSL}}{2}<\mu \tag{16.7.52}$$

then we can get rid of the absolute value:

$$\begin{aligned}k&=\frac{|T-\mu|}{\frac{1}{2}(\text{USL}-\text{LSL})}=\frac{\left|\frac{\text{USL}+\text{LSL}}{2}-\mu\right|}{\frac{1}{2}(\text{USL}-\text{LSL})}=\frac{\mu-\frac{\text{USL}+\text{LSL}}{2}}{\frac{1}{2}(\text{USL}-\text{LSL})}\\&=\frac{2\mu}{\text{USL}-\text{LSL}}-\frac{\text{USL}+\text{LSL}}{\text{USL}-\text{LSL}}\end{aligned} \tag{16.7.53}$$

(b) If:

$$\frac{\text{USL}+\text{LSL}}{2}>\mu \tag{16.7.54}$$

then we can get rid of the absolute value:

$$\begin{aligned}k&=\frac{|T-\mu|}{\frac{1}{2}(\text{USL}-\text{LSL})}=\frac{\left|\frac{\text{USL}+\text{LSL}}{2}-\mu\right|}{\frac{1}{2}(\text{USL}-\text{LSL})}=\frac{\frac{\text{USL}+\text{LSL}}{2}-\mu}{\frac{1}{2}(\text{USL}-\text{LSL})}\\&=\frac{\text{USL}+\text{LSL}}{\text{USL}-\text{LSL}}-\frac{2\mu}{\text{USL}-\text{LSL}}\end{aligned} \tag{16.7.55}$$

We have therefore when $T > \mu$:

$$\begin{aligned}C_p(1-k) &= C_p\left[1-\left(\frac{\text{USL}+\text{LSL}}{\text{USL}-\text{LSL}}-\frac{2\mu}{\text{USL}-\text{LSL}}\right)\right]\\ &= \frac{\text{USL}-\text{LSL}}{6\sigma}\left[1-\left(\frac{\text{USL}+\text{LSL}}{\text{USL}-\text{LSL}}-\frac{2\mu}{\text{USL}-\text{LSL}}\right)\right]\\ &= \frac{\text{USL}-\text{LSL}}{6\sigma}-\frac{\text{USL}+\text{LSL}}{6\sigma}+\frac{2\mu}{6\sigma}=\frac{-\text{LSL}+\mu}{3\sigma}\\ &= \frac{\mu-\text{LSL}}{3\sigma}:=\frac{1}{3}Z_{ll}\end{aligned} \tag{16.7.56}$$

and when $T < \mu$:

$$\begin{aligned}C_p(1-k) &= C_p\left[1-\left(\frac{2\mu}{\text{USL}-\text{LSL}}-\frac{\text{USL}+\text{LSL}}{\text{USL}-\text{LSL}}\right)\right]\\ &= \frac{\text{USL}-\text{LSL}}{6\sigma}\left[1-\left(\frac{2\mu}{\text{USL}-\text{LSL}}-\frac{\text{USL}+\text{LSL}}{\text{USL}-\text{LSL}}\right)\right]\\ &= \frac{\text{USL}-\text{LSL}}{6\sigma}-\frac{2\mu}{6\sigma}+\frac{\text{USL}+\text{LSL}}{6\sigma}=\frac{\text{USL}-\mu}{3\sigma}:=\frac{1}{3}Z_{ul}\end{aligned} \tag{16.7.57}$$

■ Q.E.D.

In the long term, in some companies (firms), it is interesting to know what are the worst values taken by the CPU indices and CPL (this is the case in the field of production but not necessarily in project management).

The worst values being by construction the smallest one, we often write (with a few different notations that can be found in the literature ...):

$$C_{pk}=\min\{\text{CPU},\text{CPL}\}=\min\{C_{pu},C_{pl}\}=\min\left\{\frac{1}{3}Z_{ul},\frac{1}{3}Z_{ll}\right\} \tag{16.7.58}$$

Below an example of an analysis diagram of the capability generated by the software Minitab 15.1.1 Software with the various aforementioned factors on a sample of 68 measures that can not be rejected as not following a Normal distribution (a normality test was done before):

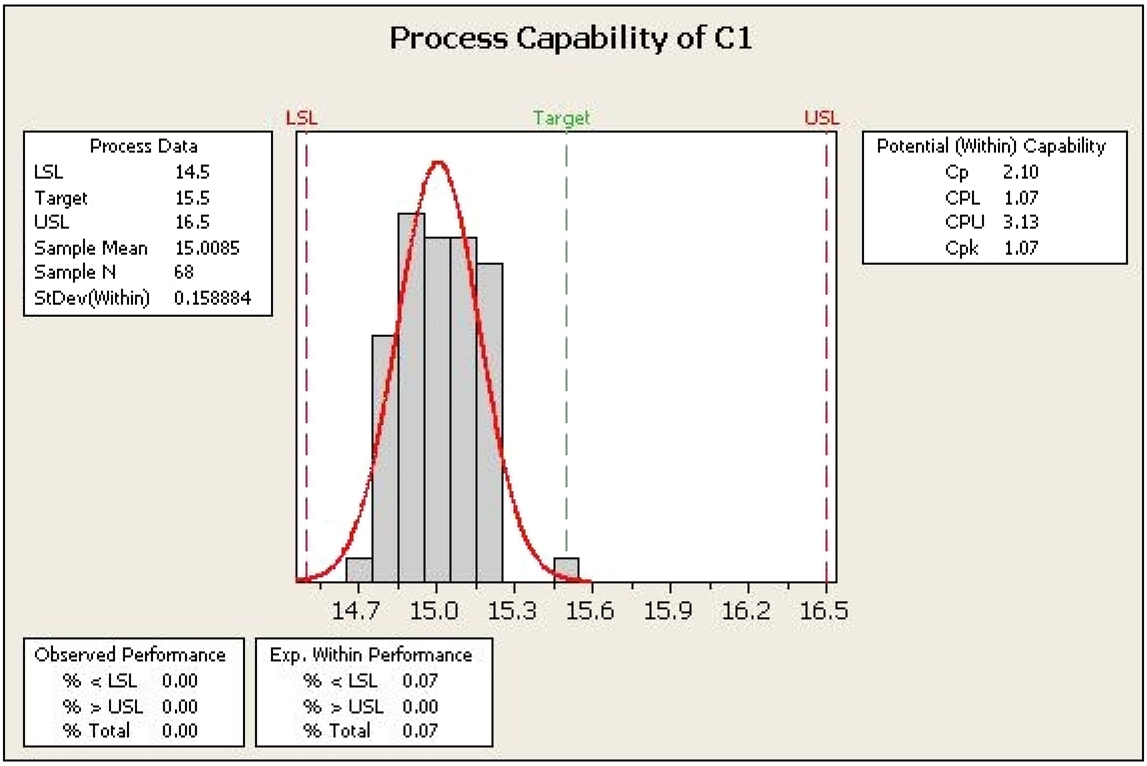

Figure 16.200: **Capability diagram generated with Minitab 15.1.1**

Two typical readings of this chart are possible (we will explain the lower left part of the chart later):

1. In manufacturing: The process is capable (value >1.33) but with a (too) strong deviation to the left in relation to the defined target, which is not good (CPL having the smallest value) and must be corrected.
2. In Project Management: Redundant tasks are under control (value>1.33) but with a strong deviation to the left, which can be good if our goal is to get ahead compared to planning (nothing to correct).

We really have to take care of the fact that in reality it is not always possible to take the Normal distribution (we recall this because all the examples given above and below are based on this simplifying assumption!)!

Always in the context of quality management in manufacturing, the figure below represents well the reality in the context of a short or long-term process:

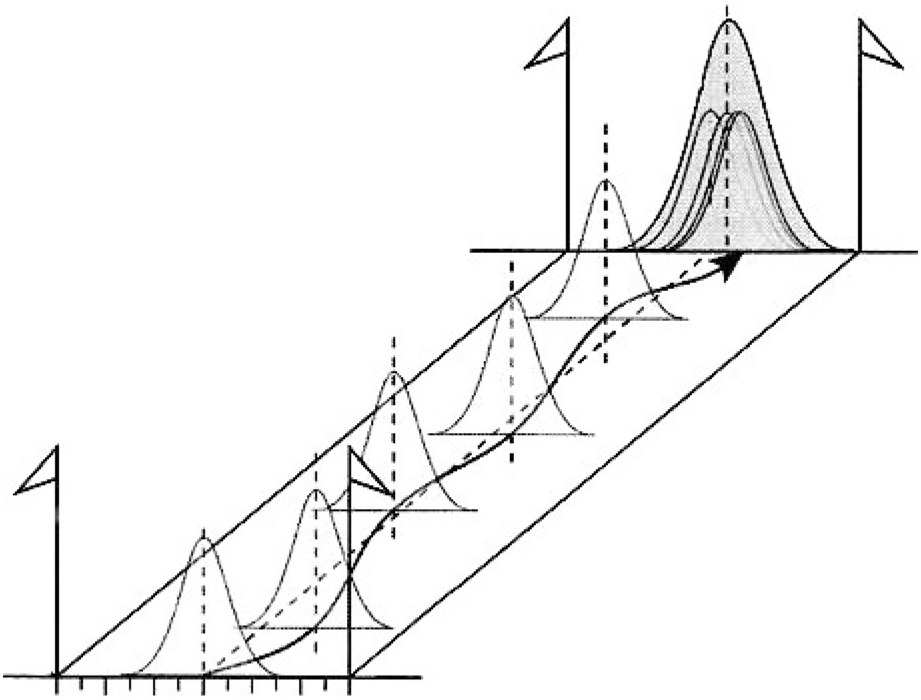

Figure 16.201: **Short/Long term process (source: Maurice Pillet ISBN13: 978-2708133495)**

Every little Gaussian in light gray, represents a batch analysis assimilated to the concept of "instantaneous dispersion". We see that their average don't keep moving during the measurement period (that this variation is large or very small) and that's what we name the "global dispersion". The goal in organizations (industries or administrations) is to ensure that the instantaneous or global variability is limited as much as possible.

But the relation defining C_p assumed, as we mentioned, that the process is under control and also centered (so all Gaussian are aligned) and on a short term.

Similarly, the relation defining C_{pk} assumed, as we mentioned it before, the that the process is under control, on a short-term perspective and non-centered by choice (or because of the fact that the law is not Normal).

If the process is not centered because it is not under control when it should be, the random variable measured could be the sum of the small random behaviour of the machine X and uncontrollable small random variations of constraint measurement of the pieces Y.

The total standard deviation is then, if the two random variables follow a Normal distribution (and that they are independent!), the square root of the sum of deviations (see section Statistics page 709):

$$\sigma=\sqrt{\sigma_X^2+\sigma_Y^2}=\sqrt{\sigma_{\text{ST}}^2+\sigma_Y^2} \tag{16.7.59}$$

Now if we only have one measure, we get taking the unbiased estimator (it's a little bit stupid to use it in this case but...):

$$\sigma_Y^2=\frac{1}{n}(Y-\mu_Y)^2=(Y-\mu_Y)^2 \tag{16.7.60}$$

But in the case of study that interests Y represents the experimental mean (measured) of the process we are trying to bring under control (this is also why we can put $n=1$). This average is traditionally denoted m in the field of industrial engineering.

Then μ_Y being not known we take what it should be: that is the target T in the process. Thus, we introduce a new index named "short term non-centered biased process potential capability":

$$\boxed{C_{pm}=\frac{\text{USL}-\text{LSL}}{6\sigma}\cong\frac{\text{USL}-\text{LSL}}{6\sqrt{\sigma^2+(m-T)^2}}} \tag{16.7.61}$$

where once again it must be remembered that the standard deviation in the denominator inside the root is the short term standard deviation of the machine!

We then see immediately that the more C_{pm} is close to C_p, the better it is (at least in manufacturing field)!

We finally have three common centered and non-centered short term capabilities indices (we deliberately chose to standardize the notations and put as much information inside the relations below):

$$\boxed{C_p=\frac{\text{USL}-\text{LSL}}{\sigma_{\text{ST}}}\qquad C_{pk}=\left\{\frac{\text{USL}-\mu}{3\sigma_{\text{ST}}},\frac{\mu-\text{LSL}}{3\sigma_{\text{ST}}}\right\}\qquad C_{pm}\cong\frac{\text{USL}-\text{LSL}}{6\sqrt{\sigma_{\text{ST}}^2+(m-T)^2}}} \tag{16.7.62}$$

Similarly we also have three common long-term capabilities indicators centered or non-centered (we deliberately chose to standardize the notations and put as much information inside the relations below):

$$\boxed{P_p=\frac{\text{USL}-\text{LSL}}{\sigma_{\text{LT}}}\qquad P_{pk}=\left\{\frac{\text{USL}-\mu}{3\sigma_{\text{LT}}},\frac{\mu-\text{LSL}}{3\sigma_{\text{LT}}}\right\}\qquad P_{pm}\cong\frac{\text{USL}-\text{LSL}}{6\sqrt{\sigma_{\text{LT}}^2+(m-T)^2}}} \tag{16.7.63}$$

Finally, it is good to know that although if this is not very relevant, sometimes some engineers do both analyses (short term + long-term) at the same time on the same measurements.

Remark

Let us indicate the capabilities of an industrial process methods when applied to machines are denoted respectively by C_m, C_{mk}, C_{mm}. Anyway ... for more information (but without proofs) refer to the standard ISO 22514-2:2013 or the old version ISO 21747:2006.

However, to make an objective analysis on the indexes of capability seen so far, the practitioner would first have to check measuring instruments are themselves capable... what we often name the "R&R methods" (Repeatability, Reproducibility).

The basic principle (a little bit more advanced principle is to make use of the two-factor ANOVA with repetition as studied in details in the section of Statistics) is then to evaluate the short term or respectively long term dispersion of the measuring instrument to calculate a "process control capability" defined by:

$$C_{pc}=\frac{E}{6\sigma_{\text{instrument}}} \tag{16.7.64}$$

or according to the type of industry some use the standard deviation based on the range for $\sigma_{\text{instrument}}$ and as we proved it in the section of Statistics during our study of extreme values (see page 1203) and therefore named "Equipment Variation (EV)" consisting in the calculation of the average of ranges of all measurements made by different operators and divide by the Hartley's constant:

$$\text{EV}=\frac{\bar{R}}{d_2(n)} \tag{16.7.65}$$

In the classical cases, we declare the control method as capable for a S.P.C. tracking when its capability is greater than 4 and we will immediately see why.

Recall for this first that:

$$C_p=\frac{E}{6\sigma} \tag{16.7.66}$$

But the variance observed is in fact the sum of the "true" variance and this of the instrument such that:

$$C_{p,\text{observed}}=\frac{E}{6\sigma}=\frac{E}{6\sqrt{\sigma_{\text{true}}^2+\sigma_{\text{instrument}}^2}} \tag{16.7.67}$$

But we have:

$$C_{p,\text{true}}=\frac{E}{6\sigma_{\text{true}}} \qquad C_{pc}=\frac{E}{6\sigma_{\text{instrument}}} \tag{16.7.68}$$

Putting it all squared, we deduce:

$$C_{p,\text{observed}}^2=\frac{E^2}{36(\sigma_{\text{true}}^2+\sigma_{\text{instrument}}^2)}=\frac{E^2}{36\left(\dfrac{E^2}{36C_{p,\text{true}}^2}+\dfrac{E^2}{36C_{pc}^2}\right)} \tag{16.7.69}$$

And now under the strong assumptions that all E are equals we have:

$$C_{p,\text{observed}}^2=\frac{1}{\dfrac{1}{C_{p,\text{true}}^2}+\dfrac{1}{C_{pc}^2}}=\frac{1}{\dfrac{C_{pc}^2+C_{p,\text{true}}^2}{C_{pc}^2C_{p,\text{true}}^2}} \tag{16.7.70}$$

Therefore:

$$C_{p,\text{observed}}^2=\frac{C_{pc}^2C_{p,\text{true}}^2}{C_{pc}^2+C_{p,\text{true}}^2} \tag{16.7.71}$$

That give us with some rearrangements:

$$C_{p,\text{observed}}^2(C_{pc}^2+C_{p,\text{true}}^2)=C_{pc}^2C_{p,\text{true}}^2 \Leftrightarrow C_{p,\text{observed}}^2C_{pc}^2=C_{p,\text{true}}^2(C_{pc}^2-C_{p,\text{observed}}^2) \tag{16.7.72}$$

Finally:

$$C_{p,\text{true}}=\frac{C_{p,\text{observed}}C_{pc}}{\sqrt{C_{pc}^2-C_{p,\text{observed}}^2}}=\frac{C_{p,\text{observed}}}{\sqrt{1-\dfrac{C_{p,\text{observed}}^2}{C_{pc}^2}}} \tag{16.7.73}$$

This can be translated into a plot in the figure below which shows the interest of a C_{pc} of at least equal to 4!

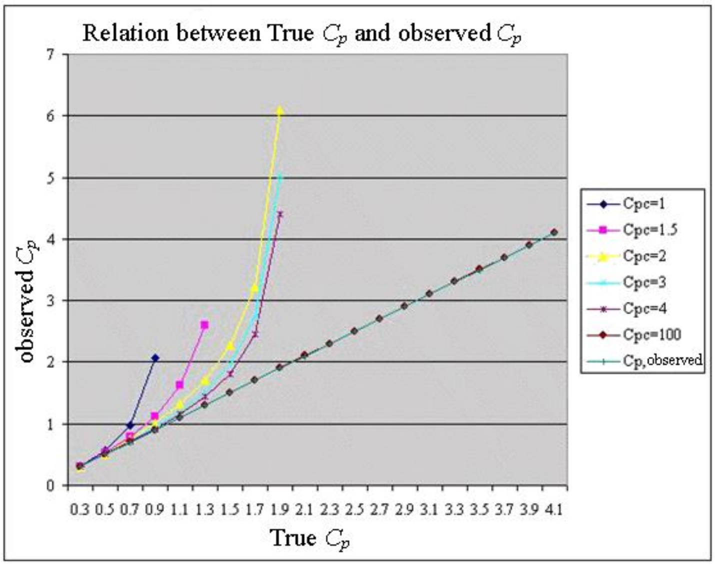

Figure 16.202: **Relations between $C_{p,\text{observed}}$ and $C_{p,\text{true}}$ for fixed C_{pc}**

In practice, note that to determine C_{pc} we use a standard prototype measured by LASER interferometry and then we ensure that all repeated measurement take place on the same two measuring points.

Once this done, we performs several measures of the standard prototype and we take the standard deviation of these measures. This will give the $\sigma_{\text{instrument}}$.

The range E is imposed by the customer or by internal engineers to the company. It will often be taken as maximum to the tenth of the tolerance unit of the standard prototype.

For example, if we have a piece with an internal diameter of $36 \pm 1\,[\mu\text{m}]$ (tolerance range of $2\,[\mu\text{m}]$ which is already a good level precision because in our time the standard is closer to $3\,[\mu\text{m}]$!), our device will then need to have according the rule cited above range of $0.2\,[\mu\text{m}]$...

16.7.1.4 Quality Levels

Some engineers, as we already mention it, like to know how many elements by million units produced (parts per million: PPM) will be considered as defective.

The calculation is then easy since the engineer has at his disposal at least the following information:

$$\mu, \sigma, \text{USL}, \text{LSL}, T \tag{16.7.74}$$

and under the strong assumption that the data follow a Normal distribution and that the target is centered on the mean it is immediate (see section Statistics page 692) in this simple case the for the defective below the LSL we get (for long term or short term):

$$\text{PPM}_{\text{LSL}} = \frac{1}{\sigma\sqrt{2\pi}} \int\limits_{-\infty}^{\text{LSL}} e^{\frac{(x-\mu)^2}{2\sigma}} \mathrm{d}x \cdot 10^6 \tag{16.7.75}$$

and:

$$\text{PPM}^{\text{USL}} = \frac{1}{\sigma\sqrt{2\pi}} \int\limits_{\text{USL}}^{+\infty} e^{\frac{(x-\mu)^2}{2\sigma}} \mathrm{d}x \cdot 10^6 = \left(1 - \frac{1}{\sigma\sqrt{2\pi}} \int\limits_{-\infty}^{\text{USL}} e^{\frac{(x-\mu)^2}{2\sigma}} \mathrm{d}x\right) \cdot 10^6 \tag{16.7.76}$$

values very easy to get with any spreadsheet like Microsoft® Excel® for example. We have therefore obviously:

$$\boxed{\text{PPM}_{\text{tot}} = \text{PPM}_{\text{LSL}} + \text{PPM}^{\text{USL}} = \frac{1}{\sigma\sqrt{2\pi}} \int\limits_{-\infty}^{\text{LSL}} e^{\frac{(x-\mu)^2}{2\sigma}} \mathrm{d}x \cdot 10^6 + \frac{1}{\sigma\sqrt{2\pi}} \int\limits_{\text{USL}}^{+\infty} e^{\frac{(x-\mu)^2}{2\sigma}} \mathrm{d}x \cdot 10^6} \tag{16.7.77}$$

If μ and T are still aligned and that USL and LSL are symmetric to this two values we have the special case:

$$\text{PPM}_{\text{tot}} = \text{PPM}_{\text{LSL}} + \text{PPM}^{\text{USL}} = 2\text{PPM}_{\text{LSL}} = 2\text{PPM}^{\text{USL}} \tag{16.7.78}$$

Note now an important point relatively to Six Sigma! In fact, objectively, the idea of this method is, of course, to make S.P.C. (among others, but that's nothing really new) but especially to: guarantee to the customer according to tradition with a commonly accepted standard deviation having an upper limit of $\sigma = 1$ with an absolute deviation to the mean (in absolute value) of 1.5σ relative to the target, which guarantees at maximum the famous 3.4 PPM (that is to say 3.4 defectives per million).

Remark

This choice seems to come from the empirical practice of Six Sigma by one of its main creator (Bill Smith). It is said that he observed in his business (Motorola) that under statistical control, it was almost always a deviation ranging between 1.2 and 1.8σ of the average for almost all its industrial processes.

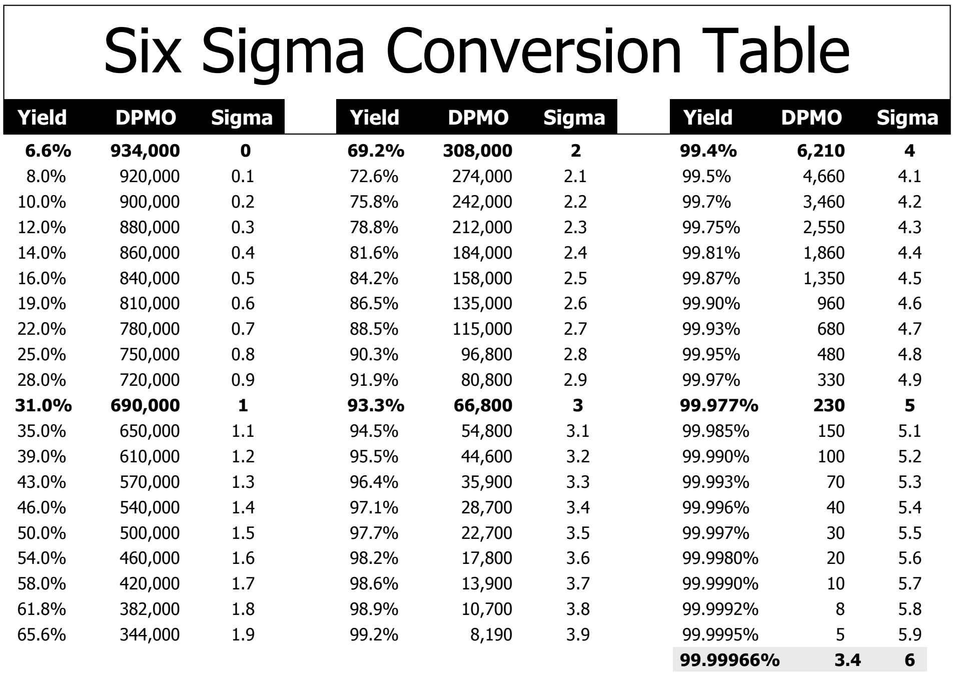
Let's see where this value comes from with the following two tables:

1. First we construct an ideal type of table presenting data from a short-term process (but the calculations are identical for a long-term process) centered on the target (target will be zero here, which is a typical case), with a zero mean (i.e. on target and therefore $C_p = C_{pk}$) and unit standard deviation with USL and LSL symmetrical (which against restricted by the scope of application):

C_p	C_{pk}	**Defectives (PPM)**	**Sigma Quality Level**	**Criteria**
0.5	0.5	133,614	1.5	Bad
0.6	0.6	71,861	1.8	
0.7	0.7	35,729	2.1	
0.8	0.8	16,395	2.4	
0.9	0.9	6,934	2.7	
1	1	2,700	3	
1.1	1.1	967	3.3	
1.2	1.2	318	3.6	
1.3	1.3	96	3.9	Limit
1.4	1.4	27	4.2	
1.5	1.5	6.8	4.5	
1.6	1.6	1.6	4.8	
1.7	1.7	0.34	5.1	
1.8	1.8	0.067	5.4	
1.9	1.9	0.012	5.7	
2	2	0.002	6	Excellent

Table 16.13: Defectives and Sigma quality level of a centered process

where all the values are obtained using the following relations from the potential capability index only. Another way to present the above table is:



Six Sigma Conversion Table

Yield	DPMO	Sigma	Yield	DPMO	Sigma	Yield	DPMO	Sigma
6.6%	**934,000**	**0**	**69.2%**	**308,000**	**2**	**99.4%**	**6,210**	**4**

35.0%	650,000	1.1	94.5%	54,800	3.1	99.985%	150	5.1
39.0%	610,000	1.2	95.5%	44,600	3.2	99.990%	100	5.2
43.0%	570,000	1.3	96.4%	35,900	3.3	99.993%	70	5.3
46.0%	540,000	1.4	97.1%	28,700	3.4	99.996%	40	5.4
50.0%	500,000	1.5	97.7%	22,700	3.5	99.997%	30	5.5
54.0%	460,000	1.6	98.2%	17,800	3.6	99.9980%	20	5.6
58.0%	420,000	1.7	98.6%	13,900	3.7	99.9990%	10	5.7
61.8%	382,000	1.8	98.9%	10,700	3.8	99.9992%	8	5.8
65.6%	344,000	1.9	99.2%	8,190	3.9	99.9995%	5	5.9
						99.99966%	**3.4**	**6**

First (remember the assumption that $T=\mu$ and $\sigma=1$:

$$\begin{aligned}\text{CPU}&=\frac{\text{USL}-(T+\mu)}{3\sigma}=\frac{\text{USL}-(0+0)}{3\sigma}=\frac{\text{USL}}{3\sigma}=\frac{\text{USL}}{3}\\ \text{CPL}&=\frac{(T+\mu)-\text{LSL}}{3\sigma}=\frac{(0+0)-\text{LSL}}{3\sigma}=-\frac{\text{LSL}}{3\sigma}=-\frac{\text{LSL}}{3}\end{aligned}\tag{16.7.79}$$

if the standard deviation is reduced (that can always be done and does not change the accuracy of the results!). And since in the above table LSL and USL are symmetrical with respect to the target:

$$C_{pk}\underset{T=\mu=0}{=}C_p=\min\{\text{CPU},\text{CPL}\}\Rightarrow\text{LSL}=-\text{USL}=-3C_p\tag{16.7.80}$$

and PPM are conforming with what we saw just before given by:

$$\begin{aligned}\text{PPM}_{\text{tot}}&=\text{PPM}_{\text{LSL}}+\text{PPM}^{\text{USL}}\\ &=\left[\frac{1}{\sigma\sqrt{2\pi}}\int\limits_{-\infty}^{\text{LSL}}e^{\frac{(x-\mu)^2}{2\sigma}}\mathrm{d}x+\left(1-\frac{1}{\sigma\sqrt{2\pi}}\int\limits_{-\infty}^{\text{USL}}e^{\frac{(x-\mu)^2}{2\sigma}}\mathrm{d}x\right)\right]10^6\end{aligned}\tag{16.7.81}$$

and therefore as in the example above LSL and USL are symmetric with respect to the target it simplifies to:

$$\text{PPM}_{\text{tot}}=2\left(1-\frac{1}{\sigma\sqrt{2\pi}}\int\limits_{-\infty}^{3C_p}e^{\frac{(x-\mu)^2}{2\sigma}}\mathrm{d}x\right)\cdot10^6\tag{16.7.82}$$

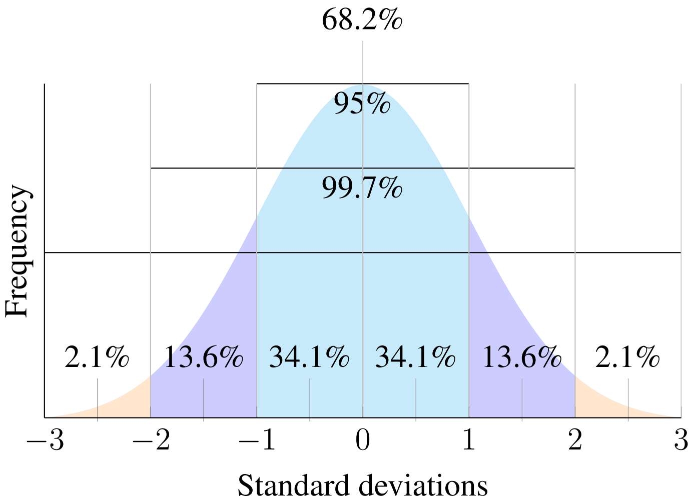
where, for example, the value of PPM given at the line "Limit" is obtained with Maple™ 4.00b using the following command:

```
>evalf((1-1/sqrt(2*Pi)*int(exp(-x^ 2/2),x=-infinity..3.9))*2)*1E6;
```

or with Microsoft® Excel® 11.8346:

```
=(1-NORMDIST(3.9,0,1,1))*1E6
```

Let us recall that the "sigma quality level" denoted by σ_q is given in fact with the following table we had built in the section Statistics under the assumption of a Normal law (thanks to John Cannin for the LaTeX figure):



Sigma Quality Level	Non-defective assured rate in %	Defective in PPM
$1\sigma_q$	68.26894	317,311
$2\sigma_q$	95.4499	45,500
$3\sigma_q$	99.73002	2,700
$4\sigma_q$	99.99366	63.4
$5\sigma_q$	99.999943	0.57
$6\sigma_q$	99.9999998	0.002

Table 16.14: **Capability, non-defective rate in% and PPM**

and for which we had given the Maple™ 4.00b command to obtain the values that are valid for all standard deviations and all means!

2. Now let us build the table at worst as considered by Six Sigma, that is to say a table for non-centered process (that is to say where $C_p = C_{pk}$ is not satisfied) with a deviation of the average of $+1.5\sigma$ (so on the right but could be taken as shifted on left and the results would be exactly the same!) against the target and unit standard deviation with symmetrical USL and LSL (which still restricts the scope of application):

C_p	C_{pk}	Defectives (PPM)	Sigma Quality Level	Criteria
0.5	0	501,350	1.5	Bad
0.6	0.1	382,572	1.8	
0.7	0.2	274,122	2.1	
0.8	0.3	184,108	2.4	
0.9	0.4	115,083	2.7	
1	0.5	66,810	3	
1.1	0.6	35,931	3.3	
1.2	0.7	17,865	3.6	
1.3	0.8	8,198	3.9	Limit
1.4	0.9	3,467	4.2	
1.5	1	1,350	4.5	
1.6	1.1	483	4.8	
1.7	1.2	159	5.1	
1.8	1.3	48	5.4	
1.9	1.4	13	5.7	
2	1.5	3.4	6	Excellent

Table 16.15: **Defectives and Sigma quality level of a non-centered process**

where all the values are obtained using the following relations from the potential capability index only. First (remember the assumption that $T = \mu$ and $\sigma = 1$:

$$\begin{aligned}\text{CPU} &= \frac{\text{USL} - (T + 1.5\sigma)}{3\sigma} = \frac{\text{USL}}{3\sigma} - 0.5 = \frac{\text{USL}}{3} - 0.5 = C_p - 0.5\\ \text{CPL} &= \frac{(T + 1.5\sigma) - \text{LSL}}{3\sigma} = \frac{T - \text{LSL}}{3\sigma} + 0.5 = -\frac{\text{LSL}}{3} + 0.5 = C_p + 0.5\end{aligned} \tag{16.7.83}$$

if the standard deviation is reduced (that can always be done and does not change the accuracy of the results!). And since in the above table LSL and USL are symmetrical with respect to the target:

$$C_{pk}=\min\{\text{CPU},\text{CPL}\}\Rightarrow \text{LSL}=-\text{USL}=C_p-0.5 \tag{16.7.84}$$

Therefore:

$$\begin{aligned}\text{USL}&=3C_p\\ \text{LSL}&=-3(C_p+1)\end{aligned} \tag{16.7.85}$$

and PPM are conforming with what we saw just before given by:

$$\begin{aligned}\text{PPM}_{\text{tot}}&=\frac{1}{\sigma\sqrt{2\pi}}\int\limits_{-\infty}^{\text{LSL}}e^{\frac{(x-\mu)^2}{2\sigma}}\mathrm{d}x\cdot 10^6+\left(1-\frac{1}{\sigma\sqrt{2\pi}}\int\limits_{-\infty}^{\text{USL}}e^{\frac{(x-\mu)^2}{2\sigma}}\mathrm{d}x\right)\cdot 10^6\\ &=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{\text{LSL}}e^{\frac{(x-\mu)^2}{2}}\mathrm{d}x\cdot 10^6+\left(1-\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{\text{USL}}e^{\frac{(x-\mu)^2}{2}}\mathrm{d}x\right)\cdot 10^6\\ &=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{-3(C_p+1)}e^{\frac{(x-1.5\sigma)^2}{2}}\mathrm{d}x\cdot 10^6+\left(1-\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{3C_p}e^{\frac{(x-1.5\sigma)^2}{2}}\mathrm{d}x\right)\cdot 10^6\\ &=\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{-3(C_p+1)}e^{\frac{(x-1.5)^2}{2}}\mathrm{d}x\cdot 10^6+\left(1-\frac{1}{\sqrt{2\pi}}\int\limits_{-\infty}^{3C_p}e^{\frac{(x-1.5)^2}{2}}\mathrm{d}x\right)\cdot 10^6\end{aligned} \tag{16.7.86}$$

where, for example, the value of PPM given at the line "Limit" is obtained with Maple™ 4.00b using the following command:

```
>evalf((1-1/sqrt(2*Pi)*int(exp(-(x-1.5)^ 2/2),x=-infinity..(1.3*3))))*1E6
+evalf((1/sqrt(2*Pi)*int(exp(-(x-1.5)^ 2/2),x=-infinity..-(3*(1.3+1)))))*1E6;
```

or with Microsoft® Excel® 11.8346:

```
=(((1-NORMDIST(3*1.3,1.5,1,1))+NORMDIST(-3*(1.3+1),1.5,1,1)))*1E6
```

We finally understand seeing this famous "limit" row, why a process under control is said to be "limit capable" with a potential capability index of 1.33 potential given the number of PPM!

So the goal in practice is obviously to be in the situation of the first table with the corresponding values and with in the first table at a quality level of $\sim 4.7\sigma$ for the equivalent of 3.4 PPM of the second table (because it is easier to center a process than to control its variations).

✍**Example:**

Let us now make a summary of all this considering a new small production of $n=50$ pieces in packs of $k=n_i=10$ (in order to adjust the machines during production). Measuring the specifications of 5 pieces per hour during 10 hours with a tolerance of 10 ± 0.07 that is to say in terms of a range of hundredths:

$$E=2\cdot 7=14 \tag{16.7.87}$$

and a target of $T=0$. We have the data:

	1	2	3	4	5	6	7	8	9	10
1	-2	-4	-1	0	4	0	3	0	1	-1
2	0	-3	0	-2	1	-2	0	1	-1	2
3	-1	0	-3	-1	0	0	-1	-1	3	1
4	1	1	-2	2	2	0	1	0	4	0
5	-1	-1	-3	0	0	3	3	2	1	0
μ	-0.6	-1.4	-1.8	-0.2	1.4	0.2	1.2	0.4	1.6	0.5
σ	1.14	2.07	1.30	1.48	1.67	1.79	1.79	1.14	1.95	1.14

Table 16.16: Application of statistical process control analysis

We immediately see that the manufacturing process was not stationary during this first production, we will therefore need to make corrections in the future:

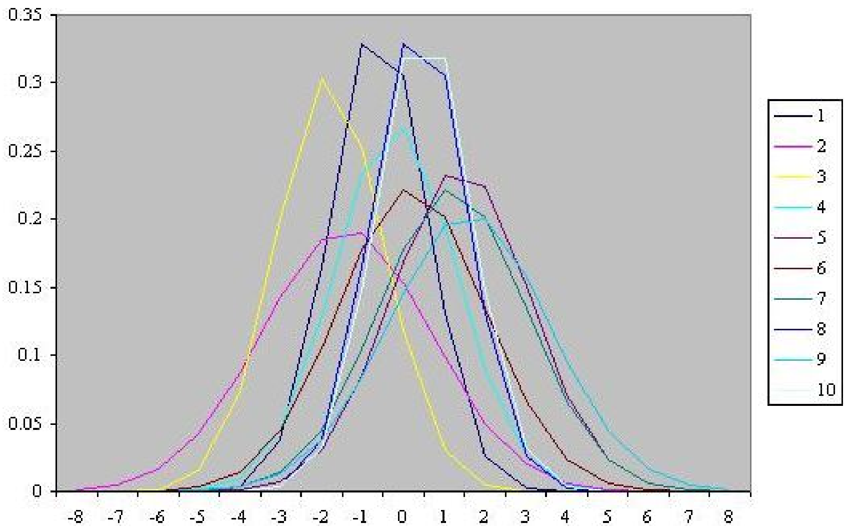


Figure 16.203: Visual evidence by a plot that the process seems not stationary

or as a very simple control average-standard deviation chart with 3σ (as I like do it for beginners):

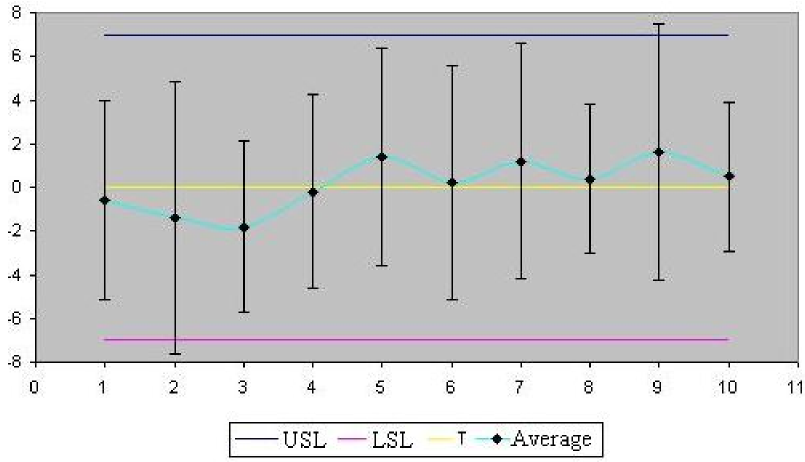

Figure 16.204: **Visual evidence by a plot that the process seems not stationary**

So we easily guess that the process is limit capable...

Remark

An interesting thing to know is that this type of chart can be analysed using the mathematical tools of the time series analysis as we will see later.

First, if we want to make a relevant statistical study of the different data above we can calculate the average of deviations that under the assumption of a Normal distribution is the arithmetic mean (see section Statistics page 819):

$$\bar{X} = 0.120 \tag{16.7.88}$$

Then the standard deviation of all pieces taken as a single group is using the maximum likelihood estimator of the variance of the Normal distribution (long term standard deviation) and taking the some notation for this variance as the one used in the section of Statistics:

$$S_{\text{LT}} = \sqrt{\sum_{i,j} \frac{(X_{i,j} - \bar{X})^2}{n-1}} = \hat{\sigma}_{\text{LT}} = 1.80294 \tag{16.7.89}$$

So the standard error (the estimator of the standard error of the mean) is as proved in the section Statistics (page 611):

$$\sigma_\mu = \frac{S_{\text{LT}}}{\sqrt{n}} = 0.25 \tag{16.7.90}$$

So the confidence interval to 95% of the average is (see section Statistics page 855):

$$\bar{X} - 1.96\frac{S_{\text{LT}}}{\sqrt{n}} \leq \mu \leq \bar{X} + 1.96\frac{S_{\text{LT}}}{\sqrt{n}} \tag{16.7.91}$$

In our case this gives:

$$-0.379 \leq \mu \leq 0.619 \tag{16.7.92}$$

And the statistical inference with our long-term standard deviation using the chi-square χ^2 bilateral hypothesis test gives (see section Statistics page 862):

$$\frac{(n-1)S_{\text{LT}}^2}{\chi^2_{\alpha/2}(n-1)} \leq \sigma_{\text{LT}}^2 \leq \frac{(n-1)S_{\text{LT}}^2}{\chi^2_{1-\alpha/2}(n-1)} \tag{16.7.93}$$

What gives us in our case:

$$2.268 \leq \sigma_{\text{LT}}^2 \leq 5.047 \tag{16.7.94}$$

Therefore:

$$1.506 \leq \sigma_{\text{LT}} \leq 2.246 \tag{16.7.95}$$

We notice therefore that on a long-term analysis we have the intervals:

$$\begin{gathered} -0.644 \leq \mu \leq 0.884 \\ 1.506 \leq \sigma_{\text{ST}} \leq 2.246 \end{gathered} \tag{16.7.96}$$

The variations can therefore be huge with a cumulative probability of 95% and we must then take care in practical cases to make adjustments as quickly as possible to reduce as possible the values of those moments!

Let us now calculate the potential long-term process capability (if assumed centered!). We have:

$$P_p = \frac{\text{USL}-\text{LSL}}{6S_{\text{LT}}} = \frac{\text{USL}-\text{LSL}}{6\sigma_{\text{LT}}} \cong \frac{14}{6\cdot 1.8} \cong 1.294 \tag{16.7.97}$$

But with an instrument having P_{pc} of 4, it really corresponds to:

$$P_{p,\text{true}} = \frac{P_{p,\text{observed}}}{\sqrt{1-\dfrac{P_{p,\text{observed}}}{P_{pc}}}} = 1.574 \tag{16.7.98}$$

Furthermore, let us indicate that if we can do a calculation of the confidence interval for σ_{LT} (see calculations done previously), it is then easy to have one too for P_p!

If the analysis of the overall performance of the long-term process is not centered (which is the case here) we use:

$$P_{pk} = \min\left\{\frac{\text{USL}-\bar{X}}{3S_{\text{LT}}}, \frac{\bar{X}-\text{LSL}}{3S_{\text{LT}}}\right\} = \min\left\{\frac{7-0.12}{3\cdot 1.80}, \frac{0.12-(-7)}{3\cdot 1.80}\right\} = \min\{1.274, 1.318\} = 1.274 \tag{16.7.99}$$

and we know once again that because of the instrument, this value is somewhat undervalued!

We have of course:

$$P_{pk} \neq P_p \tag{16.7.100}$$

So the process is not centered (as we suspected...). Then, we must calculate the potential long-term average non-centered capability P_{pm} of the process using the relations defined above:

$$P_{pm} \cong 1.291 \qquad (16.7.101)$$

To resume, either the value of P_{pk}, P_p or P_{pm}, we see that all the values are limit capable (that is to say that the value is greater than 1 - see definition above for a reminder of what means "limit capable").

If we do then our calculations of PPM according to the relations obtained above with the value of S_{LT} and $\bar{X}$ previously obtained then we have:

$$\text{PPM}_{\text{tot}}^{\text{LT}} = \text{PPM}^{UL} + \text{PPM}_{LL} \cong 114 \qquad (16.7.102)$$

Then say this number is good or bad is difficult because we lack the information to know what is the cost of production, cost of repair, the cost of a product and the whole is itself dependent of the total amount produced! But we can also use the model of Taguchi (see further below) to know the value of the parameters (moments) calculated that it would be preferable not to exceed!

Let us now calculate the short term capability indices! For this, we need the estimator of the average of the whole considering each individual as a random variable. We know (see section Statistics page 819) that this average is the arithmetic mean in the case of a Normal distribution and is strictly equal to that which is calculated by considering the set of individuals as a single random variable. So it follows that:

$$\bar{X} = 0.120 \qquad (16.7.103)$$

Regarding the standard deviation this is not the same! But we know (see section Statistics page 710) that the Normal law that is stable by the sum. For example, we have proved that given two independent random variables distributed according to a Normal distribution (by imagining that each variable represents two of our ten samples), we hat for their sum:

$$X + Y = \mathcal{N}\left(\mu_{X+Y}, \sqrt{\sigma_X^2 + \sigma_X^2}\right) \qquad (16.7.104)$$

But we have also proved in the section of Statistics using the property of linearity of expected mean, that we have:

$$\text{E}(Z) = \text{E}\left(\frac{X+Y}{2}\right) = \frac{1}{2}\text{E}(X+Y) = \frac{1}{2}(\mu_X + \mu_Y) = \frac{\mu_X + \mu_Y}{2} \qquad (16.7.105)$$

and for the variance:

$$\text{V}(Z) = \text{V}\left(\frac{X+Y}{2}\right) = \frac{1}{4}\text{V}(X+Y) = \frac{1}{4}\sqrt{\sigma_X^2 + \sigma_X^2} = \sqrt{\frac{\sigma_X^2 + \sigma_X^2}{2}} \qquad (16.7.106)$$

Therefore:

$$S_{\text{ST}} = \sqrt{\frac{\displaystyle\sum_{i=1}^{k} S_i^2}{k}} \qquad (16.7.107)$$

and in our special case:

$$S_{\text{ST}}=\sqrt{\frac{\sum\limits_{i=1}^{10}S_i^2}{10}}=1.5842979 \tag{16.7.108}$$

Remark

A software like Minitab used the pooled standard deviation (see section Statistics page 1011) that for recall is given by:

$$S_{\text{ST}}=\frac{\sum\limits_{i,j}(X_{i,j}-\bar{X})^2}{\sum_i(n_i-1)}=\frac{\sum\limits_{i,j}(X_{i,j}-0.120)^2}{10\cdot(5-1)}=1.5842979 \tag{16.7.109}$$

But it's still not accurate enough. As we will prove it further below during our study of control charts on page 8980, by default (but there is an option to deactivate this) Minitab use unbiasing constants such that finally:

$$\sigma_{\text{ST}}=\frac{S_{\text{ST}}}{c_4(k)} \tag{16.7.110}$$

So the standard error (the estimator of the standard error of the mean) is:

$$\sigma_\mu=\frac{S_{\text{ST}}}{\sqrt{k}}\cong 0.708 \tag{16.7.111}$$

So the confidence interval to 95% of the average is (see section Statistics page 852):

$$\bar{X}-1.96\frac{S_{\text{ST}}}{\sqrt{k}}\leq\mu\leq\bar{X}+1.96\frac{S_{\text{ST}}}{\sqrt{k}} \tag{16.7.112}$$

In our case this gives:

$$-1.267\leq\mu\leq 1.507 \tag{16.7.113}$$

We note that in the short term, the range is much wider in the long term, which is normal given the low value of k (which is only 5 in our example).

And the statistical inference with our short-term standard deviation using the chi-square χ^2 bilateral hypothesis test gives (see section Statistics page 862):

$$\frac{(k-1)S_{\text{ST}}^2}{\chi^2_{\alpha/2}(k-1)}\leq\sigma_{\text{ST}}^2\leq\frac{(k-1)S_{\text{ST}}^2}{\chi^2_{1-\alpha/2}(k-1)} \tag{16.7.114}$$

What gives us in our case:

$$0.899\leq\sigma_{\text{ST}}^2\leq 20.692 \tag{16.7.115}$$

Therefore:

$$0.948\leq\sigma_{\text{ST}}\leq 4.549 \tag{16.7.116}$$

We notice therefore that on a short-term analysis we have the intervals:

$$-1.267 \leq \mu \leq 1.507 \quad (16.7.117)$$

$$0.948 \leq \sigma_{\text{ST}} \leq 4.549 \quad (16.7.118)$$

The variations can therefore be huge with a cumulative probability of 95% and we must then take care in practical cases to make adjustments as quickly as possible to reduce as possible the values of those moments!

Let us now calculate the potential long-term process capability (if assumed centered!). We have:

$$C_p = \frac{\text{USL}-\text{LSL}}{6S_{\text{ST}}} = \frac{\text{USL}-\text{LSL}}{6\sigma_{\text{ST}}} = \frac{14}{6\cdot 1.58} = 1.473 \quad (16.7.119)$$

So we have logically (the opposite would be problematic):

$$C_p > P_p \quad (16.7.120)$$

But with an instrument having C_{pc} of 4, it really corresponds to:

$$C_{p,\text{true}} = \frac{C_{p,\text{observed}}}{\sqrt{1-\dfrac{C_{p,\text{observed}}}{C_{pc}}}} = 1.854 \quad (16.7.121)$$

Furthermore, let us indicate that if we can do a calculation of the confidence interval for σ_{ST} (see calculations done previously), it is then easy to have one for C_p too!

If the analysis of the overall performance of the long-term process is not centered (which is the case here) we use:

$$C_{pk} = \min\left\{\frac{\text{USL}-\bar{X}}{3S_{\text{ST}}}, \frac{\bar{X}-\text{LSL}}{3S_{\text{ST}}}\right\} = \min\left\{\frac{7-0.12}{3\cdot 1.583}, \frac{0.12-(-7)}{3\cdot 1.583}\right\} = \min\{1.448, 1.499\} = 1.448 \quad (16.7.122)$$

and we know once again that because of the instrument, this value is somewhat undervalued! We have of course:

$$C_{pk} \neq C_p \quad (16.7.123)$$

So the process is not centered (as we suspected...). Then, we must calculate the potential long-term average non-centered capability C_{pm} of the process using the relations defined above:

$$C_{pm} \cong 1.296 \quad (16.7.124)$$

To resume, either the value of C_{pk}, C_p or C_{pm}, we see that all the values are limit capable (that is to say that the value is greater than 1 - see definition above for a reminder of what means "limit capable").

If we do then our calculations of PPM according to the relations obtained above with the value of S_{ST} and $\bar{X}$ previously obtained then we have:

$$\text{PPM}_{\text{tot}}^{\text{ST}}=\text{PPM}^{UL}+\text{PPM}_{LL}\cong 10 \tag{16.7.125}$$

With same remarks as for $\text{PPM}_{\text{tot}}^{\text{LT}}$.

To close this long detailed example, here is the output of a program like Minitab 17.3.1 in which we find all the calculations above plus the control charts which we will further detailed the proofs (see the section of Statistics at page 1130 for the details about AD Anderson-Darling test):

Remark

Remember, as we have already mentioned it (!), replacing one of your specification limits with a boundary in a software like Minitab yields a one-sided capability analysis. If you select both specification limits as boundaries, all capability statistics will appear as asterisks (*) in the Six Pack Capability Analysis plot.

16.7.2 Taguchi Model

As part of the S.P.C. (Statistical Process Control), it is interesting for a manufacturer to estimate the financial losses generated by the differences in the target (caution! we can also apply this approach in other fields that the one of the industry!).

We can have a relatively simple and satisfactory estimate of his (financial) losses under the following assumptions/hypothesis:

H1. The process is under control (constant standard deviation) and follows a symmetric decreasing left and right mass probability function relative to the target (which can be a measurement, a number of errors per periods, etc.).

H2. The cost of error is zero when production (or work) is centered on the target (minimum).

H3. The cost increases in the same way as production off center on the left and on the right (which is not the case in the field of administration for example). The cost function therefore pass, following assumptions/hypothesis H2 and H3, through a minimum on the target.

Therefore, if we note Y the off-centering with respect to the target T and L financial loss. We have:

$$L = f(Y) \tag{16.7.126}$$

Although we do not know the form of this function, we can write it as a Taylor expansion (see section Sequences and Series page 1696) around T as:

$$L_n(Y) = \sum_{k=0}^{n} \frac{1}{k!}\frac{\mathrm{d}^k L(T)}{\mathrm{d}Y^k}(Y-T)^k \tag{16.7.127}$$

If we develop to the third order:

$$\begin{aligned} L_4(Y) &\cong \frac{1}{0!}\frac{\mathrm{d}^0 L(T)}{\mathrm{d}Y^0}(Y-T)^0 + \frac{1}{1!}\frac{\mathrm{d}^1 L(T)}{\mathrm{d}Y^1}(Y-T)^1 + \frac{1}{2!}\frac{\mathrm{d}^2 L(T)}{\mathrm{d}Y^2}(Y-T)^2 \\ &= L(T) + \frac{\mathrm{d}L(T)}{\mathrm{d}Y^1}(Y-T) + \frac{1}{2!}\frac{\mathrm{d}^2 L(T)}{\mathrm{d}Y^2}(Y-T)^2 \end{aligned} \tag{16.7.128}$$

But by the assumption/hypothesis H2, we have $L(T)$ is zero. It then remains:

$$L_4(Y) \cong \frac{\mathrm{d}L(T)}{\mathrm{d}Y^1}(Y-T) + \frac{1}{2!}\frac{\mathrm{d}^2 L(T)}{\mathrm{d}Y^2}(Y-T)^2 \tag{16.7.129}$$

and as by H3, the derivative of the function $L(Y)$ is zero in T as it is a minimum then:

$$L(Y) \cong \frac{1}{2}\frac{\mathrm{d}^2 L(T)}{\mathrm{d}Y}(Y-T)^2 \tag{16.7.130}$$

That is traditionally noted in S.P.C.:

$$\boxed{L(Y) \cong k(Y-T)^2} \tag{16.7.131}$$

and is named "Taguchi (centered) loss function" or just "quality loss function (centered)".

Well it's nice to have this relation, but how should we use it?

In fact, it's relatively simple. Under the assumptions mentioned above, if we have production defective measurement (ribs, delays, breakdowns, bug, etc.) then just calculate their arithmetical mean μ (estimator of the expected mean of a Normal distribution) and then to know the financial or hourly cost L that the defect generates for the company, institution or manufacture (sometimes this average is calculated on the basis of a single sample...).

Therefore, the above relation becomes:

$$L \cong k(\mu - T)^2 \tag{16.7.132}$$

with known L and μ.

And since T is given by the customer or depending on the context it is therefore easy to get the k factor:

$$k \cong \frac{L}{(\mu - T)^2} \tag{16.7.133}$$

which is in fact mathematically the inflection point of the mathematical function L (see section Differential and Integral Calculus page 1454)!

The latter relationship is sometimes denoted:

$$k \cong \frac{\Delta}{m^2} \tag{16.7.134}$$

Once we have k with a good estimation, it is possible to know L for any value of Y and so we can calculate in production the cost of any deviation from the target.

✍**Example:**

Consider a power supply for a stereo for which voltage T is $110\,[\text{V}]$. If the voltage is out of the range $110 \pm 20\,[\text{V}]$ then the stereo fails and must be repaired. Suppose the repair cost (including all direct and indirect costs!) is of $100.-$. Then, the associated cost for a given value of the voltage is:

$$L(Y) \cong \frac{100}{20^2}(y-110)^2 = 0.25 \cdot (y-110)^2 \tag{16.7.135}$$

Let us now see an elegant way to calculate the average Taguchi cost (average unit loss). We obviously have for a production line on several pieces of the same family:

$$\bar{L} = \frac{1}{n}\sum_{i=1}^{n} L(y_i) = \frac{k}{n}\sum_{i=1}^{n}(y_i - T)^2 = \frac{k}{n}\sum_{i=1}^{n} X_i^2 \tag{16.7.136}$$

where the X_i are supposed to be normal random variables (Gaussian by assumption because the manufacturing process is under statistical control). But we have proved in the section of

Statistics in our study of the confidence interval for the variance with known empirical mean (see page 862) that:

$$\chi^2(n)=\sum_{i=1}^{n}(Y_i-\mu)^2=\frac{1}{\sigma^2}\left[\sum_{i=1}^{n}(Y_i-\bar{Y})^2+n(\bar{Y}-\mu)^2\right] \tag{16.7.137}$$

Therefore:

$$\sigma^2\chi^2(n)=\sum_{i=1}^{n}(Y_i-\bar{Y})^2+n(\bar{Y}-\mu)^2 \tag{16.7.138}$$

And finally:

$$\begin{aligned}\bar{L}&=\frac{k}{n}\left[X_1^2+X_2^2+\ldots+X_n^2\right]=\frac{k}{n}\left[\sum_{i=1}^{n}(Y_i-\bar{Y})^2+n(\bar{Y}-\mu)^2\right]\\&=k\left[\frac{1}{n}\sum_{i=1}^{n}(Y_i-\bar{Y})^2+\frac{1}{n}n(\bar{Y}-\mu)^2\right]\\&=k\left[\bar{\sigma}^2+n(\bar{Y}-T)^2\right]\end{aligned} \tag{16.7.139}$$

This last expression has the advantage of showing very clearly that to minimize loss, we must act on the dispersion and the adjustment of the average on the nominal value.

Now remember that we have proved in the section Statistics (see page 822) during our study of likelihood estimator that (it is important in these developments that we use the notation which distinguish different estimators!):

$$\mathrm{E}(\hat{\sigma}^2)=\frac{n-1}{n}\sigma^2 \tag{16.7.140}$$

Therefore:

$$\bar{L}\cong k\left[\frac{n-1}{n}\sigma^2+(\bar{Y}-T)^2\right]=k\left[\frac{n-1}{n}\sigma^2+(\hat{\mu}-T)^2\right] \tag{16.7.141}$$

If n is large, then we have for a lot of products:

$$\boxed{\bar{L}\cong k\left[\sigma^2+(\hat{\mu}-T)^2\right]} \tag{16.7.142}$$

where the first term in brackets represents the variance of Y around its own mean and the second term of the deviation of Y with respect to the target T.

We also find this last expression in the literature and in softwares often denoted as follows:

$$L\cong k\left[S^2+(\bar{y}-y_N)^2\right] \tag{16.7.143}$$

where the index N means "Nominal". Obviously, when the target T (or nominal value) is taken as zero, the relations simplify even more.

Now, remember the following properties of the expected mean and variance (see section Statistics page 571):

$$\begin{gathered}\mathrm{E}(\alpha X)=\alpha\mathrm{E}(X)\\ \sigma_{\alpha X}=\alpha\sigma_X\end{gathered} \tag{16.7.144}$$

Therefore, if the process is non-centered and that we must correct the random variable to recenter it, it comes intuitively that the correction factor will then be (if linear):

$$\alpha = \frac{y_N}{\bar{y}} \tag{16.7.145}$$

Therefore, it comes immediately:

$$L \cong k\left[S^2\left(\frac{y_N}{\bar{y}}\right)^2 + \left(\bar{y}\frac{y_N}{\bar{y}} - y_N\right)^2\right] = y_N^2\left(\frac{S^2}{\bar{y}^2}\right) \tag{16.7.146}$$

So to minimize L, knowing that the other terms are imposed, it is necessary to minimize the ratio:

$$\frac{S^2}{\bar{y}^2} \tag{16.7.147}$$

or, equivalently, maximize the inverse ratio (which remains without dimensions):

$$\frac{\bar{y}^2}{S^2} \tag{16.7.148}$$

This number is often very large, it is customary in the literature and in statistical software to take the base-10 logarithm and multiply the result by 10 (it is an idea inspired by the acoustic physics). We then have what we name the "signal/noise ratio", given in decibels:

$$\boxed{S/N = 10\log_{10}\left(\frac{\bar{y}^2}{S^2}\right)} \text{[dB]} \tag{16.7.149}$$

for what engineers name "nominal is the best".

Relation that will meet in a software like Minitab during the analysis of Taguchi design of experiment (see below what are experimental designs). Some very rare software also offer the following special case:

$$S/N = 10\log_{10}\left(\frac{\bar{y}^2}{S^2}\right) = 10\log_{10}(\bar{y}^2) - 10\log_{10}(S^2) \underset{\bar{y}=1}{=} -10\log_{10}(S^2) \tag{16.7.150}$$

For what follows let us return to the following relation:

$$\begin{aligned}\bar{L} &= \frac{k}{n}\left[L(y_1) + L(y_2) + \ldots + L(y_n)\right]\\ &= \frac{k}{n}\left[(y_1 - T)^2 + (y_2 - T)^2 + \ldots + (y_n - T)^n\right]\\ &= \frac{k}{n}\left[X_1^2 + X_2^2 + \ldots + X_n^n\right]\end{aligned} \tag{16.7.151}$$

Engineers talk about minimizing the quality loss function when T (the target) must be zero and therefore it is necessary to minimize all y_i. So the above relation is finally reduced to:

$$\bar{L} = \frac{k}{n}\sum_{i=1}^{n} y_i^2 \tag{16.7.152}$$

What engineers sometimes like to summarize as follows (whereas I personally think that taking the logarithm in base 10 as well as putting a "-" in this case is really not justified...):

$$-10\log\left(\frac{1}{n}\sum_{i=1}^{n}y_i^2\right) \tag{16.7.153}$$

and even sometimes they say it is still a signal/noise ratio... while obviously there is no noise in this specific case that is named "smaller is better (SIB)". This is exactly in this form in which you can find this target in the software Minitab.

In the context of a parameter to maximize it is customary to say that we seeks to minimize:

$$\bar{L}=\frac{k}{n}\left[\left(\frac{1}{y_1}-\frac{1}{T}\right)^2+\left(\frac{1}{y_2}-\frac{1}{T}\right)^2+\ldots+\left(\frac{1}{y_n}-\frac{1}{T}\right)^2\right] \tag{16.7.154}$$

because given that T tends to infinity it would be difficult to do anything mathematically speaking.

So because T tends to infinity, the preceding relation is reduced to:

$$\bar{L}=\frac{k}{n}\sum_{i=1}^{n}\frac{1}{y_i^2} \tag{16.7.155}$$

What engineers also likes sometimes summarized as follows (here the base-10 logarithm is justified in my point of view!):

$$-10\log\left(\frac{1}{n}\sum_{i=1}^{n}\frac{1}{y_i^2}\right) \tag{16.7.156}$$

and even sometimes they say also it is still a signal/noise ratio... while obviously there is no noise in this specific case that is named "larger is better (LIB)". This is exactly under this form in which you can find this target written in a software like Minitab.

It is, however, being clever, possible to introduce noise in the relation:

$$\frac{1}{n}\sum_{i=1}^{n}\frac{1}{y_i^2} \tag{16.7.157}$$

For this let us write:

$$\frac{1}{n}\sum_{i=1}^{n}\frac{1}{y_i^2}=\frac{1}{n}\sum_{i=1}^{n}\frac{1}{(\mu+y_i-\mu)^2}=\frac{1}{n}\sum_{i=1}^{n}\frac{1}{\left(1+\dfrac{y_i-\mu}{\mu}\right)^2\mu^2}=\frac{1}{n\mu^2}\sum_{i=1}^{n}\frac{1}{\left(1+\dfrac{y_i-\mu}{\mu}\right)^2} \tag{16.7.158}$$

We put:

$$x=\frac{y_i-\mu}{\mu}<1 \tag{16.7.159}$$

So in this case, using the Taylor series as proved in the section of Sequences and Series (see page 1703):

$$\frac{1}{1+x^2}\cong 1-2x+3x^2 \tag{16.7.160}$$

Then we have:

$$\frac{1}{n\mu^2}\sum_{i=1}^{n}\frac{1}{\left(1+\dfrac{y_i-\mu}{\mu}\right)^2}\cong\frac{1}{n\mu^2}\sum_{i=1}^{n}\left(1-2\frac{y_i-\mu}{\mu}+3\left(\frac{y_i-\mu}{\mu}\right)^2\right) \tag{16.7.161}$$

and under statistical control we have:

$$\sum_{i=1}^{n}\frac{y_i-\mu}{\mu}\longrightarrow 0 \tag{16.7.162}$$

and assuming that we work on all parts of the population, we have:

$$\sigma^2=\frac{1}{n}\sum_{i=1}^{n}(y_i-\mu)^2 \tag{16.7.163}$$

It comes then:

$$\begin{aligned}\frac{1}{n\mu^2}\sum_{i=1}^{n}\left(1-2\frac{y_i-\mu}{\mu}+3\left(\frac{y_i-\mu}{\mu}\right)^2\right)&=\frac{1}{n\mu^2}\sum_{i=1}^{n}\left(1+3\left(\frac{y_i-\mu}{\mu}\right)^2\right)\\&=\frac{1}{n\mu^2}\left(n+3\frac{n\sigma^2}{\mu^2}\right)=\frac{1}{\mu^2}\left(1+3\frac{\sigma^2}{\mu^2}\right)\end{aligned} \tag{16.7.164}$$

So in the end by replacing a little bit abusively by the estimators, we get:

$$\boxed{S/N=-10\log_{10}\left(\frac{1}{\bar{y}^2}\left(1+3\frac{S^2}{\bar{y}^2}\right)\right)} \tag{16.7.165}$$

16.7.3 Preventive Maintenance

The evolution of production techniques towards greater automation of complex technical systems has increased the importance of the reliability of production machines or servers. Also, an unexpected shutdown is costly or even deadly to a business. Similarly, in the aerospace or nuclear industries, problems of reliability, maintainability, availability are crucial. Preventive maintenance has the purpose to quantify the reliability for all the components (mechanical, electromechanical, IT, etc.).

The existence of a maintenance service has for purpose to maintain the equipment (systems) and also the reduction in breakdowns. Indeed, these are expensive, they generate:

1. Intervention, repair costs
2. Cost of product non-quality
3. Indirect costs such as fixed costs, production losses, lost profit...
4. Life-loss in some cases...

Therefore, every effort should be made to avoid the blackout/failure, act quickly when it occurs to increase equipment availability. To do this, one must model the life of equipment and train people to react. The set of methods and techniques for its problems are usually classified under the name of "Failure Mode and Effects Analysis (FMEA)", but we can also found it under the name of "Probabilistic risk assessment (PRA)". Especially, that latter is a very official systematic and comprehensive methodology to evaluate risks associated with a complex engineered technological entity (such as an airliner or a nuclear power plant) or the effects of stressors on the environment (Probabilistic Environmental Risk Assessment- PERA) for example[20].

"Quantitative Reliability Engineering" analysis involves more than just reliability predictions and reliability demonstration that are performed against a given program or project requirements. Quantitative Reliability Engineering analysis can play a key role in supporting a broad range of applications. It is critical in addressing design and manufacturing deficiencies.

We distinguish two main classes of systems:

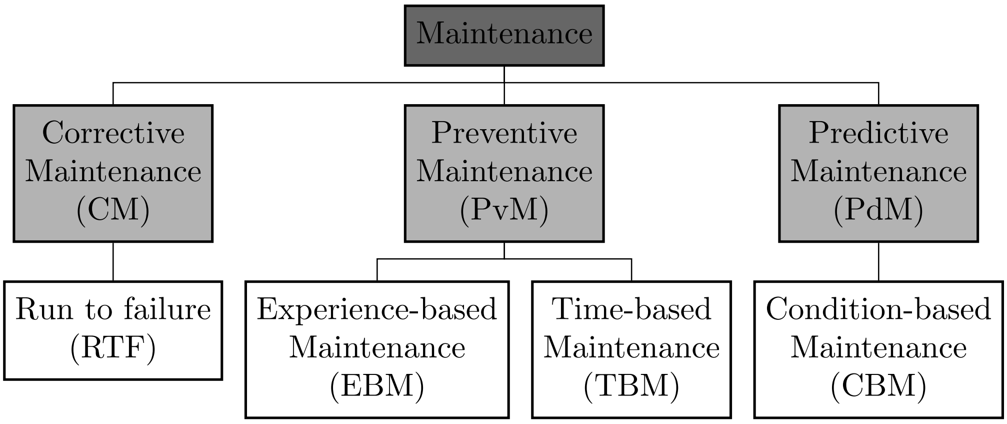
1. Non-repairable systems (satellites, although low cost goods, etc.)
2. Repairable systems (production machinery, means of transport, etc.)

where the theoretical approaches are different. For the second category, you can also use Markov chains (where the states represent the number of functional components or failure of a system in accordance with the standard ISO 31010), Petri nets or Monte Carlo simulation.

---

[20] In addition to the mentioned methods, PRA studies require special but often very important analysis tools like human reliability analysis (HRA) and common-cause-failure analysis (CCF). HRA deals with methods for modelling human error while CCF deals with methods for evaluating the effect of inter-system and intra-system dependencies which tend to cause simultaneous failures and thus significant increase in overall risk.

The idea is in the texts that follow to make the point on one of these methods, to seek their efficiency and enable engineers practitioners and technicians to better understand these problems. An emphasis will be placed on the Weibull model, which has a significant importance in this field.



Maintenance
Corrective Maintenance (CM)
Preventive Maintenance (PvM)
Predictive Maintenance (PdM)
Run to failure (RTF)
Experience-based Maintenance (EBM)
Time-based Maintenance (TBM)
Condition-based Maintenance (CBM)

Figure 16.206: **Different types of maintenance**

16.7.3.1 Planned Obsolescence

The planned obsolescence goes against preventive maintenance philosophy whose primary purpose is to provide a quality product and respectful of its environment with precise knowledge of the product's lifetime and quantifiable risk of obsolescence.

At the opposite, the purpose of planned obsolescence is to reduce the lifetime (or "lifespan") of a product in order to increase the rate of replacement by the buyer (sometimes motivated by political strategy or short term money return...). Therefore the induced demand would have for aim (not proved in the very long term ... as this is quite bad for the reputation of the brand) to benefit the manufacturer, or its competitors. The sector then has a greater production, stimulating productivity growth (economies of scale) and technical progress (which accelerates the obsolescence of previous products) and maintains the use of an ever growing population which is therefore problematic by definition.

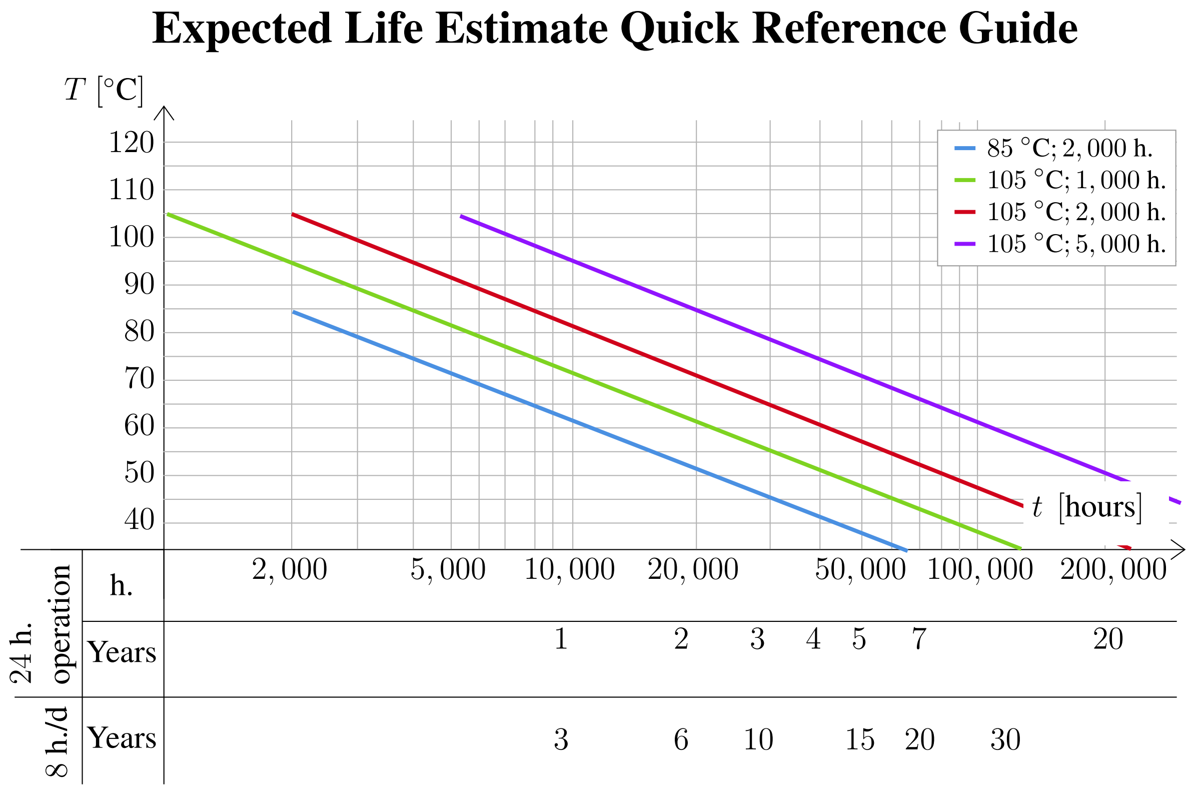


Figure 16.207: **Example of a reliability plot of capacitor (source: Cash Investigation about Samsung TV issue)**

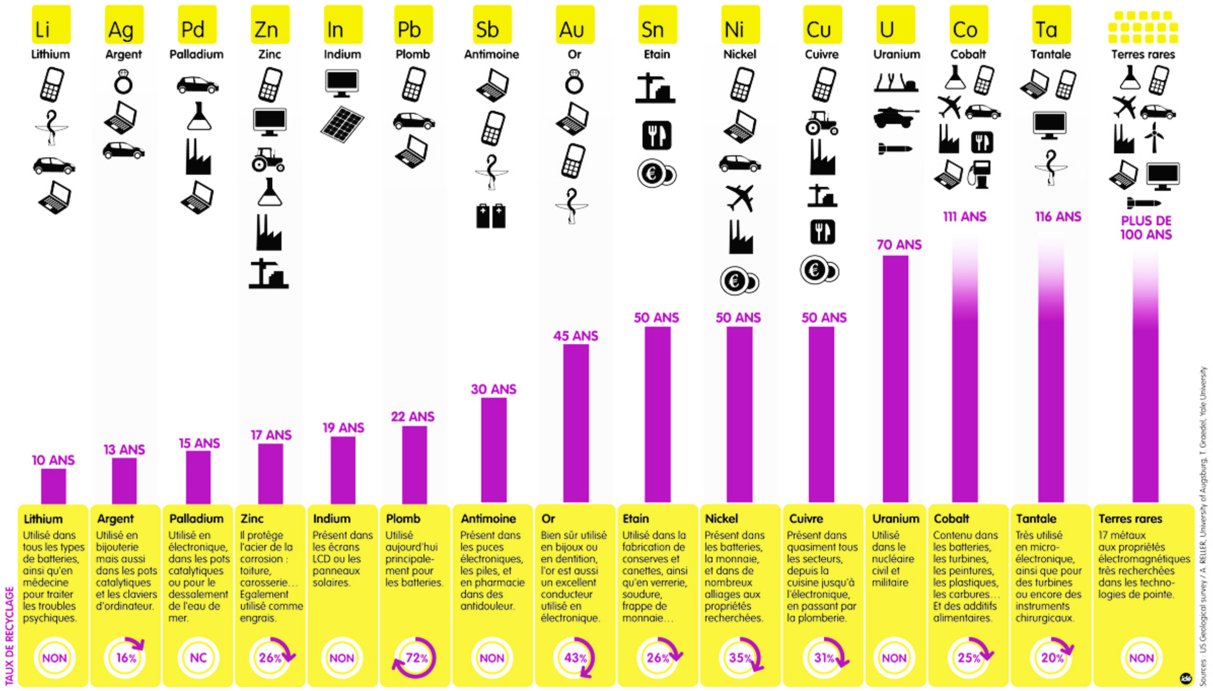
The reader will therefore have to understand that I am strongly against these methods and that every engineer and every scientist working for a company must refuse by deontology this type of request coming from the hierarchy even denounce these methods anonymously on the Internet or to consumer associations.

Remark

The consumer must be very careful with TV shows or newspapers about the subject of planned obsolescence! Indeed as they don't have any statisticians consultants, these shows or newspapers communicate numbers in a very wrong and bad way (a journalist being not a scientist...).

It must be also notice that lifetime (lifespan) will be a major subject of concern for future generations as Earth's resources are not unlimited and that in this 121st century (holocene calendar) people still don't recycle everything. So it will be a challenge for these future generations (at least if we will not be able to bring material from other planets, satellites or asteroids) to find solutions to get the longest lifespan. Having the longest lifespan is however also in the 121st century (holocene calendar) sometimes a requirement as it is an important factor in aeronautics, trains, boats or all other areas of cutting edge technologies and where human life are in concerns (or very rarely in luxury goods also).

But let us also show a small chart of the status of the known reserves - in years - of row material resources (so not including unknowns reserves!) if humans continue to consume as they do in the beginning of this 121st century (sorry we did not found the english version of this figure):



Lithium Utilisé dans tous les types de batteries, ainsi qu'en médecine pour traiter les troubles psychiques.

Argent Utilisé en bijouterie mais aussi dans les pots catalytiques et les claviers d'ordinateur.

Palladium Utilisé en électronique, dans les pots catalytiques ou pour le dessalement de l'eau de mer.

Zinc Il protège l'acier de la corrosion : toiture, carosserie… Egalement utilisé comme engrais.

Indium Présent dans les écrans LCD ou les panneaux solaires.

Plomb Utilisé aujourd'hui principalement pour les batteries.

Antimoine Présent dans les puces électroniques, les piles, et en pharmacie dans des antidouleur.

Or Bien sûr utilisé en bijoux ou en dentition, l'or est aussi un excellent conducteur utilisé en électronique.

Etain Utilisé dans la fabrication de conserves et canettes, ainsi qu'en verrerie, soudure, frappe de monnaie…

Nickel Présent dans les batteries, la monnaie, et dans de nombreux alliages aux propriétés recherchées.

Cuivre Présent dans quasiment tous les secteurs, depuis la cuisine jusqu'à l'électronique, en passant par la plomberie.

Uranium Utilisé dans le nucléaire civil et militaire

Cobalt Contenu dans les batteries, les turbines, les peintures, les plastiques, les carbures… Et des additifs alimentaires.

Tantale Très utilisé en micro-électronique, ainsi que pour des turbines ou encore des instruments chirurgicaux.

Terres rares 17 métaux aux propriétés électromagnétiques très recherchées dans les technologies de pointe.

16.7.3.2 Reliability Empirical Estimators

As part of the non-accelerated reliability study (accelerated aging will be treated in a near future in this textbook), we are led to define some variables which are listed below:

- N_0 will the number of good elements at time t_0 (initial time)
- N_i the number of good elements at time t_i
- n_i the number of defective elements between t_i and t_{i-1} also denoted by ΔN_i
- Δt_i the time interval between t_i and t_{i-1}

Definitions (#16.7.732):

D1. We define the "failure rate per time-slot" Δt by the relation:

$$\hat{\lambda}=\frac{\Delta N_i}{N_i\Delta t_i}=\frac{n_i}{N_i\Delta t_i} \tag{16.7.166}$$

which therefore is interpreted as being the number of defective elements relative to the number of surviving elements on a given timeslot (this is therefore a percentage of non-conformities related to a time slot).

The latter relation is also sometimes named "hazard function" (or "hazard ratio (HR)") or "relative survival" and often denoted by $\bar{h}(t_i)$.

D2. We define the "failure function" by the relation (probability density of failure at time t_i):

$$\hat{f}(t_i)\Delta t_i=\frac{n_i}{N_0} \tag{16.7.167}$$

noting that the denominator is not the same as that which defines the default rate per timeslot!

This function is therefore interpreted as the $\%$ of defective elements in the studied time frame relative to the total number of elements initially tested. This is the indicator that interests most often the engineer because can be assimilate to a probability and having the properties of a probability!

D3. We naturally define the "cumulative failure function" by:

$$\hat{F}(t_i)=\sum_i\hat{f}(t_i)\Delta t_i=\frac{\displaystyle\sum_i n_i}{N_0}=\frac{N_0-N_i}{N_0}=1-\frac{N_i}{N_0} \tag{16.7.168}$$

which tends to 1 when time tends to infinity.

This function is therefore interpreted as the $\%$ of cumulative defective components based on the total number of elements initially tested. It is therefore the function of empirical distribution of probabilities of failures.

D4. We define verbatim the "reliability function" by (this is the second term of the previous relation):

$$\hat{R}(t_i)=\frac{N_i}{N_0}=1-\hat{F}(t_i) \tag{16.7.169}$$

Its name comes from the interpretation of the ratio in the context of the definition of the cumulative failure function.

It must be remembered that the letter R is derived from the word "reliability" and F is derived from the word "failure" which means "breakdown".

D5. In reliability, or survival analysis, the "risk set" is the set of subjects who have not experienced the event of interest at time t, and who have not been censored by time t (and thus who are at risk at time t for the event of interest).

It follows from these definitions that:

$$\boxed{\frac{\hat{f}(t_i)}{\hat{R}(t_i)}=\hat{\lambda}(t_i) \quad\Rightarrow\quad \hat{\lambda}(t_i)\Delta t_i=\frac{\hat{f}(t_i)}{\hat{R}(t_i)}\Delta t_i} \tag{16.7.170}$$

The latter relation is used for the calculation of reliability laws as we will see later! We deduce a notation which sometimes helps to better understand the failure rate per time slot. Effectively:

$$\hat{\lambda}(t_i)=\frac{\hat{f}(t_i)}{\hat{R}(t_i)}=\frac{\hat{f}(t_i)\Delta t}{\hat{R}(t_i)\Delta t}=\frac{\dfrac{n_i}{N_0}}{\hat{R}(t_i)\Delta t}=\frac{\dfrac{\Delta N_i}{N_0}}{\hat{R}(t_i)\Delta t}=\frac{\dfrac{N_{i-1}}{N_0}-\dfrac{N_i}{N_0}}{\hat{R}(t_i)\Delta t}=\frac{\bar{R}(t_{i-1})-\bar{R}(t_i)}{\hat{R}(t_i)\Delta t} \tag{16.7.171}$$

Because:

$$\hat{f}(t_i)\Delta t_i\leqslant 1 \quad\text{and}\quad \lim_{i\rightarrow\infty}\sum_i\hat{f}(t_i)\Delta t_i=1\frac{\hat{f}(t_i)}{\hat{R}(t_i)}\Delta t_i \tag{16.7.172}$$

the failure function can be seen as a probability as we have already mentioned it, which naturally led us to define its expected mean:

$$\boxed{\mathrm{E}(T)=\sum_i t_i\hat{f}(t_i)\Delta t_i=\sum_i t_i\frac{n_i}{N_0}} \tag{16.7.173}$$

Very useful relation in practice which in theory gives the average percentage of failed elements at the moment t_i. So to summarize and with different notations that we can find in the literature, this gives (we will see later the same summary in the continuous case):

Function type	**Mathematical expression**
Failure density function	$\hat{f}\Delta t_i = \dfrac{n_i}{N_0}$
Failure repartition function	$\bar{F}(t_i) = \sum_i \hat{f}(t_i)\Delta t_i = \sum_i \dfrac{n_i}{N_0} = P(T \leq t_i)$
Survival repartition function	$\hat{R}(t_i) = \hat{S}(t_i) = 1 - \hat{F}(t_i) = P(T \geq t_i) = 1 - \sum_i \hat{f}(t_i)\Delta t_i$
Risk (hazard) function	$\hat{\lambda}(t_i) = \hat{h}(t_i) = \dfrac{\hat{f}(t_i)}{\hat{R}(t_i)}$
Cumulated risk (hazard)	$\hat{H}(t_i) = \sum_i \dfrac{n_i}{N_i \Delta t_i}$

Table 16.17: **Summary of discrete maintenance analysis functions**

Note that we will see later below a statistical mathematical model based on the Kaplan-Meier estimator that gives in fact a nonparametric estimation of the survival function. The following example will perhaps help you better understand the concept!

✍**Example:**

We have identified on a batch of 37 engines of a given type the following listed failures in slices (given by customers or internally measured on test benches):

0 to 1,000h.	**1,000 to 2,000h.**	**2,000 to 3,000h.**	**3,000 to 4,000h.**	**4,000 to 5,000h.**	**5,000 to 6,000h.**
1	4	7	12	11	2

Table 16.18: **Engine failures in effort slices**

We must consider the value of the reliability function $\hat{R}(t_i)$, of the failure function $\hat{f}(t_i)$ and the failure by time slice $\hat{\lambda}(t_i)$. The calculations are elementary and we get the following table:

i	**Observation interval**	**Failures in the interval**	**Survivors**	**Cumulated failures**	$\hat{R}(t_i)$	$\hat{f}(t_i)\Delta t_i$	$\hat{\lambda}(t_i)$ $10^{-6}[\text{h}^{-1}]$
0	0	–	37	0	100%	0%	0
1	0 to 1,000	1	36	1	97%	2.7%	$(1/36)/1000 \cong 27.7$
2	1,000 to 2,000	4	32	5	86%	10.8%	$(4/32)/1000 = 125$
3	2,000 to 3,000	7	25	12	67%	18.9%	$(7/25)/1000 = 280$
4	3,000 to 4,000	12	13	24	35.1%	32.4%	$(12/13)/1000 \cong 923$
5	4,000 to 5,000	11	2	35	5.4%	5.4%	$(11/2)/1000 \cong 5,500$
5	6,000 to 6,000	2	0	37	0%	–	–

Table 16.19: **Analysis of engine failures per effort slices**

We see above that the failure rate $\hat{\lambda}(t_i)$ is of course not constant! The failure rate $\hat{f}(t_i)$ would therefore be about 2.5% to 3% the first year, about 10% to 11% the second year, etc.

Regarding default rates, engineers often recognize three analysis slices following that the studied objects are: 1) New 2) In normal operation 3) Considered aging.

In practice we consider quite intuitively (and sometimes roughly) that for very common goods the failure rate follows a bathtub curve as shown below (in the technical tables it is often the normal operation failure rate that is given):

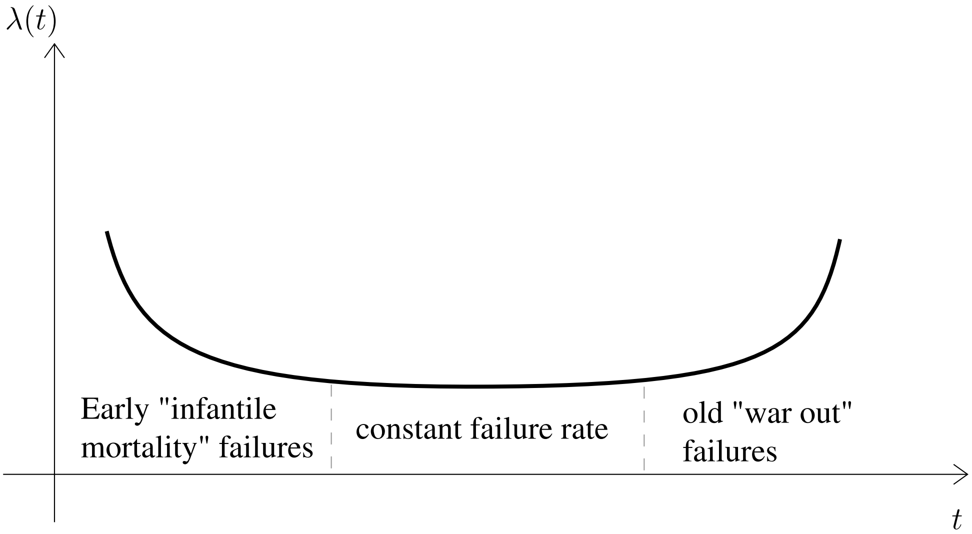

Figure 16.208: **Reliability bathtube**

whereas if you look at the table of the example above, the failure rate does not follow at all a bathtub curve (so it is a cons-example).

Reliability engineers often cut the bath in the three visible parts above, but under the following technical names:

1. D.F.R. for "Decreasing Failure Rate": young unidentified components with manufacturing problems during the process are eliminated from the batch which has the effect of reducing the failure rate. The Weibull distribution is relatively well suited to model this phase (see later below the details of this model).
2. C.F.R. for "Constant Failure Rate": the components are in stable conditions.
3. I.F.R. for "Increasing Failure Rate" components are in end of life and their failure rate increases. The Weibull distribution is again relatively well adapted to model this phase.

The Poisson distribution (see section Statistics page 686) is relatively well adapted to model the failure arrival time, and the exponential distribution (see section Statistics page 751) to model the time between successive failures. This fact follows mathematical proofs available in the section of Quantitative Management (queueing theory). So, this means that failures are often considered independent. Therefore, the law on the number of failures in a given period is then a law "without memory" and can be modelled by a Poisson distribution (proof also made in the section of Quantitative Management).

Remark

Contrary to what a lot of theorists think... many general public softwares have also sometimes a failure rate following a bathtub curve. Indeed, at the beginning there are undetected bugs that cause the failure will decrease following the identification and correction. Then, because of frequent updates of the environment that tend to add other issues (service pack), the failure rate remains fairly constant. Finally, over time, the evolution of surrounding technologies (frameworks) make the application obsolete and some functions no longer properly work which is again an increase the failure rate.

Vis-à-vis the effectiveness of renovation, let us indicate (by simplifying) that they can be frequently divided into three categories:

1. "As good as new": This is preventive maintenance in the sense that we change a piece when his life times leads it to a failure rate that we consider too high and that the unanticipated failure will cost more that its non-anticipation.
2. "As bad as old": It is the poor maintenance in the sense that we change a piece only when it comes to break, which mainly generates higher costs of maintenance that the preventative maintenance that involves in anticipating issues.
3. "Partial Restore": This is the minimum preventive maintenance in the sense that we repair the defective part rather than replace it with a new one. Again the cost of the problem must be calculated by an audit of requirements and of the deadlines of the business.

Let us return to other definitions in the passage to the limit of the continuum!

So we know that the "instantaneous failure rate" will have for unit the inverse of time as $[\lambda]=\mathrm{s}^{-1}$. This rate is, within the framework of our study, not necessarily constant over time as we have seen above!

Given $R(t)$ the cumulative percentage of objects analysed (tracked) always running well (no failures!) - reliable objects - of a sample tested at time t. The number of objects falling down during the infinitesimal time $\mathrm{d}t$ is therefore equal to:

$$\lambda(t)R(t)\mathrm{d}t \tag{16.7.174}$$

this corresponds to the decrease of the initial stock reliable at time t. $R(t)$ is also the probability that the time T of an event will occur after time t.

We can then write the relation:

$$\mathrm{d}F(t)=\lambda(t)R(t)\mathrm{d}t \tag{16.7.175}$$

therefore:

$$\frac{\mathrm{d}F(t)}{R(t)}=\frac{F(t+\mathrm{d}t)-F(t)}{R(t)}=\frac{\mathrm{d}F(t)}{1-F(t)}=\lambda(t)\mathrm{d}t \tag{16.7.176}$$

Which can often be found in the literature under the following equivalent forms:

$$\lambda(t)=h(t)=\frac{\mathrm{d}F(t)}{R(t)\mathrm{d}t}=\frac{f(t)}{R(t)}=\frac{1-\mathrm{R(t)}}{R(t)\mathrm{d}t}=\frac{\mathrm{d}R(t)}{R(t)\mathrm{d}t} \tag{16.7.177}$$

Definition (#16.7.733): The "conditional probability of failure" between t and $t+\mathrm{d}t$ is defined as the temporal conditional probability of experiencing the event at a given time t, knowing that we have not experienced before and so we survived up to a time t (i.e. it only increase with time...):

$$\boxed{\lambda(t)\mathrm{d}t=\frac{\text{cumulated probability of default between } t+\mathrm{d}t}{\text{cumulated probability of surival at time } t}=\frac{F(t+\mathrm{d}t)-F(t)}{R(t)}=\frac{\mathrm{d}F(t)}{1-F(t)}} \tag{16.7.178}$$

where $F(t)$ and $R(t)$ are, for reminder, respectively the cumulative probability function of failure (cumulative probability to fail at time t) and the cumulative probability function of reliability also named "survival function" (denoted $S(t)$ in clinical trials involving biological entities). $R(t)$ is 1 at time 0 and ... 0 after an infinite time as we have already seen before!

We have already study this conditional probability with a more pedagogical approach during our study of Cox's proportional hazard model in the section Statistics at page 1291.

Remark

By the same intellectual approach, rather than defining a function of failure $F(t)$ and survival $R(t)$ with its associated hazard function, we can define a repairability function with its function $M(t)$ which would then be a "maintainability function".

If we integrate (caution! u now represents the time!):

$$\begin{aligned}\int_0^t \lambda(u)\mathrm{d}u &= \int_0^t \frac{\mathrm{d}F(u)}{1-F(u)}\\ \Rightarrow -\int_0^t \lambda(u)\mathrm{d}u &= -\int_0^t \frac{\mathrm{d}F(u)}{1-F(u)}\\ \Rightarrow -\int_0^t \lambda(u)\mathrm{d}u &= \ln(1-F(u))\Big|_0^t\end{aligned} \tag{16.7.179}$$

As $F(t_0=0)=0$ we have:

$$-\int_0^t \lambda(u)\mathrm{d}u = \ln(1-F(t)) \quad \Rightarrow \quad \exp\left(-\int_0^t \lambda(u)\mathrm{d}u\right) = \ln(1-F(t)) \tag{16.7.180}$$

Therefore:

$$\boxed{\begin{aligned}&R(t)=e^{-\int_0^t \lambda(u)\mathrm{d}u}\\ &F(t)=1-R(t)=1-e^{-\int_0^t \lambda(u)\mathrm{d}u}\end{aligned}} \tag{16.7.181}$$

Moreover, since we have seen that $\hat{f}(t_i)=\hat{\lambda}(t_i)\hat{R}(t_i)$, then we have the "density/repartition function of instantaneous failure":

$$f(t)=\lambda(t)R(t)=\lambda(t)e^{-\int_0^t \lambda(u)\mathrm{d}u} \tag{16.7.182}$$

We can get this relation and interpretation in another way:

$$\boxed{f(t)=\frac{\mathrm{d}F(t)}{\mathrm{d}t}=\lambda(t)e^{-\int_0^t \lambda(u)\mathrm{d}u}} \tag{16.7.183}$$

So where we find back therefore $F(t)$ the function of cumulative probability of failure (also sometimes denoted CIF(t) and named "cumulative incidence function"). Obviously to determine the law $f(t)$, we use the usual statistical tools for goodness of fit (see section Statistics page 1130).

We then get the very important equation (if not the most important one!) in practice, which connects the density function of the instantaneous failure and the reliability's law:

$$\boxed{f(t)=\frac{\mathrm{d}F(t)}{\mathrm{d}t}=\frac{\mathrm{d}(1-R(t))}{\mathrm{d}t}=-\frac{\mathrm{d}R(t)}{\mathrm{d}t}} \tag{16.7.184}$$

We have above the three most general expressions binding laws of reliability and the instantaneous failure rates. Let us add that we have also the following instantaneous hazard function that follows:

$$\lambda(t)=h(t)=\frac{f(t)}{R(t)}=\frac{-\dfrac{\mathrm{d}R(t)}{\mathrm{d}t}}{R(t)}=\frac{-R'(t)}{R(t)}=\frac{\mathrm{d}}{\mathrm{d}t}(-\ln(R(t))=\frac{\mathrm{d}}{\mathrm{d}t}(-\ln(1-F(t)) \tag{16.7.185}$$

Remark

More explicitly the hazard function is related to the survivor function in the following way:

$$\begin{aligned}h(t_0)&=\lim_{\delta t\to 0}\frac{1}{\delta t}P(\text{fail in interval }[t_0,t_0+\delta t[|\text{still working at time }t_0)\\&=\lim_{\delta t\to 0}\frac{P(t_0\leq T+\delta t|T\geq t)}{\delta t}\\&=\lim_{\delta t\to 0}\frac{1}{\delta t}\frac{F(t_0+\delta t)-F(t_0)}{S(t_0)}=\frac{1}{S(t_0)}\lim_{\delta t\to 0}\frac{F(t_0+\delta t)-F(t_0)}{\delta t}\\&=\frac{1}{S(t_0)}\frac{\mathrm{d}}{\mathrm{d}t}F(t_0)=\frac{f(t_0)}{S(t_0)}\end{aligned}\tag{16.7.186}$$

It then follows immediately that:

$$\begin{aligned}H(t)=\int_0^t h(t)\mathrm{d}t=\int_0^t\frac{\mathrm{d}}{\mathrm{d}t}(-\ln(1-F(t))\mathrm{d}t=-\int_0^t\mathrm{d}\ln(1-F(t))=-\ln(1-F(t))\Big|_0^t\\=-\ln(1-F(t))=-\ln(R(t))\end{aligned}\tag{16.7.187}$$

Also sometimes denoted $\Lambda(t)$ in textbooks. From the latter result we also have obviously:

$$R(t)=S(t)=e^{-H(t)}\tag{16.7.188}$$

Since $f(t)$ is the failure density function, the expected value of the failure is given by:

$$\mathrm{E}(t)=\int_0^{+\infty}tf(t)\mathrm{d}t=\text{MTBF}\tag{16.7.189}$$

Thus, if the distribution of failures is equally likely (uniform density function), which is rare..., half of the equipment will be off at $\mathrm{E}(t)$.

Remark

Tracking $100,000$ hard drives, Google engineers have observed an average of 8% loss per year! So a higher loss rate than were announcing the manufacturer that was about $300,000$ hours average! The loss rate is higher the first 3 years! But maybe the disks that survive works longer and therefore compensate the low average observed by Google...!?

We also have use the integration by parts and the above relation:

$$\begin{aligned}\mathrm{E}(t)=\int_0^{+\infty}t\frac{\mathrm{d}F(t)}{\mathrm{d}t}\mathrm{d}t=\int_0^{+\infty}t\mathrm{d}F(t)=-\int_0^{+\infty}t\mathrm{d}R(t)\\=-tR(t)|_0^{\infty}+\int_0^{+\infty}R(t)\mathrm{d}t=\int_0^{+\infty}R(t)\mathrm{d}t=\text{MTBF}\end{aligned}\tag{16.7.190}$$

Hence another way to express it:

$$\boxed{\mathrm{E}(t)=\int_0^{+\infty} tf(t)\mathrm{d}t=\int_0^{+\infty} R(t)\mathrm{d}t=\text{MTBF}} \tag{16.7.191}$$

So to summarize and with different notations that we can find in the literature, this gives:

Function type	**Mathematical expression**
Failure density function	$f(t)=\lim\limits_{\mathrm{d}t\rightarrow 0}\dfrac{P(T\in[t+\mathrm{d}t])}{\mathrm{d}t}=\dfrac{\mathrm{d}F(t)}{\mathrm{d}t}$
Failure repartition function	$F(t)=\int_0^T f(t)\mathrm{d}t=P(T\leq t)$
Survival repartition function	$R(t)=S(t)=1-F(t)=P(T\geq t)=1-\int_0^T f(t)\mathrm{d}t$
Risk (hazard) function	$h(t)=\lim\limits_{\mathrm{d}t\rightarrow 0}\dfrac{P(T\in[t+\mathrm{d}t]\lvert T\geq t)}{\mathrm{d}t}=\dfrac{f(t)}{R(t)}$
Cumulated risk (hazard)	$H(t)=\int_0^t h(s)\mathrm{d}s=\int_0^t \dfrac{f(s)}{R(s)}\mathrm{d}s=-\ln(S(t))$

Table 16.20: **Summary of continuous maintenance analysis functions**

Let us notice again (!) that we will see further statistical mathematical model based on the Kaplan-Meier estimator giving a nonparametric estimation of the survival function!

Before continuing let us give some other definitions of maintenance indicators, the most important are the European Maintenance Standard EN 13306:2010 (I precise it because on the web we can find the best and the worst on the definitions of these reliability indicators...)!

Definitions (#16.7.734):

D1. The "Time Between Maintenance (T.B.M.)" is the contractual time between two visits or maintenance control (not defined in the EN 13306:2010 standard).

D2. The "Mean Operating Time Between Failures (M.O.T.B.F.)" applicable only for repairable items is the expected mean of the operational time of a system between the end of the first failure and the beginning of the next (defined in the EN 13306:2010 standard). In the industry M.O.T.B.F. is also named "Mean Up Time (M.U.T.)".

D3. The "Mean Time Between Failures (M.T.B.F.)" applicable only for repairable items is the expected mean of operational time of a system between the start of two failures (defined in the standard EN 13306:2010). This indicator includes the time of non-operation. In the area of services, the M.T.B.F. is sometimes named "Mean Time Between System Accidents (M.T.B.A.)". In the field of the production lines M.T.B.F. is named "Mean

Time Between Defects (M.T.B.D.)" (we do not stop the production because only one defect was detected as we will see during our study of control charts further below). In the field of computing science the M.T.B.F. is named "Mean Time Between Errors (M.T.B.E.)" (we also rarely stops a software or a website because one bug or error was detected!).

D4. The "Mean Time To Failure (M.T.T.F.)" applicable for repairable or not repairable items is the expected mean of operational time of a system to its first failure (not defined in the standard EN 13306:2010). In fact it is the latter which is calculated most often in tests laboratories.

D5. The "Mean Repair Time (M.R.T.)" applicable only for repairable items is the expected mean of repair time (defined in the standard EN 13306:2010).

D6. The "Mean Time To Restore (M.T.T.R.)" applicable only for repairable items is the expected mean restart time (defined in the standard EN 13306:2010). In the area of services, M.T.T.R. is sometimes named "Mean Time To Restore Service (M.T.T.R.S.)".

D7. The "Mean Down Time (M.D.T.)" is equal to the mathematical expected mean of the time that the system is not operational. This indicator (not defined in the standard EN 13306:2010) therefore includes the M.R.T. It follows that the M.T.B.F. is equal to the sum of the M.O.T.B.F. (M.U.T.) and of the M.D.T.

D8. The "Mean Time To Detection (M.T.T.D.)" is equal to the mathematical expected mean of the time that the system is not detected as being non operational. This indicator (not defined in the standard EN 13306:2010), as well as the M.R.T. is included in the M.D.T.

D9. The "Mean Time to Answer (M.T.T.A.)" is equal to the mathematical expected mean of the time during which the user expected an answer or response of manufacturer after reporting a failure. This indicator (not defined in the standard EN 13306:2010), as well as the M.R.T. and M.T.T.D. are included in the M.T.T.A.

D10. The "Overall Equipment Effectiveness (O.E.E.)" in the field of maintenance is traditionally defined as being simply the ratio of the operational running time and time expected operational performance (not defined in the standard EN 13306:2010).

D11. The "Service Ability (S.A.)" which in the field of maintenance is often given by the following two relations and whose goal is to make it as close as possible to 1 (that is to say to make the M.D.T. approaching zero):

$$\mathrm{SA}=\frac{\mathrm{MTBF}-\mathrm{MDT}}{\mathrm{MTBF}}=\frac{\mathrm{MOTBF}}{\mathrm{MOTBF}+\mathrm{MDT}} \quad (16.7.192)$$

and we can continue to define many others indicators outside the standard...

The below diagram summarizes maybe a little better all these definitions:

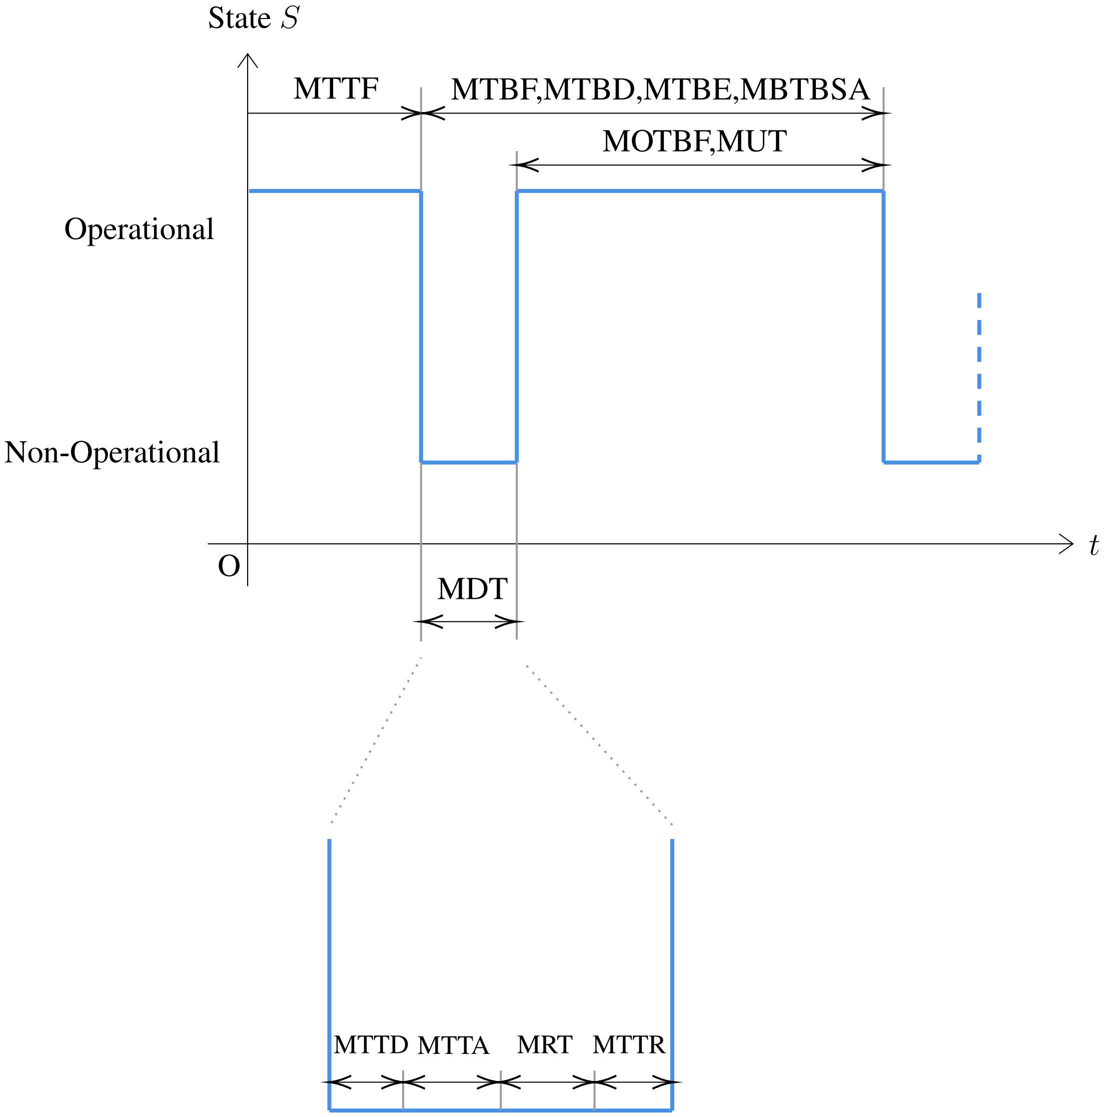

Figure 16.209: **Common reliability indicators**

Remarks

R1. For each of these indicators it will be indicated if external causes have been taken into account or not.

R2. If the tested sample size is very small or just unitary (only one machine), it is customary to use the arithmetic average as an estimator of the expected mean.... Obviously it can lead to huge errors...

R3. It is of course possible from the defined indicators to calculate whether a machine (element) is able to ensure the desired service (such as a number of pieces per year to produce for example!). So not only do these indicators can be measured, but they can therefore also be used to verify the achievement of a desired goal!

R4. In the beginning of the 121st century (holocene calendar) countries should strictly speaking legislate to require all manufacturers to communicate the MTTF of their products so that consumers can make the best choice to buy and compare the values in relation to the guarantee provided! Unfortunately, this is not the case and it would highlight a current bad tradition in the consumer products industry that is to manufacture components whose life revolves around 200,000 hours to ensure industrial renewal of their market.

✍**Example:**

A machine is supposed to work 24/24 hours 7/7 days. It turned up today for $5,020$ hours with 2 stops of a total of 20 hours (thus included in the $5,020\,[\text{h}]$). The conventional indicators relative to the limited information provided are given by:

$$\begin{aligned}
\text{MTBF} &= \frac{5,020}{2} = 2,510\,[\text{h}]\\
\text{MDT} &= \frac{20}{2} = 10\,[\text{h}]\\
\text{MOTBF} = \text{MUT} &= \frac{5,020-20}{2} = 2,500\,[\text{h}]\\
\text{SA} &= \frac{\text{MOTBF}}{\text{MOTBF+MDT}} = \frac{2,500}{2,500+10} \cong 99.6\%
\end{aligned}\tag{16.7.193}$$

The classification of systems in terms of availability commonly leads to 7 classes from "not available" (system available 90% of the time, and therefore unavailable over a month per year) to "ultra available" (available 99.99999% of the time and therefore unavailable only 3 seconds per year): these classes corresponds arbitrarily to the numbers of "9" in the percentage of time that the class systems are available (one year includes $525,600$ minutes for refresh):

Type	Non-availability [min/year]	Percentage availability	Class
non-managed	$50,000$ (~ 3.5 days)	90%	1
managed	$5,000$ (~ 3.5 days)	99%	2
well-managed	500 (~ 8 hours)	99.9%	3
faultily tolerance	50	99.99%	4
high availability	5	99.999%	5
very high availability	0.5	99.9999%	6
very high availability	0.05	99.99999%	7

Table 16.21: **Classes failures in FMEA**

The use of these parameters in the context of reliability framework told us that we have an "approach through average values".

Note however one thing! This is not because an event has a smaller or infinitely less probability than another one that it is less important!! Indeed we must obviously take into account (certainly a little in a empirical way) the gravity of the failure. Thus, a nuclear power plant may well be $1,000$ times more secure than a thermal central in terms of probabilities ... nothings is comparable in terms of severity when a major failure occurs in a nuclear plant! Indeed in the case of a thermal central there may be in the worst case 500 persons affected while with a nuclear power plant that is another story (see Tchernobyl or Fukushima...)!

Let us also note a simple case: Some components (typically electronic) have in their period of a maturity constant failure rate. The cumulative probability distribution of the failure that results is then immediately deducted as the instantaneous hazard function is given by $\lambda(t)=\lambda$ and therefore:

$$F(t)=1-\exp\left(-\int_0^t \lambda(t)\mathrm{d}t\right)=1-e^{-\lambda t} \tag{16.7.194}$$

Let us indicate that we find very often the latter relation in the following form in the literature:

$$1-F(t)=R(t)=e^{-\lambda t} \tag{16.7.195}$$

and then we have well:

$$h(t)=\frac{f(t)}{R(t)}=\frac{\lambda e^{-\lambda t}}{e^{-\lambda t}}=\lambda \tag{16.7.196}$$

To summarize a bit for the exponential law:

$$\boxed{\begin{aligned}F(t)&=1-e^{-\lambda t}\\ f(t)&=\lambda e^{-\lambda t}\\ R(t)&=e^{-\lambda t}\\ h(t)&=\lambda\end{aligned}} \tag{16.7.197}$$

And as we have:

$$\text{MTBF}=\int_0^{+\infty} tf(t)\mathrm{d}t=\int_0^{+\infty} t\lambda e^{-\lambda t}\mathrm{d}t \tag{16.7.198}$$

And we proved in the section of Differential and Integral Calculus that (see page 1536):

$$\int t\lambda e^{-\lambda t}\mathrm{d}t=\lambda e^{-\lambda t}\left(-\frac{1}{\lambda}-\frac{1}{\lambda^2}\right) \tag{16.7.199}$$

Therefore:

$$\text{MTBF}=\int_0^{+\infty} t\lambda e^{-\lambda t}\mathrm{d}t=-\lambda\left(-\frac{1}{\lambda^2}\right)=\frac{1}{\lambda} \tag{16.7.200}$$

The previous hazard and survival are then graphically of the following form:

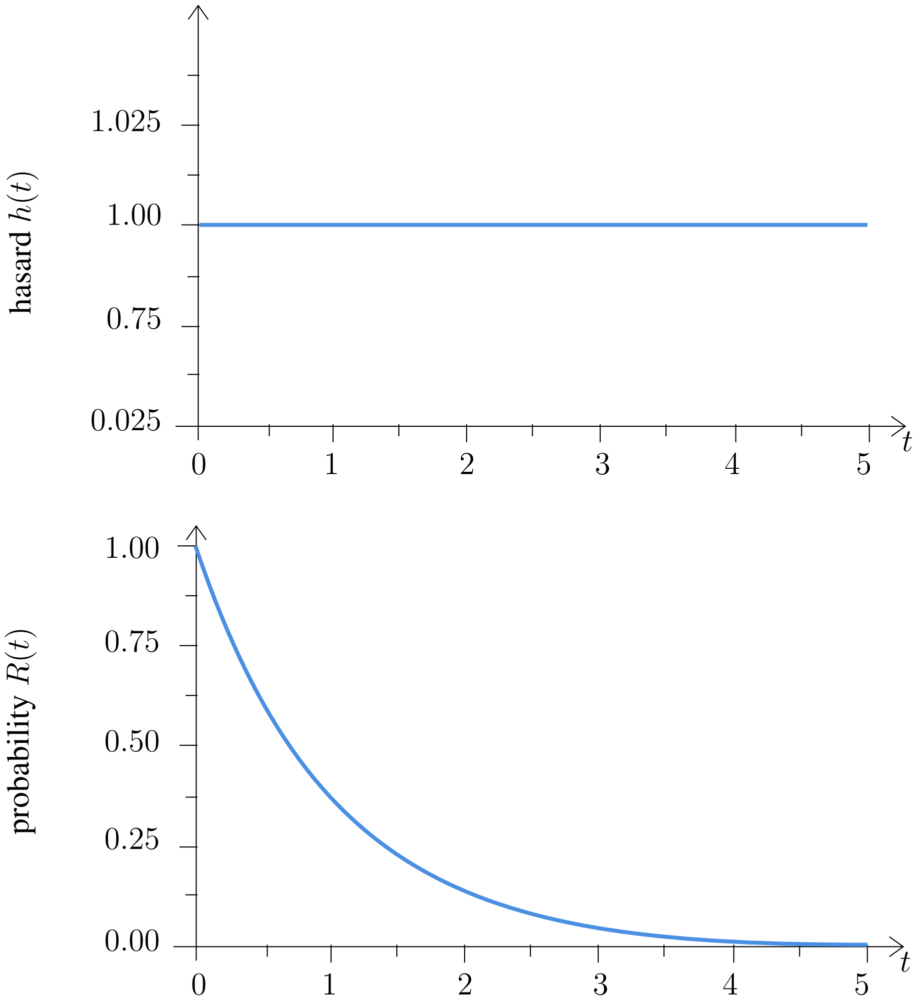

Figure 16.210: **Plot of the hazard function and reliability of the exponential law**

The density function of faulty components at time t is obviously:

$$f(t)=\frac{\mathrm{d}F(t)}{\mathrm{d}t}=\lambda e^{-\lambda t} \qquad (16.7.201)$$

It therefore follows an exponential law! This law and its moments are known to us (see section Statistics page 751). It then becomes easier to determine the M.T.T.F. and its standard deviation (inverse of failure rate) and also a confidence interval for it.

Furthermore, if we calculate the reliability $R(t)$ at the time corresponding to the M.T.T.F. (inverse of the failure rate in the case of the exponential law) we will always obtain a cumulative probability of $F(t)=1-e^{-1}=36.8\%$ (so basically almost one chance on three to run at this time and 2 chances on 3 to be down) and not 50% as sometimes we can intuitively think (this is the case only if the probability distribution is symmetric).

Since the technical tables of reliability in the industry almost always assume the reliability rate to be constant then we better understand the importance of it (we will have an example in our presentation further below of topological systems).

Also remember that we saw in the section of Probability (see page 480) that if we have a set of independent events (independent mechanisms) with a given probability, then the probabilities calculated on the whole as a globality involve the multiplication of probabilities!

Therefore in a mechanism having independent but essential parts (system said to be "serial system") the overall reliability density function will be equal to the multiplication of cumulative probability distributions $R(t)$ and which is therefore equivalent in the case of an exponential distribution having a single exponential law whose overall failure rate is equal to the sum of the various parts failure rate (i.e. $e^{\lambda_1} \cdot e^{\lambda_2}) \cdot \ldots = e^{\lambda_1 + \lambda_1 + \cdots}$!

Another example... in mechanics, where the phenomenon of wear is the cause of the failure, the failure rate is often linear (so it increases steadily over time and is not zero at the initial starting of the device):

$$\lambda(t) = at + b \tag{16.7.202}$$

Then:

$$F(t) = 1 - \exp\left(-\int_0^t (at+b)\,\mathrm{d}t\right) = 1 - \exp\left(-\frac{at^2}{2} - bt\right) \tag{16.7.203}$$

Therefore:

$$f(t) = \frac{\mathrm{d}F(t)}{\mathrm{d}t} = (at+b)\exp\left(-\frac{at^2}{2} - bt\right) \tag{16.7.204}$$

As (for an equipment whose repair time is negligible):

$$\text{MTBF} = \int_0^{+\infty} R(t)\mathrm{d}t = \int_0^{+\infty} \exp\left(-\frac{at^2}{2} - bt\right) \mathrm{d}t \tag{16.7.205}$$

this integral can be calculated by numerical integration methods (see section Statistics page 6621). Therefore, in practice, we prefer to take closed form type of law thanks to goodness of fit type statistical tests (see section Statistics page 1111), such as the Weibull distribution (see just below for detailed developments), which is a little bit the trash to put everything in the field of reliability engineering...

In common and free public reliability data banks on the market are normally given: the name of the material or component, the M.T.B.F., the average default rate, the statistical heritage (...), a multiplicative factor of failure rates depending on the environment or usage constraints.

16.7.3.2.1 Average Failure Rate

As we have seen, the hazard function usually varies with time. What is sometimes of interest to the practitioner is the average rate of failures within a given time interval, which is clearly specified by the functional specification. We then define the "average failure rate" as:

$$\begin{aligned}\text{AFR}(t_1,t_2) &= \frac{\displaystyle\int_{t_1}^{t_2} h(t)\mathrm{d}t}{t_2 - t_1} = \frac{\displaystyle\int_{t_1}^{t_2} h(t)\mathrm{d}t}{t_2 - t_1} = \frac{H(t_2) - H(t_1)}{t_2 - t_1}\\ &= \frac{-\ln(R(t_2)) - (-\ln(R(t_1)))}{t_2 - t_1} = \frac{\ln(R(t_1)) - \ln(R(t_2))}{t_2 - t_1}\end{aligned} \tag{16.7.206}$$

Therefore:

$$\boxed{\text{AFR}(t_1,t_2)=\frac{\ln(R(t_1))-\ln(R(t_2))}{t_2-t_1}} \tag{16.7.207}$$

This rate, denoted $\text{AFR}(t_1,t_2)$, is a single number that can be used as a specification or target for the population failure rate over that interval. If t_1 is 0, it is dropped from the expression. Thus, for example, $\text{AFR}(40,000)$ would be the average failure rate for the population over the first $40,000$ hours of operation.

An interval often taken in practice is 0 to τ. Then in comes:

$$\text{AFR}(0,\tau)=\text{AFR}(\tau)=\frac{H(\tau)}{\tau}=\frac{-\ln(R(\tau))}{\tau} \tag{16.7.208}$$

Sometimes in the literature considering the following variation:

$$\text{AFR}(\tau)=\frac{-\ln(R(\tau))}{\tau}=\frac{-\ln(1-F(\tau))}{\tau} \tag{16.7.209}$$

and considering that $F(\tau)$ is small, by a Taylor development to the second order, we have:

$$\text{AFR}(\tau)\cong\frac{-(0-F(\tau))}{\tau}=\frac{F(\tau)}{\tau} \tag{16.7.210}$$

We can transform the antecedent relations into a failure distribution function:

$$-\tau\text{AFR}(\tau)=\ln(R(\tau)) \tag{16.7.211}$$

and therefore:

$$e^{-\tau\text{AFR}(\tau)}=R(\tau)=1-F(\tau) \tag{16.7.212}$$

And finally:

$$\boxed{F(\tau)=1-e^{-\tau\text{AFR}(\tau)}} \tag{16.7.213}$$

16.7.3.3 Weibull Distribution

Once again maintenance techniques use probability and statistics so we refer the reader to the section of the same name in this textbook. However, there exists in the field of maintenance (and not only!) a probability density function widely used and named "Weibull law".

It seemed to be completely empirical and defined by:

$$f(x)=\frac{\beta}{\eta}\left(\frac{x-\gamma}{\eta}\right)^{\beta-1}e^{-\left(\frac{x-\gamma}{\eta}\right)^{\beta}} \tag{16.7.214}$$

where $f(x)\geq 0, x\geq 0$ with $\beta>0,\eta>0,-\infty<\gamma<+\infty$ that are named respectively "scale parameter" η, "shape parameter" β and "location parameter" γ.

Remark

The engineers in corporations have to refer to *IEC 61649 Weibull analysis* to make a standardized usage of this law!

The Weibull distribution is often written as following by putting $x:=x-\gamma$, $\eta:=\beta$, $\beta:=\alpha$ (in this case the location parameter is implicitly posed as equal to zero):

$$f(x)=\frac{\alpha}{\beta}\frac{x^{\alpha-1}}{\beta^{\alpha-1}}e^{\left(-\frac{x^{\alpha}}{\beta^{\alpha}}\right)}=\frac{\alpha}{\beta^{\alpha}}x^{\alpha-1}e^{\left(-\left(\frac{x}{\beta}\right)^{\alpha}\right)} \tag{16.7.215}$$

It can be calculated in the English version of Microsoft® Excel® 11.8346 in this latter form using `WEIBULL( )` function.

The Weibull law can be seen as a generalization of the exponential distribution function (we'll see why later!) with the advantage that it is possible to play with the three parameters to obtain almost anything.

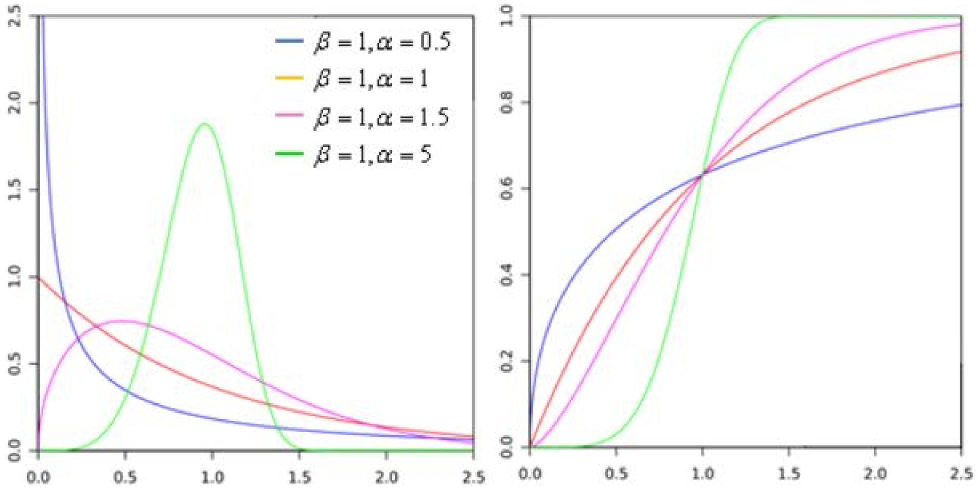

Figure 16.211: Weibull density and distribution functions for different α values (source: Wikipedia)

By cancelling the location parameter γ, we get the "two-parameters Weibull distribution":

$$f(x)=\frac{\beta}{\eta}\left(\frac{x}{\eta}\right)^{\beta-1}e^{-\left(\frac{x}{\eta}\right)^{\beta}} \tag{16.7.216}$$

which has an important practical application and for which we have calculated the estimators of the parameters in the Statistics section (see page 827).

By assuming again $\gamma=0$ and assuming also that we have $\beta=C=c^{te}$ we get "one-parameter Weibull distribution" (it's a little stupid as a definition but never-mind...):

$$f(x)=\frac{C}{\eta}\left(\frac{x}{\eta}\right)^{C-1} e^{-\left(\frac{x}{\eta}\right)^C} \tag{16.7.217}$$

where the only unknown parameter is the scale parameter η. We assume that the parameter β is known a priori from past experiences on similar samples. Notice that the two-parameter Weibull distribution function a is the derivative of the following repartition function (cumulative probability function or "unreliability" as say some practitioners in the field of maintenance...) where there are three successive interiors derivatives to fall back on the Weibull distribution function ... which is a good application of this we saw in the section of Differential and Integral Calculus:

$$F(x)=1-e^{\left(-\left(\frac{x}{\beta}\right)^\alpha\right)} \tag{16.7.218}$$

It follows therefore in reliability engineering that in this special case, we have then:

$$R(t)=1-F(t)=F(x)=1-\left(1-e^{\left(-\left(\frac{t}{\beta}\right)^\alpha\right)}\right)=e^{\left(-\left(\frac{t}{\beta}\right)^\alpha\right)} \tag{16.7.219}$$

We also find sometimes this relation in the literature in the form:

$$\begin{aligned}f(x)&=C\frac{1}{\eta}\left(\frac{1}{\eta}\right)^{C-1} x^{C-1}e^{-\left(\frac{x}{\eta}\right)^C}=C\left(\frac{1}{\eta}\right)^{C} x^{C-1}e^{\left(-\left(\frac{1}{\eta}\right)^C x^C\right)}\\&=abx^{\alpha-1}e^{-bx^c}\end{aligned} \tag{16.7.220}$$

Note that if $\beta=1$, then we fall back on an exponential distribution of mean η:

$$f(x)=\frac{\beta}{\eta}\left(\frac{x}{\eta}\right)^{\beta-1} e^{-\left(\frac{x}{\eta}\right)^\beta}=\frac{1}{\eta}e^{-\frac{x}{\eta}} \tag{16.7.221}$$

The M.T.B.F. is then given by the mean of the Weibull distribution with non-zero γ:

$$\mathrm{E}(X)=\int\limits_{\gamma}^{+\infty} xf(x)\mathrm{d}x=\int\limits_{\gamma}^{+\infty} x\frac{\beta}{\eta}\left(\frac{x-\gamma}{\eta}\right)^{\beta-1} e^{-\left(\frac{x-\gamma}{\eta}\right)^\beta}\mathrm{d}x \tag{16.7.222}$$

Let us put:

$$t=\left(\frac{x-\gamma}{\eta}\right)^\beta \quad\Rightarrow\quad \mathrm{d}t=\frac{\beta}{x-\gamma}\left(\frac{x-\gamma}{\eta}\right)^\beta\mathrm{d}x=\frac{\beta}{x-\gamma}t\mathrm{d}x \quad\Rightarrow\quad \mathrm{d}x=\frac{x-\gamma}{\beta}t^{-1}\mathrm{d}t \tag{16.7.223}$$

with:

$$t=\left(\frac{x-\gamma}{\eta}\right)^\beta \Leftrightarrow t^{1/\beta}\eta+\gamma=x \tag{16.7.224}$$

What gives:

$$\begin{aligned}\mathrm{E}(X)&=\int\limits_0^{+\infty} x\frac{\beta}{\eta}t\left(\frac{x-\gamma}{\beta}\right)e^{-t}\left(\frac{x-\gamma}{\beta}t^{-1}\right)\mathrm{d}t\\&=\int\limits_0^{+\infty} xe^{-t}\mathrm{d}t=\int\limits_0^{+\infty}(t^{1/\beta}\eta+\gamma)e^{-t}\mathrm{d}t=\eta\int\limits_0^{+\infty}t^{1/\beta}e^{-t}\mathrm{d}t+\gamma\end{aligned}\tag{16.7.225}$$

The first integral above is already known to us, we have already study it in the section of Integral and Differential Calculus (see page 1574). This is the gamma Euler function:

$$\Gamma_{-1}(x)=\int\limits_0^{+\infty}t^{x-1}e^{-t}\mathrm{d}t=x!\quad\Rightarrow\quad\Gamma_{-1}\left(\frac{1+\beta}{\beta}\right)=\int\limits_0^{+\infty}t^{1/\beta}e^{-t}\mathrm{d}t\tag{16.7.226}$$

Therefore we have finally:

$$\mathrm{E}(X)=\text{MTBF}=\eta\int\limits_0^{+\infty}t^{1/\beta}e^{-t}\mathrm{d}t+\gamma=\gamma+\eta\Gamma_{-1}\left(\frac{1+\beta}{\beta}\right)\tag{16.7.227}$$

By cancelling the location parameter γ we get the following current case in reliability:

$$\boxed{\mathrm{E}(X)=\text{MTBF}=\eta\Gamma_{-1}\left(1+\frac{1}{\beta}\right)}\tag{16.7.228}$$

Remark

If then by chance $\beta^{-1}\in\mathbb{N}$, then as we have proved during our study of the gamma Euler function:

$$\mathrm{E}(X)=\text{MTBF}=\gamma+\eta\Gamma_0\left(\frac{1}{\beta}\right)=\gamma+\eta\left(\frac{1}{\beta}\right)!\tag{16.7.229}$$

In case where $\beta^{-1}\in\mathbb{R}$ we must make use of the numerical tables obtained by the algorithms seen in the section of Theoretical Computing.

Similarly:

$$\begin{aligned}\mathrm{E}(X^2)&=\int\limits_0^{+\infty}x^2f(x)\mathrm{d}x=\int\limits_0^{+\infty}(t^{1/\beta}\eta+\gamma)^2e^{-t}\mathrm{d}t\\&=\eta^2\Gamma_{-1}\left(\frac{\beta+2}{\beta}\right)+2\eta\gamma\Gamma_{-1}\left(\frac{\beta+1}{\beta}\right)+\gamma^2\end{aligned}\tag{16.7.230}$$

Finally when the location parameter is equal to zero, we get:

$$\sigma^2=\mathrm{V}(X)=\mathrm{E}(X^2)-\mathrm{E}(X)^2=\eta^2\left(\Gamma_{-1}\left(\frac{\beta+2}{\beta}\right)-\Gamma_{-1}\left(\frac{\beta+1}{\beta}\right)^2\right)\tag{16.7.231}$$

Remark

Some specialists, when it is made usage of two moments of order two in the probabilistic analysis of reliability, sometimes talk about "mean square approach method"...

To conclude on the Weibull law, note that it is customary to consider four important and relevant situations of the Weibull distribution based on the values of its parameters:

1. Survival density function looks like a rapid exponential decay and therefore the hazard function (failure rate) is high initially and decreases over time (first portion of the "bathtube" hazard function/failure rate). This is typically the situation where the failures are early because failures occur in the initial period of the life of the product.
2. Survival density looks like an exponential decay and therefore the hazard function (failure rate) is constant over time (second portion of the "bathtube" hazard function/failure rate). This is typically a situation where failures are random and sources of multiple causes. In this situation, the Weibull models the phase of "useful life" of the product.
3. The survival density function rises to a peak and then decreases with a fairly pronounced asymmetry (high density on the left) and therefore the hazard function (failure rate) increases rapidly at first and eventually stabilize. This is typically a situation where the initial wear is very fast.
4. The survival density function looks like a half large Gaussian Law and the hazard function (failure rate) is growing rapidly (exponential type of growth). This is typically the situation where we reach the end of life of a set of parts (third portion of the "bathtube" hazard function/failure rate).

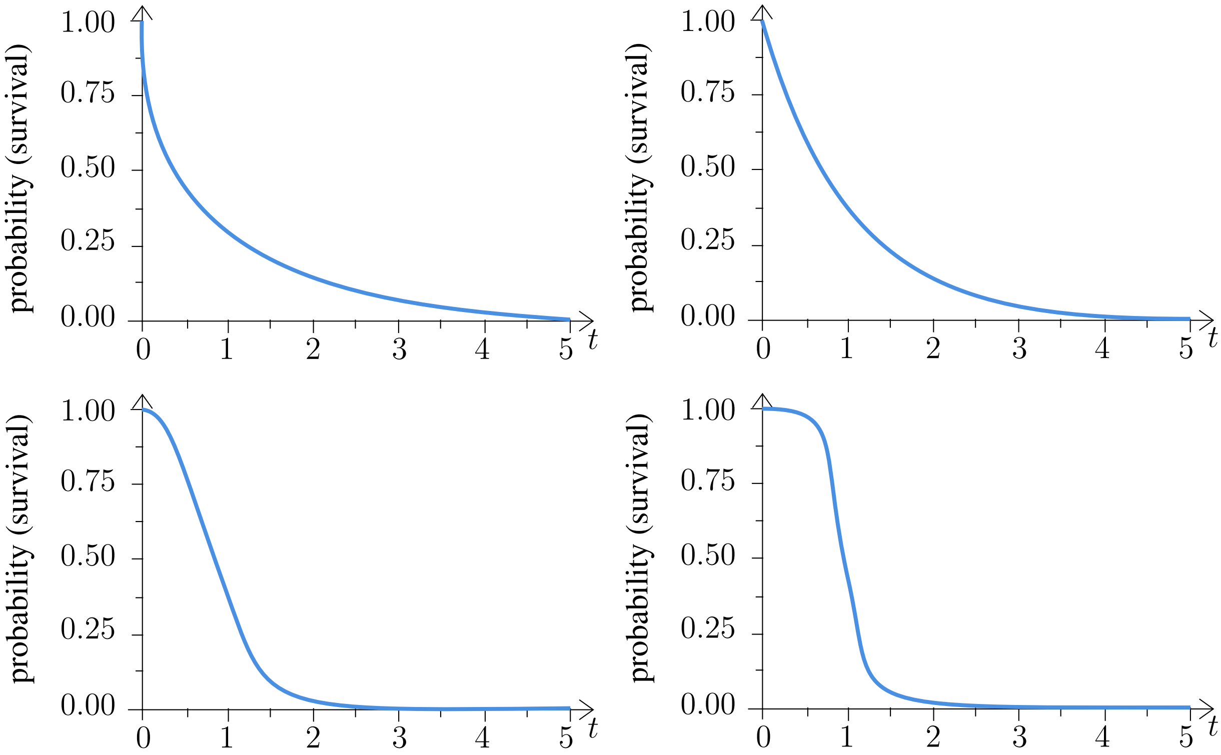

Figure 16.212: **Plot of four Weibull survival functions for different parameter values**

And with the corresponding hazard functions:

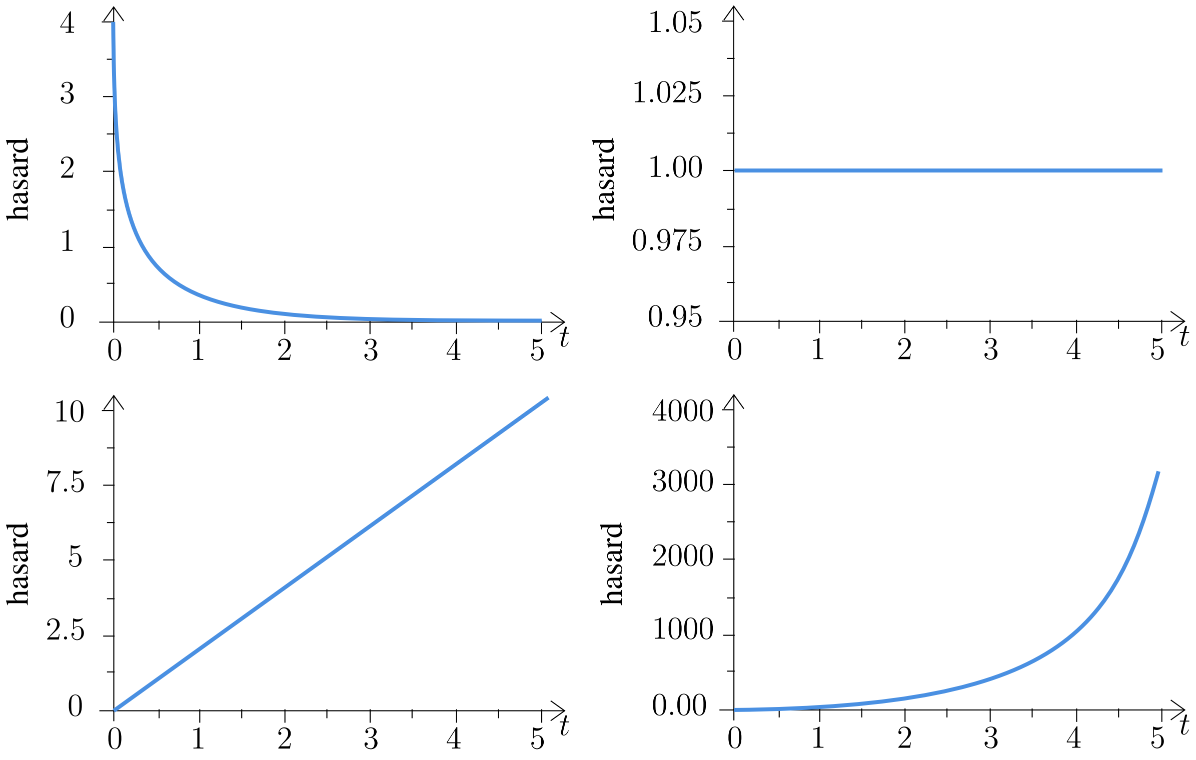

Figure 16.213: **Plot of four Weibull hazard functions for different parameter values**

To summarize we have therefore for the Weibull distribution with two parameters:

$$\boxed{\begin{aligned}
F(x)&=1-e^{-\left(\frac{x}{\eta}\right)^{\beta}}:=1-e^{-(\lambda x)^{\beta}}=1-e^{-(\lambda t)^{\beta}}=F(t)\\
f(x)&=\frac{\beta}{\eta}\left(\frac{x}{\eta}\right)^{\beta-1}e^{-\left(\frac{x}{\eta}\right)^{\beta}}=\lambda\beta(\lambda t)^{\beta-1}e^{-(\lambda t)^{\beta}}=\lambda^{\beta}\beta t^{\beta-1}e^{-(\lambda t)^{\beta}}=f(t)\\
R(x)&=e^{-\left(\frac{x}{\eta}\right)^{\beta}}=e^{-(\lambda t)^{\beta}}=R(t)\\
h(x)&=\frac{\beta}{\eta}\left(\frac{x}{\eta}\right)^{\beta-1}=\lambda^{\beta}\beta t^{\beta-1}=h(t)
\end{aligned}} \qquad (16.7.232)$$

So we see that if we put $\beta=1$ we fall back on all the reliability functions based on the exponential law.

✍**Example:**

A car manufacturer knows the distribution of time until the first failure of one of its vehicles under average driving conditions. The Weibull distribution function obtained by the tests is a two-parameter Weibull function given by:

$$f(x)=1-e^{-\left(\frac{x}{\eta}\right)^{\beta}}=1-e^{-\left(7.7\cdot 10^{-6}x\right)^{1.22}} \tag{16.7.233}$$

where x is the distance in kilometres of the tested vehicles. If we want to find the warranty in kilometres encompassing 5% of the vehicles, then we must solve the equation:

$$1-e^{-\left(7.7\cdot 10^{-6}x\right)^{1.22}}=5\% \tag{16.7.234}$$

That is to say with some elementary algebra:

$$t=\frac{\left[-\ln(95\%)\right]^{1/1.22}}{7.7\cdot 10^{-6}}=11,138\,[\text{km}] \tag{16.7.235}$$

16.7.3.3.1 Two-parameter Weibull distribution linearisation

In the case of the 2-parameter Weibull, the CDF (also the "unreliability" for recall) is given as we have just seen by (we use the temporal variables t instead of x now):

$$F(t)=1-e^{-\left(\frac{t}{\eta}\right)^{\beta}} \tag{16.7.236}$$

This function can then be linearised (i.e., put in the common form of $y=ax+b$ format) as follows for practical regression (adequation) analysis.

We start from the previous relation and rearrange the whole:

$$1-F(t)=e^{-\left(\frac{t}{\eta}\right)^{\beta}} \tag{16.7.237}$$

and we take the natural logarithm:

$$\ln(1-F(t))=\ln\left[e^{-\left(\frac{t}{\eta}\right)^{\beta}}\right] \tag{16.7.238}$$

Therefore:

$$\ln(1-F(t))=-\left(\frac{t}{\eta}\right)^{\beta} \tag{16.7.239}$$

Rearranging and taking the natural logarithm again we get:

$$\ln\left(-\ln(1-F(t))\right)=\beta\left(\ln\left(\frac{t}{\eta}\right)\right) \tag{16.7.240}$$

Using the properties of the logarithm (see section Functional Analysis page 2284):

$$\boxed{\ln\left(\ln\left(\frac{1}{1-F(t)}\right)\right)=\beta\ln(t)-\beta\ln(\eta)} \tag{16.7.241}$$

Then by setting:

$$y=\ln\left(\ln\left(\frac{1}{1-F(t)}\right)\right) \tag{16.7.242}$$

and:

$$x=\ln(t) \tag{16.7.243}$$

the equation can then be rewritten as:

$$y=\beta x-\beta\ln(\eta) \tag{16.7.244}$$

which is now a linear equation with a slope of:

$$a=\beta \tag{16.7.245}$$

and an intercept of:

$$b=-\beta\ln(\eta) \tag{16.7.246}$$

✍**Example:**

Let us now calculate as application example the Average Failure Rate of this Weibull law:

$$\begin{aligned}\text{AFR}(t_1,t_2)&=\frac{\ln(R(t_1))-\ln(R(t_2))}{t_2-t_1}=\frac{\ln\left(e^{-\left(\frac{t_1}{\eta}\right)^\beta}\right)-\ln\left(e^{-\left(\frac{t_2}{\eta}\right)^\beta}\right)}{t_2-t_1}\\&=\frac{-\left(\frac{t_1}{\eta}\right)^\beta-\left(-\left(\frac{t_2}{\eta}\right)\right)}{t_2-t_1}=\frac{\left(\frac{t_2}{\eta}\right)^\beta-\left(\frac{t_1}{\eta}\right)^\beta}{t_2-t_1}\end{aligned} \tag{16.7.247}$$

In the case of a time interval of the type $[0,\tau]$ we then have:

$$\text{AFR}(t_1,t_2)=\frac{\left(\frac{\tau}{\eta}\right)^\beta}{\tau}=\frac{1}{\eta}\left(\frac{\tau}{\eta}\right)^{\beta-1} \tag{16.7.248}$$

16.7.3.4 Topology of Systems

When working with non-repairable real systems (mechanical, electronic or other), we face different constraints depending on the type of installation that we have. The study of such systems is also named "Reliability Block Diagram[21]".

The two main assumptions of the study of these systems are:

1. The failure of a component is independent of the others.
2. No breakdowns arrive at the same time.

We recognize five main topologies in which each component is represented by a block:

T1. Serial topology:

If only one component fails the whole system does not work anymore (the examples are so numerous and easy to find that we did not mention any of them).

So in the hypothesis that the failure of a component is independent of the other, the cumulative probability of failure is the product of cumulative probabilities (see section Probabilities page 480).

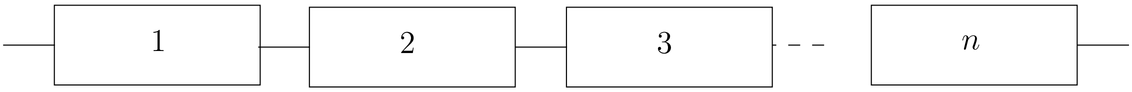

Figure 16.214: **Serial topology**

In the study of probabilistic fault tree (see further below), this topology corresponds to an OR gate with n inputs, as it is sufficient that one blocks may be down so that the output no longer works:

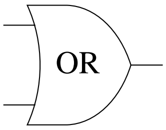

Figure 16.215: **OR gate**

As often practitioners made use of the exponential distribution!

The multiplication of several terms of the accumulated probabilities are relatively long to write, we prefer the use of the cumulative probability of reliability R.

Thus, the reliability (probability of operation) of a series system is given by:

$$\boxed{R_S = 1 - F_S = \prod_{i=1}^{n} R_i} \tag{16.7.249}$$

---

[21] The mathematical tools that are presented and build here can also be used to calculate the reliability of humans communication chains. This explained quite well why testimonials - oral or written - have zero scientifical values (but however don't have zero juridical value...).

Which brings us well to zero reliability if at least one block has zero reliability.

What is traditionally noted in the field:

$$\varphi(x)=\min(x_1,x_2,\ldots,x_n)=\prod_{i=1}^{n}x_i \tag{16.7.250}$$

Remark

The attentive reader will have noticed that the serial system is always less reliable than its least reliable component!

In the case of electronic components, the failure rate is often regarded as constant for simplicity and the density function is then that of an exponential law (solution of a well known differential equation):

$$f(t)=\lambda e^{-\lambda t} \tag{16.7.251}$$

However, we have proved that in the case of a non-repairable system:

$$\mathrm{E}(t)=\int_{0}^{+\infty}tf(t)\mathrm{d}t=\text{MTBF} \tag{16.7.252}$$

And as we have proved it in the section Statistics (see page 751) the expected mean of the exponential law:

$$\mathrm{E}(t)=\int_{0}^{+\infty}t\lambda e^{-\lambda t}\mathrm{d}t=\frac{1}{\lambda}=\text{MTBF} \tag{16.7.253}$$

We have also proved earlier that:

$$f(t)=\frac{\mathrm{d}F}{\mathrm{d}t}=-\frac{\mathrm{d}R}{\mathrm{d}t} \tag{16.7.254}$$

Therefore:

$$R(t)=e^{-\lambda t}=e^{-\frac{1}{\text{MTBF}}t} \tag{16.7.255}$$

So for a series constant failure rate system:

$$R_S=\prod_i e^{-\lambda_i t}=\prod_i e^{-\frac{1}{\text{MTBF}_i}t}=e^{-\left(\sum_i\frac{1}{\text{MTBF}_i}\right)t} \tag{16.7.256}$$

Thus, in this special case:

$$\text{MTBF}_S=\left(\sum_{i=1}^{n}\frac{1}{\text{MTBF}_i}\right)^{-1} \tag{16.7.257}$$

or written differently:

$$\lambda_S=\sum_{i=1}^{n}\lambda_i \tag{16.7.258}$$

and... the problem is that the a lot of Internet pages that talk about serial topology systems (or parallel) implicitly use an exponential law, this is why sometimes beginner practitioners use this last relation without having studied the underlying mathematical details and this brings them to huge errors in the reliability of the products their are in charge to analyse.

T2. Parallel topology:

Unlike the previous system, parallel system continues to operate if at least one component still works (typically redundancy systems in airplanes, rockets, nuclear power plants or critical computer systems). Therefore is considered as the most important system to study.

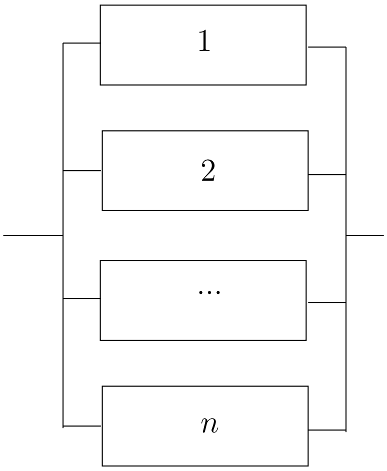

Figure 16.216: **Parallel topology**

In the study of probabilistic fault tree (see further below), this topology corresponds to an AND gate with n inputs, as it is necessary that all blocks are down so that the output no longer works:

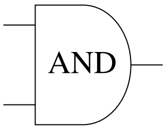

Figure 16.217: **AND gate**

In other words, it stops working if and only if the cumulated probability failure is equal to:

$$\prod_{i=1}^{n} F_i = \prod_{i=1}^{n} (1-R_i) = 1 \tag{16.7.259}$$

So it comes immediately for a purely parallel system:

$$\boxed{R_P = 1 - \prod_{i=1}^{n} F_i = 1 - \prod_{i=1}^{n} (1-R_i)} \tag{16.7.260}$$

In the very common case where the blocks are redundant with equal reliability $R_i = R$ and that R_P is fixed by the customer we must found a component such that is reliability is therefore equal to:

$$\boxed{R_P = 1 - \sqrt[n]{1 - R_P}} \tag{16.7.261}$$

Remark

In Project management this type of parallel structure is typically used when one wishes to know the total reliability of several supplier of identical parts (in this case if any of them has delays or other problems, the others must afford to mitigate the negative impact) knowing or believing obviously the reliability of each...

We therefore have the parallel system whose components have a constant failure rate and all identical (to simplify the study):

$$R_P = 1 - \prod_{i=1}^{n}(1 - R_i) = 1 - \prod_{i=1}^{n}\left(1 - e^{-\lambda t}\right) \tag{16.7.262}$$

Therefore we have:

$$\text{MTBF}_S = \int_0^{+\infty}\left[1 - \prod_{i=1}^{n}\left(1 - e^{-\lambda t}\right)\right]\mathrm{d}t = \int_0^{+\infty}\left[1 - \left(1 - e^{-\lambda t}\right)^n\right]\mathrm{d}t \tag{16.7.263}$$

If we put:

$$u = 1 - e^{-\lambda t} \quad \Rightarrow \quad \mathrm{d}u = \lambda e^{-\lambda t}\mathrm{d}t = \lambda(1 - u)\mathrm{d}t \tag{16.7.264}$$

and replacing in the prior-previous expression we get:

$$\text{MTBF}_S = \int_0^1 \frac{1 - u^n}{\lambda(1 - u)}\mathrm{d}u = \frac{1}{\lambda}\int_0^1 \frac{u^n - 1}{u - 1}\mathrm{d}u \tag{16.7.265}$$

As far as we know is not possible to integrate this latter relation, but if we compared for different values of n fixed then we see quickly that:

$$\text{MTBF}_S = \frac{1}{\lambda}\sum_{i=1}^{n}\frac{1}{i} \tag{16.7.266}$$

or written in another way:

$$\lambda_S = \lambda\left(\sum_{i=1}^{n}\frac{1}{i}\right)^{-1} \tag{16.7.267}$$

Let us still do the detailed development for a parallel system with two components whose failure rate is constant and not identical. For this, we start from the relation proved earlier above:

$$R_P = 1 - \prod_{i=1}^{n} F_i = 1 - \prod_{i=1}^{n}(1 - R_i) \tag{16.7.268}$$

Either in the case where n is equal to 2, we have:

$$R_P = 1-(1-R_1)(1-R_2) = R_1+R_2-R_1R_2 \tag{16.7.269}$$

and therefore:

$$\begin{aligned}
\text{MTBF}_S &= \int\limits_0^{+\infty}\left[1-\prod_{i=1}^{2}(1-R_i)\right]\text{d}t = \int\limits_0^{+\infty}(R_1+R_2-R_1R_2)\text{d}t \\
&= \int\limits_0^{+\infty} e^{-\lambda_1 t}\text{d}t + \int\limits_0^{+\infty} e^{-\lambda_2 t}\text{d}t - \int\limits_0^{+\infty} e^{-\lambda_1 t}e^{-\lambda_2 t}\text{d}t \\
&= \int\limits_0^{+\infty} e^{-\lambda_1 t}\text{d}t + \int\limits_0^{+\infty} e^{-\lambda_2 t}\text{d}t - \int\limits_0^{+\infty} e^{-(\lambda_1+\lambda_2) t}\text{d}t \\
&= -\frac{1}{\lambda_1}e^{-\lambda_1 t}\Big|_0^{+\infty} - \frac{1}{\lambda_2}e^{-\lambda_2 t}\Big|_0^{+\infty} + -\frac{1}{\lambda_1+\lambda_2}e^{-(\lambda_1+\lambda_2)t}\Big|_0^{+\infty} = \frac{1}{\lambda_1}+\frac{1}{\lambda_2}-\frac{1}{\lambda_1+\lambda_2}
\end{aligned} \tag{16.7.270}$$

So if $\lambda_1=\lambda_2$, we have:

$$\text{MTBF}_S = \frac{1}{\lambda}+\frac{1}{\lambda}-\frac{1}{\lambda+\lambda} = \frac{2}{\lambda}-\frac{1}{2\lambda} = \frac{3}{2\lambda} \tag{16.7.271}$$

Therefore:

$$\lambda_S = \frac{2}{3}\lambda \tag{16.7.272}$$

Before continuing with other topologies, here is an example of a small school assignment (with solution!) mixing parallel/serial topology that shows that this does not apply only to machines.

✍**Example:**

A laborant must perform three different tests on a sample set: Tests A, B and C in the given order! We know that the laborant miss the test A one out of four times but may start it again 2 times in case of failure (so they can do it 3 times in total), they succeed the test B in 96% of times and may also start it again only once on failure (so they can do it 2 times in total), they fail the test C half of time and can not start it again. What is the probability that a laborant having successfully made the 3 lab tests in only one time (without failed)?

To solve this example we have to see each of the reproducible test as a parallel process and all the tests as a serial process. We then have the total probability that is given by:

$$R_P = \underbrace{\underbrace{\left(1-\prod_{i=1}^{3}F_{A,i}\right)}_{R_{S,A,\text{parallel}}}\underbrace{\left(1-\prod_{i=1}^{2}F_{B,i}\right)}_{R_{S,B,\text{parallel}}}(1-F_C)}_{R_A R_B R_C} \tag{16.7.273}$$

$$= \left(1-\left(\frac{1}{4}\right)^3\right)\left(1-(4\%)^2\right)(1-50\%) = 41.34\%$$

T3. Topology k/n: This system works if k out of n components of same reliability law R still work. This is typically the case of RAID hard disks computer where it is necessary to more than one to always works in the end and this number is determined by the volume of data. It is also operating principle of redundancy voting system on airplanes where we have a $2/3$ system named "triplex".

We then have the following schematic representation:

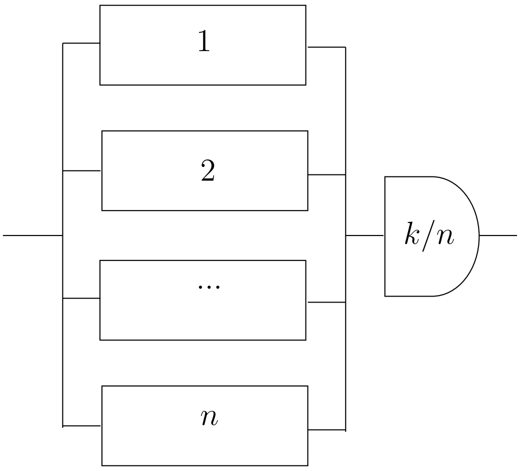

Figure 16.218: k/n **topology**

In the study of probabilistic fault tree (see further below), this topology corresponds to a k-OR (voting OR), as it is necessary that k blocks are down so that the output no longer works:

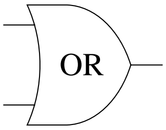

Figure 16.219: **Gate** k**-OR (voting OR)**

Therefore seek the cumulative probability law of reliability returns to the question of the cumulative probability of having k elements that work among n that are indistinguishable.

This therefore is equivalent to use the binomial distribution (see section Statistics page

658) for which we have proved that the cumulative probability was given by:

$$\boxed{R_{k/n}=\sum_{x=k}^{n}C_x^nR^x(1-R)^{n-x}} \tag{16.7.274}$$

This relationship is extremely important in the practice of reliability engineering !!! We notice as well as for $k=n$ we find the reliability of a series system whose elements all have the same reliability:

$$R_{k/n}=\sum_{x=n}^{n}C_x^nR^x(1-R)^{n-x}=C_n^nR^n(1-R)^{n-n}=\frac{n!}{n!(n-n!)}R^n=R^n \tag{16.7.275}$$

And for $k=1$, we fall back on the reliability of a parallel system whose elements all have the same reliability (remember the properties of the binomial coefficient in the section Calculus if necessary):

$$\begin{aligned}R_{k/n}&=\sum_{x=1}^{n}C_x^nR^x(1-R)^{n-x}=\sum_{x=0}^{n}C_x^nR^x(1-R)^{n-x}-C_0^nR^0(1-R)^{n-0}\\&=(R+(1-R))^n-C_0^n(1-R)^n=1^n-(1-R)^n=1-(1-R)^n\end{aligned} \tag{16.7.276}$$

✍**Example:**

In the case of the triplex, we have therefore:

$$\begin{aligned}R_{k/n}&=\sum_{x=2}^{3}C_x^nR^x(1-R)^{n-x}=\sum_{x=2}^{3}\frac{3!}{x!(3-x)!}R^x(1-R)^{3-x}\\&=\frac{3!}{2!(3-2!)}R^2(1-R)^{3-2}+\frac{3!}{3!(3-3!)}R^3(1-R)^{3-3}\\&=\frac{3!}{2!1!}R^2(1-R)^1+\frac{3!}{3!0!}R^3(1-R)^0=3R^2(1-R)+R^3=3R^2-3R^3+R^3\\&=3R^2-2R^3\end{aligned} \tag{16.7.277}$$

So, if the reliability is given by an exponential law where we have already proved that:

$$R(t)=e^{-\lambda t}=e^{-\frac{1}{\text{MTBF}}t} \tag{16.7.278}$$

Then we have:

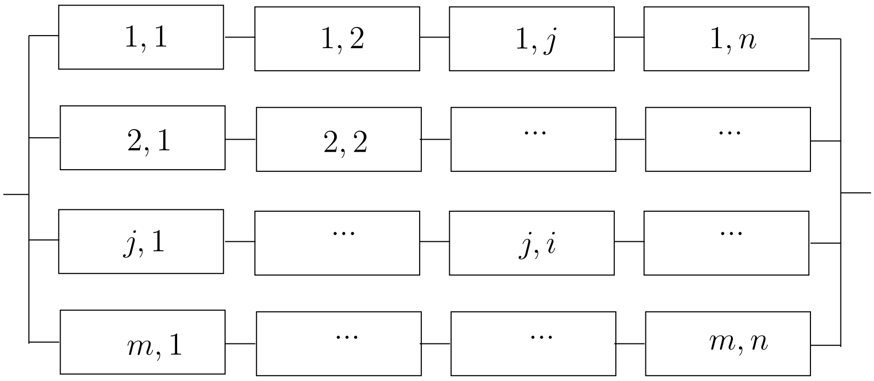
$$\text{MTBF}=\int_0^{+\infty}(3R^2(t)-2R^3(t))\mathrm{d}t=\int_0^{+\infty}(3e^{-2\lambda t}-2e^{-3\lambda t})\mathrm{d}t=\frac{5}{6\lambda}<\frac{1}{\lambda} \tag{16.7.279}$$

So the overall MTBF of the $2/3$ system is larger than a simple system which obviously the goal.

T4. Serial/Parallel and Parallel/Serial topology with symmetrical configuration:

These are just simple compositions of the first two previously studied systems.

We first have the series/parallel system:



$1,1$
$1,2$
$1,j$
$1,n$
$2,1$
$2,2$
$\cdots$
$\cdots$
$j,1$
$\cdots$
j,i
$\cdots$
$m,1$
$\cdots$
$\cdots$
m,n

Figure 16.220: Serial/Parallel symmetric topology

However, as the series systems are given by:

$$R_S=1-F_S=\prod_{i=1}^{n}R_i \tag{16.7.280}$$

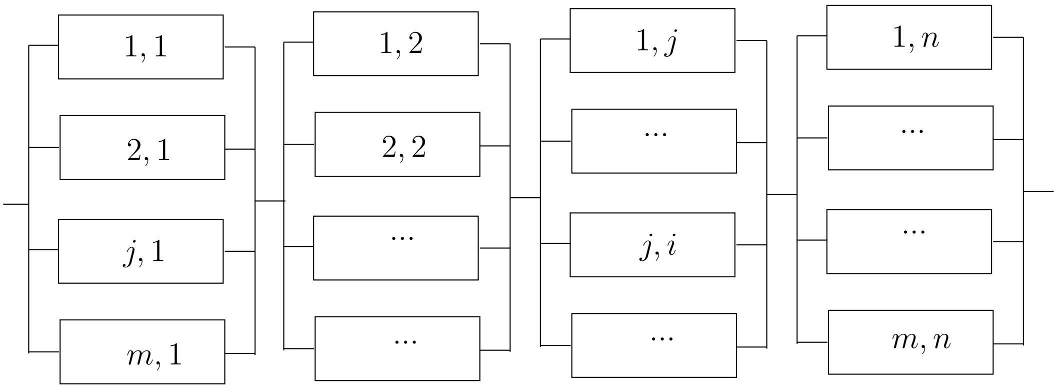
and the parallel by:

$$R_P=1-\prod_{i=1}^{n}F_i=1-\prod_{i=1}^{n}(1-R_i) \tag{16.7.281}$$

the composition of the two gives trivially in the case above:

$$\boxed{R_{S/P}=1-\prod_{j=1}^{m}(1-R_j)=\prod_{j=1}^{m}\left(1-\prod_{i=1}^{n}R_{ij}\right)} \tag{16.7.282}$$

And we also have in the family of parallel/series system:



$1,1$
$1,2$
$1,j$
$1,n$
$2,1$
$2,2$
$\cdots$
$\cdots$
$j,1$
$\cdots$
j,i
$\cdots$
$m,1$
$\cdots$
$\cdots$
m,n

Figure 16.221: Parallel/Serial symmetric topology

when by using exactly the same approach as previously we have:

$$\boxed{R_{P/S}=\prod_{i=1}^{n}R_i=\prod_{i=1}^{n}\left(1-\prod_{j=1}^{m}(1-R_{ij})\right)} \tag{16.7.283}$$

T5. Complex Topology:

In fact, it is not really about complex systems but they just require a little knowledge of probability axioms. The particular example which will interest us is the following (typical cascading RLC filter):

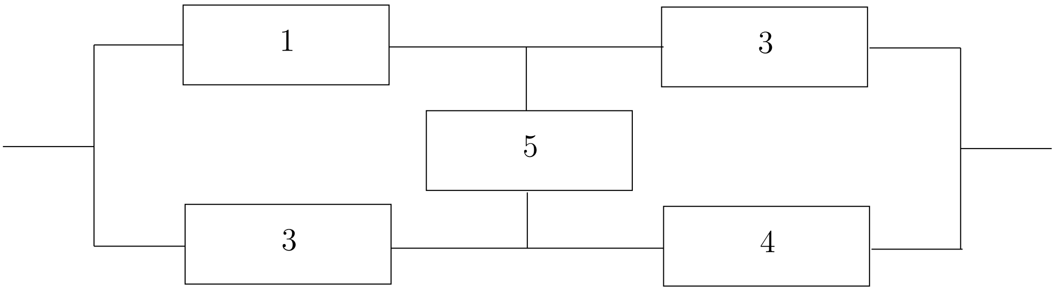


Figure 16.222: **Complex topology (bridge type)**

named "bridged network".

And we guess that what makes the complex system robust is the component number 5. We can then consider a first approach that is to break down the problem.

The system relatively to component 5 will be in one of the state:

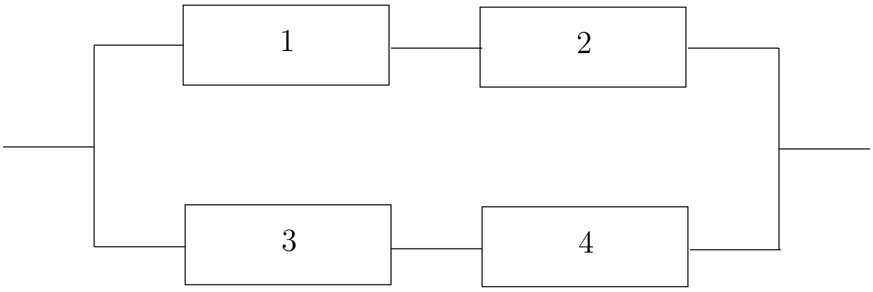

Figure 16.223: **Bridged Network system decomposition (first stage)**

if defective with a probability density function:

$$F_5 = 1 - R_5 \tag{16.7.284}$$

and having itself a reliability:

$$R_{S1} = 1 - \prod_{j=1}^{2}\left(1 - \prod_{i=1}^{2} R_{ij}\right) = 1 - (1 - R_1R_2)(1 - R_3R_4) \tag{16.7.285}$$

according to our previous results of complex series/parallel system.

Or in the following state if 5 is functional with a probability density law R_5:

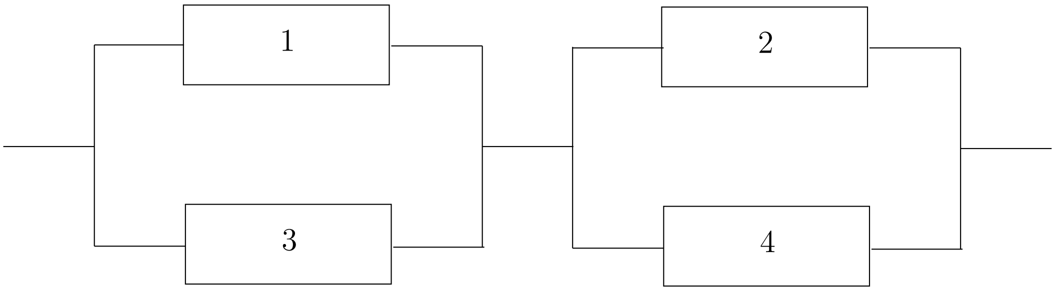

Figure 16.224: **Bridged Network system decomposition (second stage)**

and having itself a reliability of:

$$R_{S2}=\prod_{j=1}^{2}\left(1-\prod_{i=1}^{2}(1-R_{ij})\right)=(1-(1-R_1)(1-R_3))(1-(1-R_2)(1-R_4)) \tag{16.7.286}$$

according to our previous results on the parallel/serial complex system.

Since the system can not be in both states at the same time (at this time it is not a quantum system...), we are dealing with a disjoint probability (see section Probabilities page 453) that is to say the sum of the densities to which we must join the other components. Therefore we have:

$$\begin{aligned}&R_B=(1-R_5)R_{S1}+R_5R_{S2}\\&=(1-R_5)(1-(1-R_1R_2)(1-R_3R_4))+R_5((1-(1-R_1)(1-R_3))(1-(1-R_2)(1-R_4)))\end{aligned} \tag{16.7.287}$$

We can then using all 5 previous topologies evaluate the reliability of any system!

Another strategy for complex systems is to decompose them into simple series or parallel systems. If this is not possible, we can calculate the reliability of each system configuration that is considered to operate and then sum the probabilities of operation of each configuration.

✍**Example:**

Let's make an example by considering the following case:

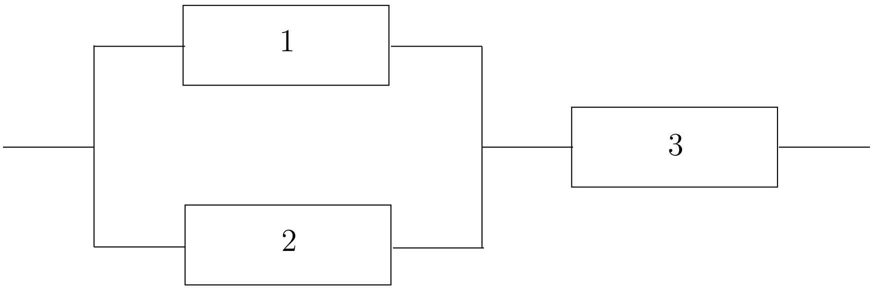

Figure 16.225: **Special case assumed as a complex system**

And consider the following truth table with the 2^n possible configurations:

State Number	Block 1	Block 2	Block 3	Output
1	0	0	0	0
2	1	0	0	0
3	0	1	0	0
4	1	0	1	1
5	0	1	1	1
6	1	1	1	1
7	1	1	0	0
8	0	0	1	0

Table 16.22: **Truth table of a preventive maintenance system**

The principle (not always easy to guess...) is to say that an UP state (thus worth equal 1) is assigned to the value R_1 of the concerned block i and the DOWN state (thus worth equal 0) is assigned to the value $1-R_i$ of the concerned block i. Each value will be multiplied with others to get the total reliability of the system in a given state.

Thus, in the previous example, we have 3 states that allow the system to operate. Let us calculate their respective reliability. The states No 4 and No 5 thus provide by definition:

$$R_{S4}=R_1R_3(1-R_2) \qquad R_{S5}=R_2R_3(1-R_1) \tag{16.7.288}$$

The State Number 6 gives him by definition:

$$R_{S6}=R_1R_2R_3 \tag{16.7.289}$$

and we sum all as previously indicated:

$$\begin{aligned}R_S&=R_{S4}+R_{S5}+R_{S6}=R_1R_3(1-R_2)+R_2R_3(1-R_1)+R_1R_2R_3\\&=R_1R_3-R_1R_3R_2+R_2R_3-R_2R_3R_1+R_1R_2R_3=R_1R_3-R_1R_3R_2+R_2R_3\\&=R_1R_3+R_2R_3-R_1R_3R_2\end{aligned} \tag{16.7.290}$$

And we can check that this approach is actually correct by taking the general relation of such a system proved above:

$$\begin{aligned}R_S&=\prod_{i=1}^{n}R_i=\prod_{i=1}^{n}\left(1-\prod_{j=1}^{m}(1-R_{i,j})\right)=\left(1-\prod_{j=1}^{2}(1-R_{1,j})\right)\left(1-\prod_{j=1}^{1}(1-R_{2,j})\right)\\&=\left(1-\prod_{j=1}^{2}(1-R_{1,j})\right)(1-(1-R_{2,j}))=\left(1-\prod_{j=1}^{2}(1-R_{1,j})\right)R_3\\&=(1-(1-R_1)(1-R_2))R_3=R_3-R_3(1-R_1)(1-R_2)=R_3-(R_3-R_3R_1)(1-R_2)\\&=R_3-(R_3-R_3R_1-R_3R_2+R_3R_1R_2)=R_3R_1+R_3R_2-R_3R_1R_2\end{aligned} \tag{16.7.291}$$

this shows that we have the same result and that the decomposition approach also works.

Finally, let us notice in conclusion that when we include in the systems elements that can tolerate or accept some errors, we then speak of "fault tolerance" and we distinguish mainly three types:

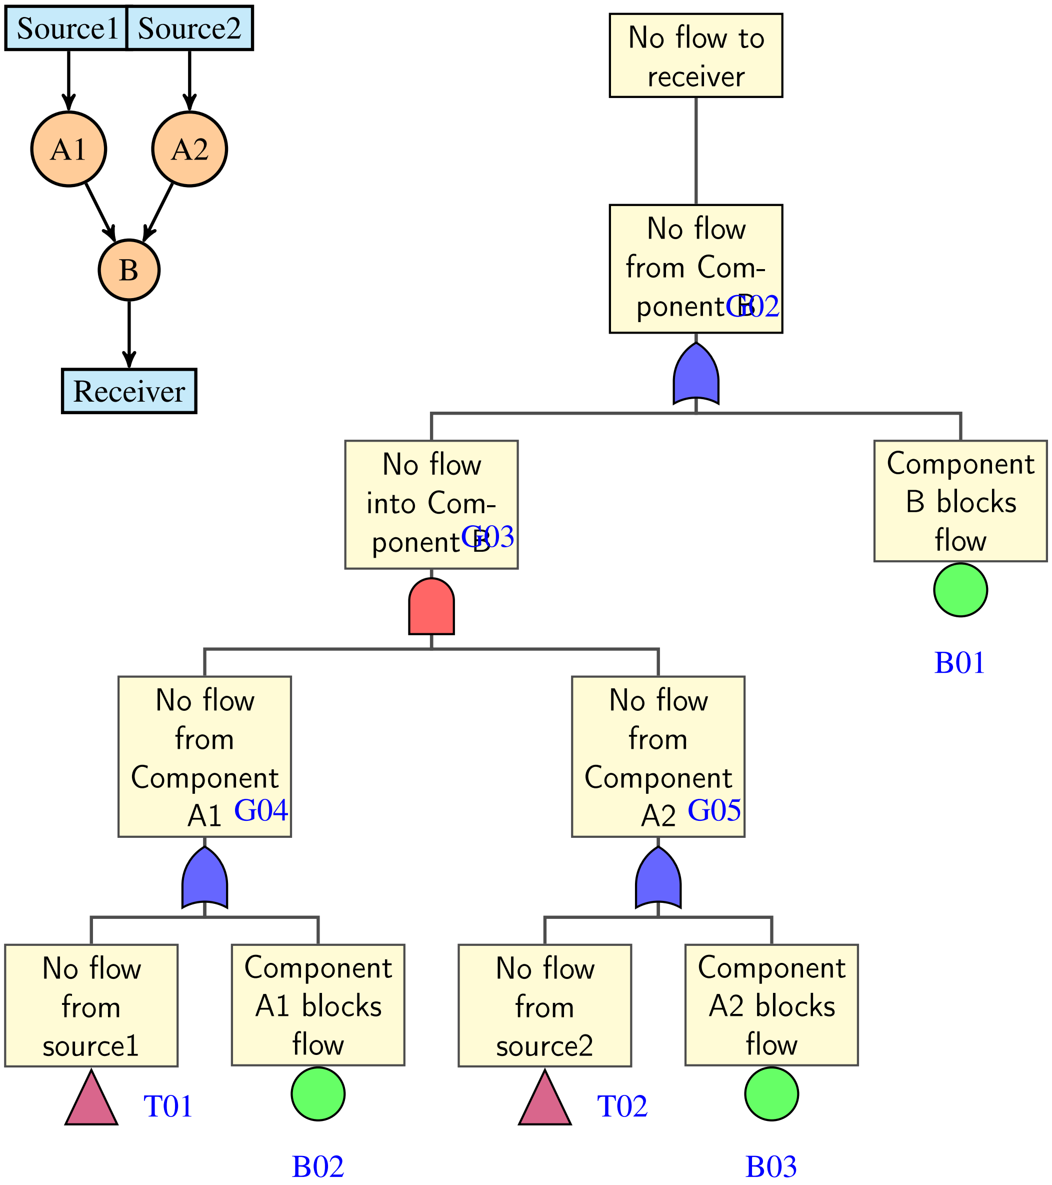
1. **Active redundancy**: In this case all redundant components operate simultaneously.

2. **Passive redundancy**: One redundant element is working, the others are waiting, which has for advantage to reduce or remove the aging of redundant elements, but in return requires the insertion of a component of failure detection and switching.

3. **Majority Redundancy**: This redundancy mainly concerns signal processing. The output signal will be that of the majority of redundant components.

16.7.3.4.1 Fault Tree Analysis

A "fault tree" is a widely used technique in engineering safety studies and reliability of systems consisting of represent the possible combinations of events that allow the realization of a predefined undesirable event. Such a representation therefore highlights the relationships of cause and effect:



Source1
Source2
A1
A2

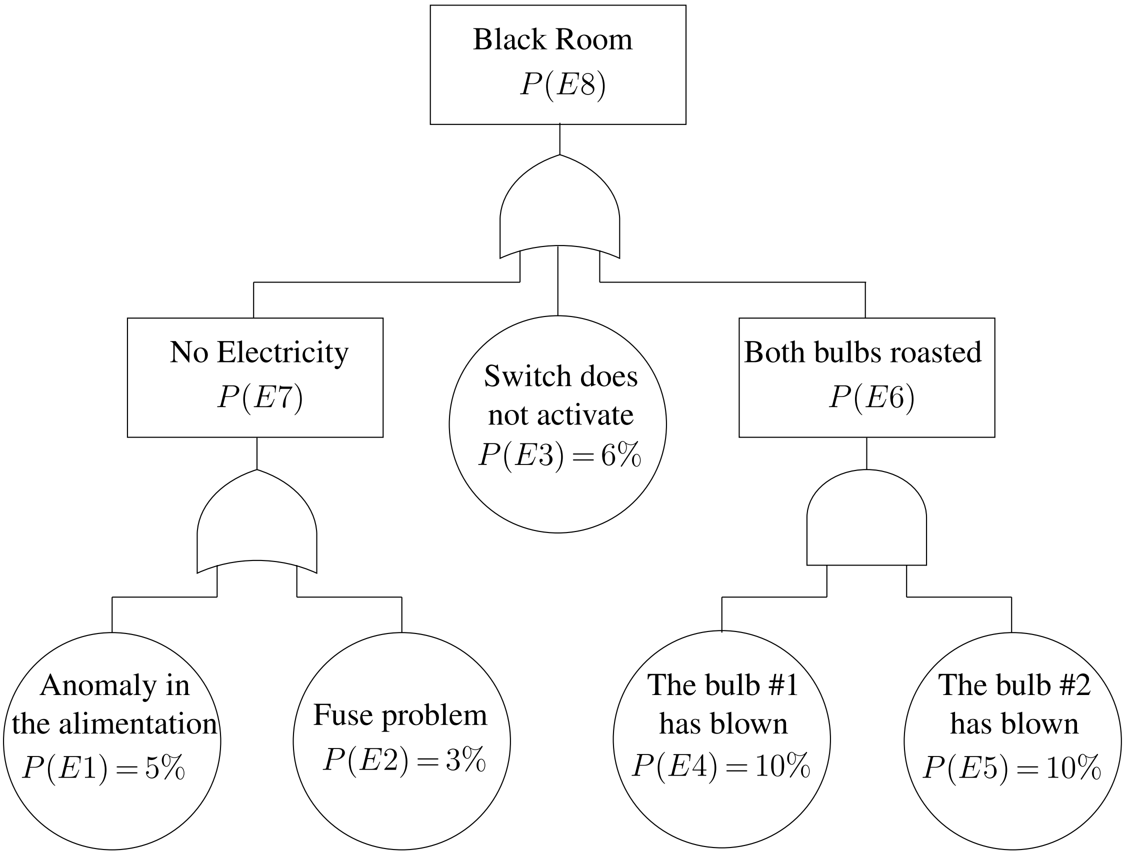
T01
Component A1 blocks flow
B02
No flow from source2
T02
Component A2 blocks flow
B03

Figure 16.226: **Example of simple fault tree (author: Zhang Long)**

This technique is complemented by mathematical processing that allows the combination of single failures and their probability of occurrence. It therefore allows to quantify the probability of occurrence of an adverse event.

The idea is very simple as long as we use only binary probabilities, by cons when it is necessary to use continuous distributions functions (the most common case in practice), we must go through Monte Carlo simulations (section Theoretical Computing) with typical software like Weibull++.

Consider the following fault tree that has 5 primitive events and 3 combined events and where the probabilities of the primitive events are assumed to be known:



Black Room
$P(E8)$
No Electricity
$P(E7)$
Switch does not activate
$P(E3)=6\%$
Both bulbs roasted
$P(E6)$
Anomaly in the alimentation
$P(E1)=5\%$
Fuse problem
$P(E2)=3\%$
The bulb #1 has blown
$P(E4)=10\%$
The bulb #2 has blown
$P(E5)=10\%$

Figure 16.227: **Example of simple fault tree with binary probabilities and AND / OR gates only**

We then have for the next event $E6$ the following probability since it is an AND gate (equivalent to a parallel system):

$$P(E_6)=F_6=\prod_{i=1}^{5} F_i=P(E_4)P(E_5)=0.1\cdot 0.1=0.01=1\% \tag{16.7.292}$$

and for the event $E7$ since it is an OR gate (similar to a series system), we have:

$$\begin{aligned}P(E_7)=F_7=1-\prod_{i=1}^{2}(1-F_i)=1-(1-P(E_1))(1-P(E_2))=1-(1-0.05)\cdot(1-0.03)\\ =0.0785=7.85\%\end{aligned} \tag{16.7.293}$$

And so in the end:

$$\begin{aligned}P(E_8)=F_8=1-(1-F_3)(1-F_6)(1-F_7)=1-(1-P(E_3))(1-P(E_6))(1-P(E_7))\\ =1-(1-0.06)(1-0.0785)(1-0.01)=0.1424=14.24\%\end{aligned} \tag{16.7.294}$$

Thus, the probability of having the room without light is (a posteriori) of 14.24%.

16.7.3.4.2 Markov Chain Reliability Model

The notable strengths of Markov chain (see section Statistics page 537) models for reliability analysis is that they can account for repairs as well as failures. This makes the technique particularly useful for assessing the long-term average reliability of one or more devices with established maintenance and repair strategies. With the advent of high-integrity "fault-tolerant" systems, the ability to account for repairs of partially failed (but still operational) systems has become increasingly important. Markov modelling is well-suited to the task of determining inspection and repair intervals needed to achieve a desired level of safety.

For any given system, a "Markov chain reliability model" consists of a list of the possible states of that system, the possible transition paths between those states, and the rate parameters of those transitions.

Remark

We should speak rigorously about "semi-Markov chain reliability model" as mathematicians do the difference between a Markov chain where the jumps from one state to another are at constant probability an a semi-Markov chain where the jumps are random variables with any distribution, whose distribution function may depend on the two states between which the jump is made. For example semi-Markov process where all the holding times are exponentially distributed is named a "continuous time Markov chain/process".

In reliability analysis the transitions usually consist of failures and repairs. When representing a Markov model graphically, each state is usually depicted as a "bubble", with arrows denoting the transition paths between states, as depicted in the figure below for a single component that has just two states: healthy and failed.

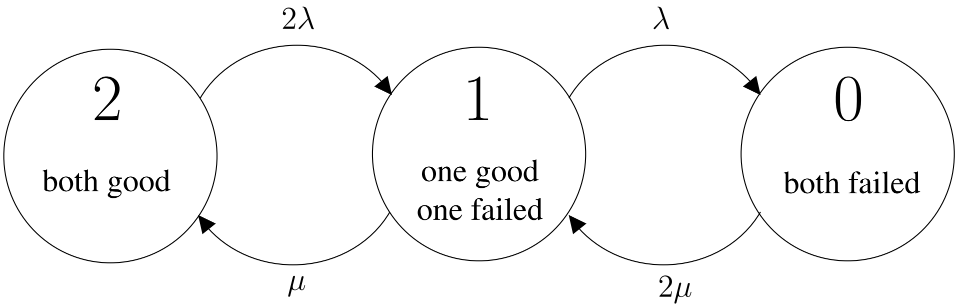


Figure 16.228: **Markov chain reliability model example**

This system is then formalized in the following form (not obvious to guess the very first time):

$$\begin{aligned}\frac{\mathrm{d}P_2(t)}{\mathrm{d}t}&=-2\lambda P_2(t)+\mu P_1(t)\\ \frac{\mathrm{d}P_1(t)}{\mathrm{d}t}&=2\lambda P_2(t)+2\mu P_0(t)-(\lambda+\mu)P_1(t)\end{aligned} \tag{16.7.295}$$

We can rewrite this system in matrix form as well:

$$\vec{P}\,'=M\vec{P} \tag{16.7.296}$$

With:

$$\vec{P}=(P_2,P_1,P_0)^T \qquad M=\begin{pmatrix}-2\lambda & \mu & 0\\ 2\lambda & -(\lambda+\mu) & 2\mu\\ 0 & \lambda & -2\mu\end{pmatrix} \tag{16.7.297}$$

A possible way to solve this system consists in a first time in diagonalizing (if possible) the matrix, that is to say to find an invertible matrix and a diagonal matrix such that:

$$M=SDS^{-1} \tag{16.7.298}$$

We thus fall back an application of the spectral theorem proved in the section of Linear Algebra (see page 2004) and applied to the resolution of differential equations (it is sometimes terrifying and admirable the extent of the striking power of pure mathematics...).

From here we want to be able to write:

$$\vec{P}\,'=SDS^{-1}\vec{P} \tag{16.7.299}$$

or also (it remains the same):

$$S^{-1}\vec{P}\,'=DS^{-1}\vec{P} \tag{16.7.300}$$

By doing the change of variable:

$$\vec{X}=S^{-1}\vec{P}\,' \tag{16.7.301}$$

the system to be solved becomes obviously:

$$\vec{X}\,'=DS^{-1}\vec{P} \tag{16.7.302}$$

Let us denote by γ_2,γ_1, γ_0 the diagonal elements of D and $\vec{X}=(X_2,X_1,X_0)^T$. We then want to rewrite the previous system as:

$$\begin{gathered}\frac{\mathrm{d}X_2(t)}{\mathrm{d}t}=\gamma_2X_2(t)\\ \frac{\mathrm{d}X_1(t)}{\mathrm{d}t}=\gamma_1X_1(t)\\ \frac{\mathrm{d}X_0(t)}{\mathrm{d}t}=\gamma_0X_0(t)\end{gathered} \tag{16.7.303}$$

But the solutions of this system are easy to determine, they are given by:

$$X_i(t)=c_i^{te}e^{\gamma_i t} \tag{16.7.304}$$

for $i=0,1,2$ where $c_i^{te}\in\mathbb{R}$.

Finally, we will determine the solutions of the system of departure with the help of the equality:

$$\vec{P}=S\vec{X} \tag{16.7.305}$$

Well... now let us put all this into practice!

To diagonalize M (if it is possible) we must determine its eigenvalues and its eigenspaces. Calculations made (see also the section of Linear Algebra for the general method at page 1998) we find that the values of M are:

$$0,-2(\lambda+\mu),-(\lambda+\mu) \tag{16.7.306}$$

The corresponding eigenspaces are given by the vectors (see chapter of Linear Algebra for the general method at page 1999):

$$\begin{pmatrix}\mu^2\\2\lambda\mu\\\lambda^2\end{pmatrix},\begin{pmatrix}1\\-2\\1\end{pmatrix},\begin{pmatrix}-\mu\\\mu-\lambda\\\lambda\end{pmatrix} \tag{16.7.307}$$

Hence, if we write:

$$D=\begin{pmatrix}0&0&0\\0&-2(\lambda+\mu)&0\\0&0&-(\lambda+\mu)\end{pmatrix}\qquad S=\begin{pmatrix}\mu^2&1&-\mu\\2\lambda\mu&-2&\mu-\lambda\\\lambda^2&1&\lambda\end{pmatrix} \tag{16.7.308}$$

We can then indeed write:

$$M=SDS^{-1} \tag{16.7.309}$$

The diagonal elements of D are:

$$\gamma_2=0\qquad\gamma_1=-2(\lambda+\mu)\qquad\gamma_0=-(\lambda+\mu) \tag{16.7.310}$$

The components of the vector $\vec{X}$ being given earlier above by:

$$X_i(t)=c_i^{te}e^{\gamma_i t} \tag{16.7.311}$$

we therefore have:

$$\vec{X}(t)=\begin{pmatrix}c_2^{te}\\c_1^{te}e^{-2(\lambda+\mu)t}\\c_0^{te}e^{-(\lambda+\mu)t}\end{pmatrix} \tag{16.7.312}$$

To finish the solutions of the original system are for recall given by:

$$\vec{P}=S\vec{X} \tag{16.7.313}$$

So finally:

$$\begin{aligned}P_2(t)&=c_2^{te}\mu^2+c_1^{te}e^{-2(\lambda+\mu)t}-\mu c_0^{te}e^{-(\lambda+\mu)t}\\P_1(t)&=2c_2^{te}\lambda\mu-2c_1^{te}e^{-2(\lambda+\mu)t}+(\mu-\lambda)c_0^{te}e^{-(\lambda+\mu)t}\\P_0(t)&=c_2^{te}\lambda^2+c_1^{te}e^{-2(\lambda+\mu)t}+\lambda c_0^{te}e^{-(\lambda+\mu)t}\end{aligned} \tag{16.7.314}$$

If we impose the initial condition:

$$P_2(0)=1\qquad P_1(0)=0\qquad P_0(0)=0 \tag{16.7.315}$$

we then have the system of three equations with three unknowns:

$$\begin{aligned}&c_2^{te}\mu^2+c_1^{te}-\mu c_0^{te}=1\\&2c_2^{te}\lambda\mu-2c_1^{te}+(\mu-\lambda)c_0^{te}=0\\&c_2^{te}\lambda^2+c_1^{te}+\lambda c_0^{te}=0\end{aligned}\tag{16.7.316}$$

Its resolution should be quite trivial for the reader (if it is not the case do not hesitate to contact us we will add the details) and we get:

$$\begin{aligned}&c_2=(\lambda+\mu)^{-2}\\&c_1=\lambda^2(\lambda+\mu)^{-2}\\&c_0=-2\lambda(\lambda+\mu)^{-2}\end{aligned}\tag{16.7.317}$$

So at the end:

$$\begin{aligned}&P_2(t)=\frac{\mu^2}{(\lambda+\mu)^2}+\frac{\lambda^2}{(\lambda+\mu)^2}e^{-2(\lambda+\mu)t}+\frac{2\lambda\mu}{(\lambda+\mu)^2}e^{-(\lambda+\mu)t}\\&P_1(t)=\frac{2\lambda\mu}{(\lambda+\mu)^2}-\frac{2\lambda^2}{(\lambda+\mu)^2}e^{-2(\lambda+\mu)t}+\frac{2\lambda(\lambda-\mu)}{(\lambda+\mu)^2}e^{-(\lambda+\mu)t}\\&P_0(t)=\frac{\lambda^2}{(\lambda+\mu)^2}+\frac{\lambda^2}{(\lambda+\mu)^2}e^{-2(\lambda+\mu)t}-\frac{2\lambda^2}{(\lambda+\mu)t}\end{aligned}\tag{16.7.318}$$

We can also verify that for any t we have:

$$P_0(t)+P_1(t)+P_2(t)=0\tag{16.7.319}$$

This is the reason why we often find the above system in the following form:

$$\begin{aligned}&P_2(t)=\frac{\mu^2}{(\lambda+\mu)^2}+\frac{\lambda^2}{(\lambda+\mu)^2}e^{-2(\lambda+\mu)t}+\frac{2\lambda\mu}{(\lambda+\mu)^2}e^{-(\lambda+\mu)t}\\&P_1(t)=\frac{2\lambda\mu}{(\lambda+\mu)^2}-\frac{2\lambda^2}{(\lambda+\mu)^2}e^{-2(\lambda+\mu)t}+\frac{2\lambda(\lambda-\mu)}{(\lambda+\mu)^2}e^{-(\lambda+\mu)t}\\&P_0(t)=1-P_2(t)-P_1(t)\end{aligned}\tag{16.7.320}$$

From the above formulas it follows that the availability on the long-term system is given by:

$$\lim_{t\rightarrow+\infty}P_2(t)+P_1(t)=\frac{\mu^2}{(\lambda+\mu)^2}+\frac{2\lambda\mu}{(\lambda+\mu)^2}\tag{16.7.321}$$

Because $\lambda+\mu>0$ and because we also have:

$$\lim_{t\rightarrow+\infty}e^{-(\lambda+\mu)t}=0\tag{16.7.322}$$

16.7.3.5 Maximum Likelihood for failure rate determination of samples

We studied in the section Statistics (see page 818) and Theoretical Computing (see page 6386) that the techniques using the maximum likelihood allowed us to estimate the maximum or minimum value of the parameters of a statistical law under the assumption that events are independent.

This technique, even empirical and sometimes quite questionable, is also used in the field of the reliability. As the theory has already been developed in the section Statistics let us see directly some practical cases.

✍**Examples:**

E1. Consider a system whose time intervals between failures is distributed according to an exponential law:

$$f(t)=\frac{\mathrm{d}F}{\mathrm{d}t}=\lambda e^{\lambda t} \tag{16.7.323}$$

of unknown parameter λ and where we consider (as always ...) that every failure is independent.

Observations gave us the following number of months between each failure: $10, 5, 11, 12, 15$.

Then using maximum likelihood which idea is for reminder to maximize (minimize) the total probability of independent events (therefore we must multiply the probabilities), we have:

$$L_5(\lambda)=\lambda e^{-10\lambda}\lambda e^{-5\lambda}\lambda e^{-11\lambda}\lambda e^{-12\lambda}\lambda e^{-15\lambda}=\lambda^5 e^{-53\lambda} \tag{16.7.324}$$

Therefore determine the failure rate that maximizes the likelihood is equivalent as we know to calculate when the derivative (see section Differential and Integral Calculus page 1450) is zero:

$$\frac{\mathrm{d}L_5(\lambda)}{\mathrm{d}\lambda}=\frac{\mathrm{d}\lambda^5 e^{-53\lambda}}{\mathrm{d}\lambda}=(5\lambda^4-53\lambda^5)e^{-53\lambda}=\lambda^4(5-53\lambda)e^{-53\lambda} \tag{16.7.325}$$

We then have two roots that are trivial:

$$\lambda_1=0 \qquad \lambda_2=\frac{5}{53} \tag{16.7.326}$$

and of course we will keep the second as root failure rate of our system.

E2. We consider now see the same data as before but this time with a Weibull distribution with the following simplified notation:

$$f(x)=\frac{\alpha}{\beta^\alpha}x^{\alpha-1}e^{-\left(\frac{x}{\beta}\right)^\alpha}=\alpha\lambda x^{\alpha-1}e^{-\lambda x^\alpha} \tag{16.7.327}$$

and therefore:

$$\begin{aligned}&L_5(\alpha,\lambda)=f(10)f(5)f(11)f(12)f(15)\\&=\left[\alpha\lambda 10^{\alpha-1}e^{-\lambda 10^{\alpha}}\right]\left[\alpha\lambda 5^{\alpha-1}e^{-\lambda 5^{\alpha}}\right]\left[\alpha\lambda 11^{\alpha-1}e^{-\lambda 11^{\alpha}}\right]\left[\alpha\lambda 12^{\alpha-1}e^{-\lambda 12^{\alpha}}\right]\left[\alpha\lambda 15^{\alpha-1}e^{-\lambda 15^{\alpha}}\right]\end{aligned}\tag{16.7.328}$$

To maximize this kind of function, as far as we know, we can use only numerical methods. By cons, a simple spreadsheet software like Microsoft® Excel® with its solver allows to find the two parameters of the Weibull distribution in three clicks!

E3. We imagine that we put under observation 10 similar manufactured elements. On the 10, we observed a stop of 4 of them after respectively $700, 800, 900$ and 950 hours. The remaining 6 items will be considered as being over the $1,000$ work hours and we stop observing from this value. Assuming that the failure distribution is exponentially again, then we have (the idea is subtle but simple):

$$\begin{aligned}L_10(\lambda)&=f(700)f(800)f(900)f(950)\\&=\lambda e^{-700\lambda}\lambda e^{-800\lambda}\lambda e^{-900\lambda}\lambda e^{-950\lambda}\left(1-\left(1-e^{-1000\lambda}\right)\right)^6\\&=\lambda^4e^{-3350\lambda}e^{-6000\lambda}=\lambda^4e^{-9350\lambda}\end{aligned}\tag{16.7.329}$$

It comes then:

$$\dfrac{\mathrm{d}L_10(\lambda)}{\mathrm{d}\lambda}=\dfrac{\mathrm{d}\lambda^4e^{-9350\lambda}}{\mathrm{d}\lambda}=(4\lambda^3-9350\lambda^4)e^{-9350\lambda}=\lambda^3(4-9350)e^{-9350\lambda}=0\tag{16.7.330}$$

We then have two roots that are trivial:

$$\lambda_1=0\qquad\lambda_4=\dfrac{4}{9,350}\tag{16.7.331}$$

and of course we will keep the second root as failure rate of our system.

16.7.3.6 Kaplan-Meier Survival Rate

In areas such as high-level industry, high-level medicine or high-level biology, we are often interested in the:

1. Survival duration after a serious event
2. Duration of remission after treatment or surgery
3. Duration of symptoms after an abnormality
4. Duration of a symptomless infection

We seek very often to distinguish at least "the event of interest":

1. System shutdown after serious event
2. End of remission
3. End of a symptom after anomaly
4. Beginning of a symptom during an infection

of the variable to explain "duration before the event of interest":

1. Elapsed duration before shutdown
2. Elapsed duration before the end of remission
3. Elapsed duration before the end of the symptom
4. Elapsed duration without symptoms

Definitions (#16.7.735):

D1. We name "remission", the reduction of a disease or a temporarily malfunction.

D2. The "survival time" or "lifetime" T means the time which elapses from an initial time (start of treatment, diagnosis or failure, etc.) until the occurrence of a final event of interest (patient death, relapse, remission, cure, repair, etc.). We say that the object of the study "survives at time t" if at this moment the final interest event has not yet occurred.

Remark

Although this type of study can be associated with preventive maintenance (see page 8716), statisticians associate this type of study rather to the domain of "survival analysis".

We will focus in this textbook on a particular context but that can be easily generalized:

- Cohort/Clinical trial where we study the survival time of each patient (machine).
- All patients (machines) do not have the same observation time (different instants of entry into the study).
- We have information on the survival time of each patient (machine) but we do not know exactly when it happens.

From the last two points, we conclude that the survival time can be censored. So the usual statistical techniques does not apply directly as censored data require special treatment (of course, if we remove the censored data we lose information). It goes without saying that this situation is extremely common and therefore the study of the Kaplan-Meier estimator is very important (for other survival models the reader should refer to the Statistics section especially the part concerning Survival Models at page 1271).

Definition (#16.7.736): The duration T is said to be censored if the duration is not observed completely. The different types of censoring are:

- Type I censoring: fixed right. In this situation, the time is not observable beyond a maximum, fixed, named "fixed-censoring" and imposed. So either we have the opportunity to observe the real duration of the event of interest for the item if it occurs before the fixed-censoring, or we limit ourselves to the fixed-censoring time if the event of interest has not occurred before.
- Type II censoring: wait. In this situation, we observe the lives of n individuals until $m \leq n$ individuals have seen the event to occur (deceased). The duration considered is therefore that of the beginning of the experiment until the event of interest for the m-th.
- Type III censoring: random left. In this situation, we do not know when the event of interest has occurred (because we started to observe the subject of study too late). We can not then deal with "durations" in the measurable sense and we have to limit ourselves to a simple count.
- Type III censoring: random right. In this situation, we do not know when the event will take place (because we stopped to observe the subject before it occurs for any reason). We can not then also not deal with "times" in the measurable sense and we must limit ourselves to a simple count.
- Type IV censoring: random intervals. In this situation, we have a mixture of random left and right censoring. That is to say that for some study subjects, we do not know when the event of interest has begun, and for others we do not know when it will occur (if any. ...).

In the machinery industry, we often deal with the type I censoring: fixed right. In the medical field, in clinical trials, we often deal with a type III censoring: random right. In the case of pandemics, we are dealing with type III censoring: random left.

To introduce this subject, rather than doing obscure theory, as always in this textbook we prefer at pragmatic approach. Suppose that the study is a clinical trial involving two groups of patients receiving two types of treatments. Two important questions raised to the physicians in a Phase II clinical trial (phase I is for non-toxicity approval to human and phase 0 for animals):

1. Is one of the two treatments more effective than the other in terms of improving patient survival?
2. Can we highlight prognostic factors, that is to say that improve / deteriorate survival?

To answer the first question we can develop statistical methods that will allow us to compare the two groups of patients who receive both types of treatment.

To answer the second question we propose a model that links patient survival time for explanatory variables and highlight the prognostic factors.

Let us as always assist the theory with an example. For this consider the following table where two cohorts of patients (we move from mechanical engineering to human engineering...) of same initial size with acute leukemia drug test (6-MP) against a placebo[22] (of course blindly).

We have the following remission times for 21 patients (the table of 21 lines therefore indicates the number of weeks for where patient is considered cured after treatment before falling again ill):

6-mercaptopurine (6-MP) Group	Placebo Group
6	1
6	1
6	2
6+	2
7	3
9+	4
10	4
10+	5
11+	5
13	8
16	8
17+	8
19+	8
20+	11
22	11
23	12
25	12
32+	15
32+	17
34+	22
35+	23

Table 16.23: **Two cohort survival analysis with right censoring**

The "+" sign corresponds to patients who left the study for that week. They are therefore censored! For example, the fourth patient was lost of view for any reason after 6 weeks of treatment with 6-MP: it has therefore a duration of remission greater than 6 weeks! So in the study 6-MP, there are 21 patients and 11 of them are censored data.

---

[22] In the science of drugs, a "pure placebo" is a treatment without any active substance; an "impure placebo" is a pharmacologically active product but has no effect on the pathology treated, or whose efficacy has not been sufficiently demonstrated.

Remark

The theoretical model assumes that censoring is independent of the survival time (not informative censoring). But if censoring is due to the discontinuation of treatment, the independence assumption is not valid anymore!

For the placebo group it is simple to make a survival curve. It is sufficient to produce the following table (for the omitted weeks, obviously we impose the number of remission as constants):

Week i	Total # remission at week i	Proportion (probability) of remission at week i
0	21	100%
1	19	$19/21=90\%$
2	17	$17/21=81\%$
3	16	$16/21=76\%$
4	14	$14/21=67\%$
5	12	$12/21=57\%$
8	8	$8/21=38\%$
11	6	$6/21=29\%$
12	4	$4/21=19\%$
15	3	$3/21=14\%$
17	2	$2/21=10\%$
22	1	$1/20=0.05\%$
23	0	0%

Table 16.24: **Two cohort survival analysis with right censoring**

So if the data are not censored, the survival $S(t)$ can be estimated by the proportion of individuals surviving at time t, that is customary to write under the following mathematical form:

$$\hat{S}_k(t)=P_k(T_k>t)=\frac{1}{n}\sum_{i=1}^{k}1_{T_i>t} \tag{16.7.332}$$

The idea is therefore to estimate:

$$P(T>t)=P(\text{probability to survive until time } t) \tag{16.7.333}$$

by the proporbo of patients who survived until time t.

If the data are censored, the estimated survival function requires specific tools. Kaplan and Meier have proposed in this special case the following calculation:

$$\begin{aligned}&P(\text{be in remission a the } i\text{-th week})\\&=P(\text{to not relapse at the } i\text{-th week})\cdot P(\text{be in remission a the } i-1\text{-th week})\end{aligned} \tag{16.7.334}$$

Let's see it in a slightly more mathematical form. If we denote by $X(1)\leq X(2)\leq\ldots\leq X(n)$ the moments (sorted) where an event occurred (death or censored), then we have:

$$P(T>X(k))=P(T>X(k)|T>X(k-1))P(T>X(k-1)) \tag{16.7.335}$$

With of course:

$$P(T>0)=1 \tag{16.7.336}$$

We estimate:

$$\hat{P}_k=\left(1-\frac{d_k}{R_k}\right) \tag{16.7.337}$$

where d_k is the number of deaths (failures) observed in the time corresponding to the event $X(k)$ and R_k is the number of individuals at risk (at risk of death/failure) just before $X(k)$.

We define the "Kaplan-Meier estimator" for any $X(0)\leq t<X(k)$ by:

$$\boxed{\hat{S}_{\text{KM}}(t)=\prod_{k=1}^{n}\hat{P}_k=\prod_{k=1}^{n}\left(1-\frac{d_k}{R_k}\right)=\prod_{k=1}^{n}\left(1-\hat{\lambda}_k\right)} \tag{16.7.338}$$

where $\hat{\lambda}_k$ is the discrete hazard (i.e. conditional probability of death).

Therefore we get doing now for 6-MP group (not the placebo group!!!!!) the following table:

Remission duration (uncensored) observed	**Items in remission at the beginning of k**	**Probability of not relapse at k knowing that we are at at $k-1$ ($\hat{P}_k$)**	**Survival probability of Kaplan-Meier**
0	21	$21/21=100\%$	100%
6	21	$18/21=1-3/21=85.7\%$	$100\%\cdot 85.7\%=85.7\%$
7	17	$16/17=1-1/17=94.1\%$	$85.7\%\cdot 94.1\%=80.7\%$
10	15	$14/15=1-1/15=93.3\%$	$80.7\%\cdot 93.3\%=75.3\%$
13	12	$11/12=1-1/12=91.7\%$	$75.3\%\cdot 91.7\%=69\%$
16	11	$10/11=1-1/11=90.9\%$	$69\%\cdot 90.9\%=62.7\%$
22	7	$6/7=1-1/7=85.7\%$	$62.7\%\cdot 85.7\%=53.8\%$
23	6	$5/6=1-1/6=83.3\%$	$53.8\%\cdot 83.3\%=44.8\%$

Table 16.25: **6-MP survival analysis**

With the corresponding survival curves (including the confidence interval):

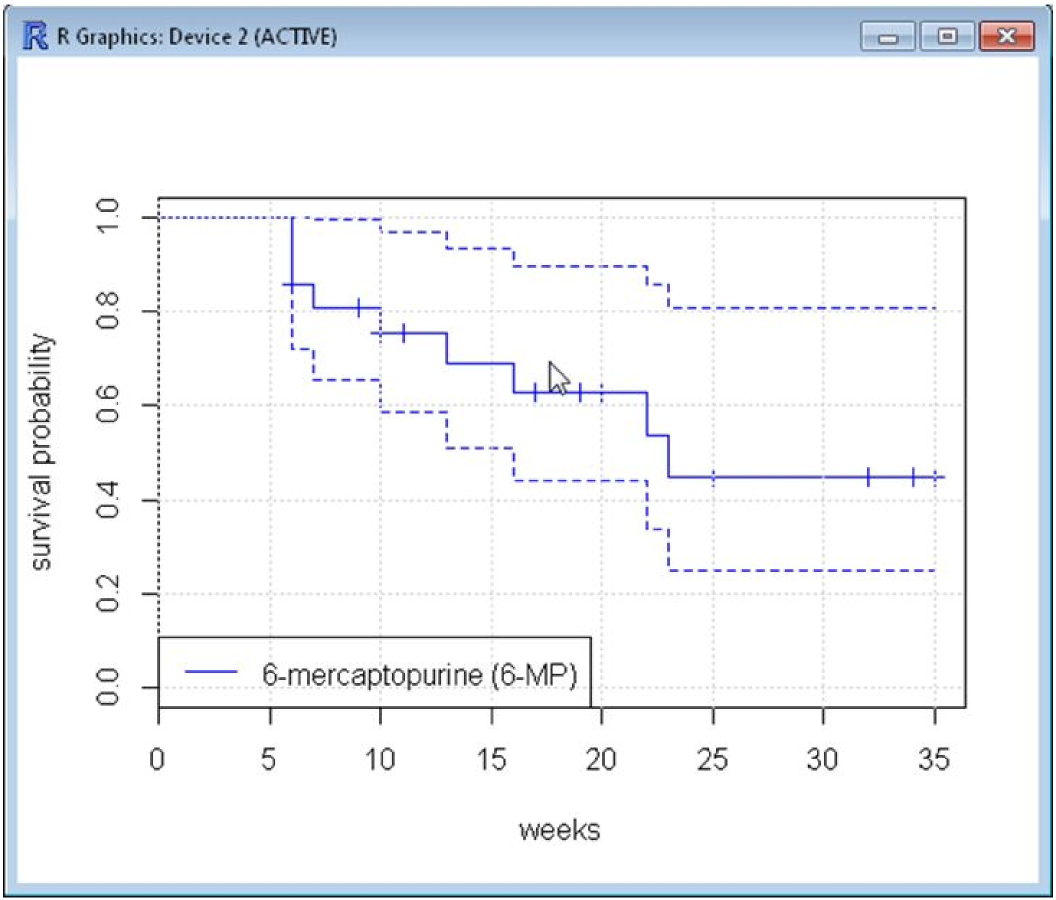

Figure 16.229: **Kaplan-Meier typical survival curves in `R` software**

We thus find the same values as those given for example by Minitab Statistical Software 15.1.1 and `R` (see the companion books on Minitab or `R` for the details).

If we assume that the $\hat{\lambda}_k$'s are just binomial proportions given the R_k's we have the following normalized variance and mean of binomial random variable (see page 663):

$$\mathrm{E}(\hat{\lambda}_k)=\hat{\lambda}_k \qquad \mathrm{V}(\hat{\lambda}_k)=\frac{\hat{\lambda}_k(1-\hat{\lambda}_k)}{R_k} \tag{16.7.339}$$

Remark

Sadly it is a tradition in survival analysis to denote the normalized variance of $\hat{\lambda}_k$ by $\mathrm{V}(\hat{\lambda}_k)$ instead of $\mathrm{V}(\hat{\lambda}_k/r_k)$...

and we will assume also that the $\hat{\lambda}_k$'s are asymptotically independent (...).

Since $\hat{S}_{\text{KM}}(t)$ is a function of the $\hat{\lambda}_k$'s, we can estimate its variance using the Delta method (see section Numerical Methods page 6504) that has for important result for recall that:

$$g(X_n) \underset{n\to+\infty}{\cong} \mathcal{N}\left(0,g'(\mu)^2\sigma^2\right) \tag{16.7.340}$$

with:

$$\mathrm{V}(g(X_n))\cong g'(\mu)^2\sigma^2 \tag{16.7.341}$$

Therefore instead of dealing with $\hat{S}_{\text{KM}}(t)$ directly, we will look at its natural logarithm:

$$\ln(\hat{S}_{\text{KM}}(t))=\sum_{k=1}^{n}\ln(1-\hat{\lambda}_k) \tag{16.7.342}$$

Thus, by the approximate independence of the $\hat{\lambda}_k$'s and keeping in mind that we just chose $g()$ as the natural logarithm and using the Delta method (see section Numerical Methods page 6504):

$$\begin{aligned}\hat{\text{V}}\left[\ln(\hat{S}_{\text{KM}}(t))\right]&\cong\sum_{k=1}^{n}\hat{\text{V}}\left[\ln(1-\hat{\lambda}_k)\right]\underset{\text{delta method}}{\cong}\sum_{k=1}^{n}\left(\frac{1}{1-\hat{\lambda}_k}\right)^2\hat{\text{V}}(\hat{\lambda}_k)\\&=\sum_{k=1}^{n}\left(\frac{1}{1-\hat{\lambda}_k}\right)^2\frac{\hat{\lambda}_k(1-\hat{\lambda}_k)}{R_k}=\sum_{k=1}^{n}\frac{\hat{\lambda}_k}{(1-\hat{\lambda}_k)R_k}=\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}\end{aligned} \tag{16.7.343}$$

And applying on it the Delta method (see section Numerical Methods page 6504):

$$\text{V}(g(X_n))\cong g'(\mu)^2\sigma^2=g'(\mu)^2\text{V}(X_n)\Rightarrow\text{V}\left(\ln(\hat{S}_{\text{KM}}(t)\right)\cong\frac{1}{\hat{S}^2_{\text{KM}}(t)}\hat{\text{V}}\left(\hat{S}_{\text{KM}}(t)\right) \tag{16.7.344}$$

then rearranging and injecting the previous result we get:

$$\hat{\text{V}}\left(\hat{S}_{\text{KM}}(t)\right)\cong\hat{S}^2_{\text{KM}}(t)\text{V}\left(\ln(\hat{S}_{\text{KM}}(t)\right)=\hat{S}^2_{\text{KM}}(t)\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k} \tag{16.7.345}$$

The following approximation:

$$\boxed{\hat{\text{V}}\left(\hat{S}_{\text{KM}}(t)\right)\cong\hat{S}^2_{\text{KM}}(t)\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}} \tag{16.7.346}$$

is named the "Greenwood's relation". If we take the square root then the result is associated to the standard error (because of the division by R_k):

$$\text{SE}\left(\hat{S}_{\text{KM}}(t)\right)\cong\hat{S}_{\text{KM}}(t)\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}}=\hat{S}_{\text{KM}}(t)\frac{\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)}}}{\sqrt{R_k}}=\hat{S}_{\text{KM}}(t)\frac{\sigma_{\hat{S}_{\text{KM}}(t)}}{\sqrt{R_k}} \tag{16.7.347}$$

In order to construct an error bar for $\hat{S}_{\text{KM}}(t)$ we need to make some sort of distributional assumption. The simplest is to assume that $\hat{S}_{\text{KM}}(t)$ is normally distributed such that we can write:

$$\hat{S}_{\text{KM}}(t)\pm Z_{\alpha/2}\text{SE}\left(\hat{S}_{\text{KM}}(t)\right) \tag{16.7.348}$$

Or more explicitly:

$$\boxed{\hat{S}_{\text{KM}}(t)-Z_{\alpha/2}\hat{S}_{\text{KM}}(t)\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}}\leq S_{\text{KM}}(t)\leq\hat{S}_{\text{KM}}(t)+Z_{\alpha/2}\hat{S}_{\text{KM}}(t)\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}}} \tag{16.7.349}$$

A snag with this of course is that the distribution of $\hat{S}_{\text{KM}}(t)$ is not really normal. Problems arise when $\hat{S}_{\text{KM}}(t)$ is close to 0 or 1 as indeed the confidence interval can yield values to >1 or <0. A common empirical approach (among others!) is then to take for the confidence interval the complementary log-log transformation:

$$\hat{W}(t)=\ln\left(-\ln\left(\hat{S}_{\text{KM}}(t)\right)\right) \tag{16.7.350}$$

Since this quantity is unrestricted, the confidence interval will be in the right range when we transform back:

$$\hat{S}_{\text{KM}}(t)=e^{-e^{\hat{W}(t)}} \tag{16.7.351}$$

To see why this works:

$$0\leq \hat{S}_{\text{KM}}(t)\leq 1 \tag{16.7.352}$$

$$-\infty\leq \ln\left(\hat{S}_{\text{KM}}(t)\right)\leq 0 \tag{16.7.353}$$

$$0\leq -\ln\left(\hat{S}_{\text{KM}}(t)\right)\leq +\infty \tag{16.7.354}$$

$$-\infty\leq \ln\left(-\ln\left(\hat{S}_{\text{KM}}(t)\right)\right)\leq +\infty \tag{16.7.355}$$

To get a confidence interval we need now also to find the standard error corresponding to this log-log transformation, and for this purpose we need to calculate:

$$\hat{\text{V}}(\hat{W}(t))=\hat{\text{V}}\left(\ln\left(-\ln\left(\hat{S}(t)\right)\right)\right) \tag{16.7.356}$$

From our previous calculations, we know:

$$\hat{\text{V}}\left[\ln(\hat{S}_{\text{KM}}(t))\right]\cong\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k} \tag{16.7.357}$$

Applying the Delta method again, we get:

$$\hat{\text{V}}(\hat{W}(t))=\hat{\text{V}}\left(\ln\left(-\ln\left(\hat{S}(t)\right)\right)\right)\cong\frac{1}{\left[\ln\left(\hat{S}(t)\right)\right]^2}\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k} \tag{16.7.358}$$

We take the square root of the above to get the standard error:

$$\text{SE}(\hat{W}(t))\cong\frac{1}{\ln\left(\hat{S}(t)\right)}\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}} \tag{16.7.359}$$

And therefore we have :

$$\hat{W}(t)-Z_{\alpha/2}\frac{1}{\ln\left(\hat{S}(t)\right)}\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}}\leq W(t)\leq\hat{W}(t)+Z_{\alpha/2}\frac{1}{\ln\left(\hat{S}(t)\right)}\sqrt{\sum_{k=1}^{n}\frac{d_k}{(R_k-d_k)R_k}} \tag{16.7.360}$$

Since $\hat{S}_{\text{KM}}(t)=e^{-e^{\hat{W}(t)}}$, the ("modern") bounds for the confidence interval of $\hat{S}_{\text{KM}}(t)$ are finally (note that the upper and lower bound switch!):

$$\exp\left\{-e^{\hat{W}(t)+Z_{\alpha/2}\frac{1}{\ln(\hat{S}(t))}\sqrt{\sum_{k=1}^{n}\dfrac{d_k}{(R_k-d_k)R_k}}}\right\}\leq S_{\text{KM}}(t)\leq\exp\left\{-e^{\hat{W}(t)-Z_{\alpha/2}\frac{1}{\ln(\hat{S}(t))}\sqrt{\sum_{k=1}^{n}\dfrac{d_k}{(R_k-d_k)R_k}}}\right\}\tag{16.7.361}$$

Substituting $\hat{W}(t)=\ln\left(-\left(\hat{S}_{\text{KM}}(t)\right)\right)$ back into the above bounds, we get the definitive "modern" relation for the Kaplan-Meier estimator confidence interval:

$$\boxed{\hat{S}_{\text{KM}}(t)\exp\left\{e^{Z_{\alpha/2}\frac{1}{\ln(\hat{S}(t))}\sqrt{\sum_{k=1}^{n}\dfrac{d_k}{(R_k-d_k)R_k}}}\right\}\leq S_{\text{KM}}(t)\leq\hat{S}_{\text{KM}}(t)\exp\left\{e^{-Z_{\alpha/2}\frac{1}{\ln(\hat{S}(t))}\sqrt{\sum_{k=1}^{n}\dfrac{d_k}{(R_k-d_k)R_k}}}\right\}}\tag{16.7.362}$$

16.7.3.7 ABC Method

In a company, the tasks are various and the maintenance teams are systematically reduced to a minimum. In addition, the most advanced technologies in maintenance can be very expensive, and should not be applied indiscriminately.

It is therefore appropriate to be organized effectively and efficiently. The "ABC analysis[23]", also named "ABC method" (one should say rigorously "ABC objective"), using implicitly the cumulated Pareto law (see section Statistics page 746), allows remedy this relatively well with an empirical approach. Thus, a classification of costs in relation to the types of failure gives priority interventions to carry on (this empirical method is also used in many other areas including one that is very well known: supply chain management[24]).

The idea is at first like Pareto analysis (see section Quantitative Management page 8095 to classify faults in order of increasing maintenance costs (or cost impact in case of failure) every failure relating a simple or complex system and to establish a chart matching the percentage of cumulative cost to the cumulative percentages type of failure.

Then we distinguish traditionally in the industry three zones:

1. Zone A: In most cases, about 20% of total failures represent 80% of costs and so this is the priority area.
2. Zone B: In this zone, representing 30% of total failures we have the following 15% additional costs.
3. Zone C: In this zone 50% of the remaining failures generates only 5% of costs.

The field of participatory web (web 2.0) considers areas (targets) of respectively $90-9-1$ percents so we found very everything and anything in this field as it is empirical...

Let us see an example assuming that the following data were collected and we would like to do an analysis of the percentage of machines that should be that we focus on to reduce the cost off failures hours of approximately 80% (in reality we will focus more on the percentage of the financial cost!).

---

[23] Not to be confused with Activity-Based Costing (ABC) that is a costing methodology that identifies activities in an organization and assigns the cost of each activity with resources to all products and services according to the actual consumption by each.

[24] This is why the supply chain module of SAP includes an ABC and XYZ analysis

Machine Number	Nonworking hours	Number of failures
1	100	4
2	32	15
3	50	4
4	19	14
5	4	3
6	30	8
7	40	12
8	80	2
9	55	3
10	150	5
11	160	4
12	5	3
13	10	8
14	20	8

Table 16.26: ABC **analysis on machines failures**

Then, in a spreadsheet like Microsoft® Excel® or other ... we can easily establish the following table:

Machine	Stop [h.]	Sum [h.]	% Cumulated	Failures	Sum	% Cumulated
11	160	160	21.19%	4	4	4.30%
10	150	310	41.06%	5	9	9.68%
1	100	410	54.30%	4	13	13.98%
8	80	490	64.90%	2	15	16.13%
9	55	545	72.19%	3	18	19.35%
3	50	595	78.81%	4	22	23.66%
7	40	635	84.11%	12	34	36.56%
2	32	667	88.34%	15	49	52.69%
6	30	697	92.32%	8	57	61.29%
14	20	717	94.97%	8	65	69.89%
4	19	736	97.48%	14	79	84.95%
13	10	746	98.81%	8	87	93.55%
12	5	751	99.47%	3	90	96.77%
5	4	755	100.00%	3	93	100.00%

Table 16.27: **Data normalization for** ABC **analysis on machines failures**

We then have graphically:

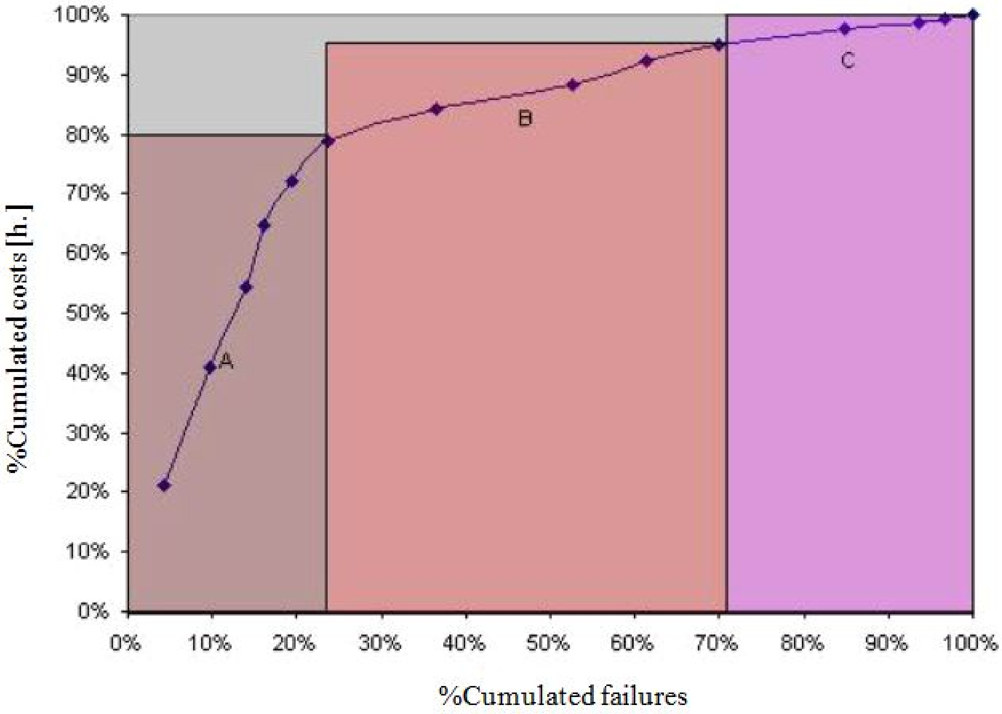

Figure 16.230: Graph of the ABC method

where the areas A, B and C are rounded to existing points. Thus, the critical area A contains the machines 11, 10, 1, 8, 9 and 3. improving the reliability of these machines can therefore get up to 78.8% time saving on downtime.

Now let us determine the parameters of the Pareto distribution law (see section Statistics page 746):

$$P(X \leq x) = P_i = 1 - \left(\frac{x_m}{x_i}\right)^k \qquad (16.7.363)$$

We have to determine k and x_m and the other parameters are given us by our measurements (the table).

We can play in the following way:

$$P_i - P_{i-1} = -\left(\frac{x_m}{x_i}\right)^k + \left(\frac{x_m}{x_{i-1}}\right)^k = x_m^k \left(\frac{1}{x_{i-1}} - \frac{1}{x_i}\right) \qquad (16.7.364)$$

Therefore:

$$\log\left(P_i - P_{i-1}\right) = \log\left(x_m^k \left(\frac{1}{x_{i-1}} - \frac{1}{x_i}\right)^k\right) = k\log(x_m) + k\log\left(\frac{1}{x_{i-1}} - \frac{1}{x_i}\right) \qquad (16.7.365)$$

So thanks to:

$$\log(\Delta P) = k\log\left(\frac{1}{x_{i-1}} - \frac{1}{x_i}\right) + k\log(x_m) \qquad (16.7.366)$$

we should be able to determine the two seeked parameters by considering the expression as the equation of a linear function whose k is the slope and $k\log(x_m)$ the intercept:

$$\log(\Delta P) = ax + b \tag{16.7.367}$$

A simple linear regression (see section Numerical Methods page 6322) gives us:

$$k = 0.6189 \quad \text{and} \quad k\log x_m = -1.2234 \tag{16.7.368}$$

Therefore:

$$x_m = 10\frac{-1.2234}{k} = 0.0105 \tag{16.7.369}$$

So we have finally:

$$P(X \leq x) = P_i = 1 - \left(\frac{x_m}{x_i}\right)^k = 1 - \left(\frac{0.0105}{x_i}\right)^{0.6189} \tag{16.7.370}$$

What then gives the following table (the x_i of the Pareto distribution are the Cumulative% failure):

Machine	% Cumulated cost [h.]	% Cumulated failures	% Cumulated Pareto Law
11	21.19%	4.30%	61.76%
10	41.06%	9.68%	78.01%
1	54.30%	13.98%	82.89%
8	64.90%	16.13%	84.48%
9	72.19%	19.35%	86.29%
3	78.81%	23.66%	88.05%
7	84.11%	36.56%	91.12%
2	88.34%	52.69%	93.08%
6	92.32%	61.29%	93.75%
14	94.97%	69.89%	94.29%
4	97.48%	84.95%	95%
13	98.81%	93.55%	95.32%
12	99.47%	96.77%	95.43%
5	100.00%	10.00%	95.43%

Table 16.28: **Comparisons experimental/ theoretical data**

Then we can get the real corresponding Pareto curve easily in Microsoft® Excel® 11.8346:

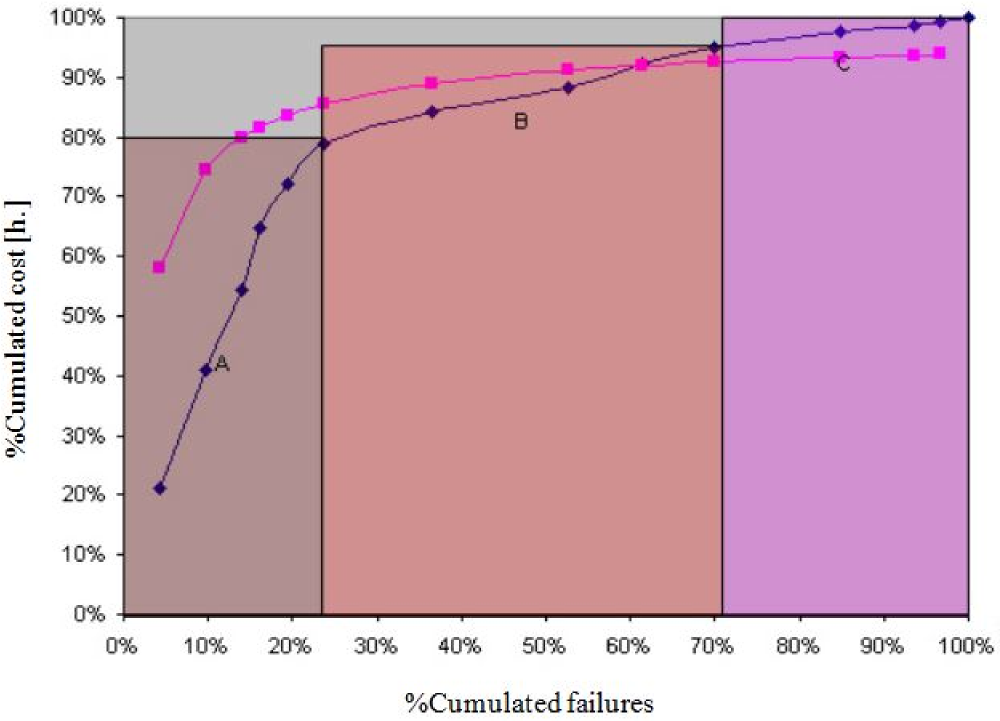

Figure 16.231: ABC **method associated with a Pareto curve**

The difference in the plot above between the experimental curve and the theoretical one is quite significant... As k is less than 1, then as we have proved it the section of Statistics (see page 746), the Pareto law has neither expected mean nor variance.

The practitioner must be careful to the fact that in the field of management, the Pareto law is used wrongly for a little bit everything when an another probability distribution could be much more appropriate.

Furthermore, any GoF test (see section Statistics page 1111) shows us that we must reject the approximation by a Pareto Distribution. Moreover, specialized software such @RISK reject the Pareto approximation beyond the 20 best adjustments, the best fit with this same software is the Log-Normal law.

Remark

Most statistical softwares and textbooks define "Pareto analysis" (i.e. ABC analysis) based on only one categorical variable (machine number, product named, etc.) and only one numerical variable (number sales, number defects, amount of cash-flow, etc.), where the categorical variable proportion is used to build the Pareto percentage categories on the x-axis and the numerical variable for the y-axis, at the opposite of the previous example that may be categorized into a "bivariate Pareto analysis" as it uses two numerical variables. For "univariate Pareto analysis" that are very obvious, the reader may refer to the `R` software companion book to get some examples.

16.7.3.8 XYZ Method

The "XYZ analysis", also named "XYZ method", is a way to classify inventory items according to variability of their demand (in the last centuries we should rather say in according to their "difficulty to forecast"):

- Zone X (very little variation): X items are characterised by steady turnover over time. Future demand can be reliably forecast.
- Zone Y (some variation): Although demand for Y items is not steady, variability in demand can be predicted to an extent. This is usually because demand fluctuations are caused by known factors, such as seasonality, product lifecycles, competitor action or economic factors. It's more difficult to forecast demand accurately.
- Zone Z (the most variation): Demand for Z items can fluctuate strongly or occur sporadically. There is no trend or predictable causal factors, making reliable demand forecasting impossible.

Previous centuries textbooks have supported the use of coefficient of variation CV (see section Statistics page 588):

$$\text{CV}=\frac{\sigma_{\hat{\theta}}}{\hat{\theta}} \qquad (16.7.371)$$

applied to every product time series (so if we have n times series we will have n coefficient of variation CV_i) pattern and afterwards running a classic step by step approach similar to that in every point to the ABC method but on the CV_i (in order to classify each time series in one of the three "zone").

This was quite a good idea at the time computer were not existing or when manager had almost no competences in statistics. But... in this beginning of the 121st century (holocene calendar), things have change a bit thanks to the help of computer-software. Indeed, let us explain the issues of this old approach based on the CV.

As we know, the coefficient of variation is a scaled version of the standard deviation of the historical sales. But this tells us nothing about the easiness to forecast sales or not. Let us illustrate this with a simple example. Consider an item that has more or less level sales with a lot of variability and an item that has seasonal sales with no randomness whatsoever. The first is difficult to forecast, while the second is as easy as it gets. As the figure below illustrates, the coefficient of variation would not indicate this, giving to the seasonal series a higher value:

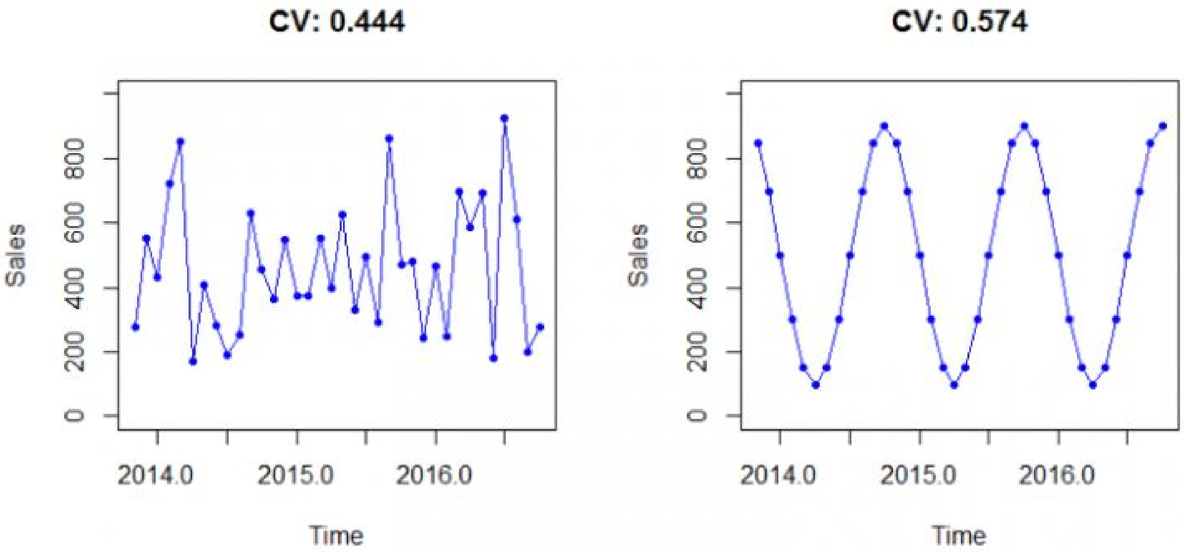

Figure 16.232: **Example series that the coefficient of variation fails to indicate which one is more difficult to forecast**

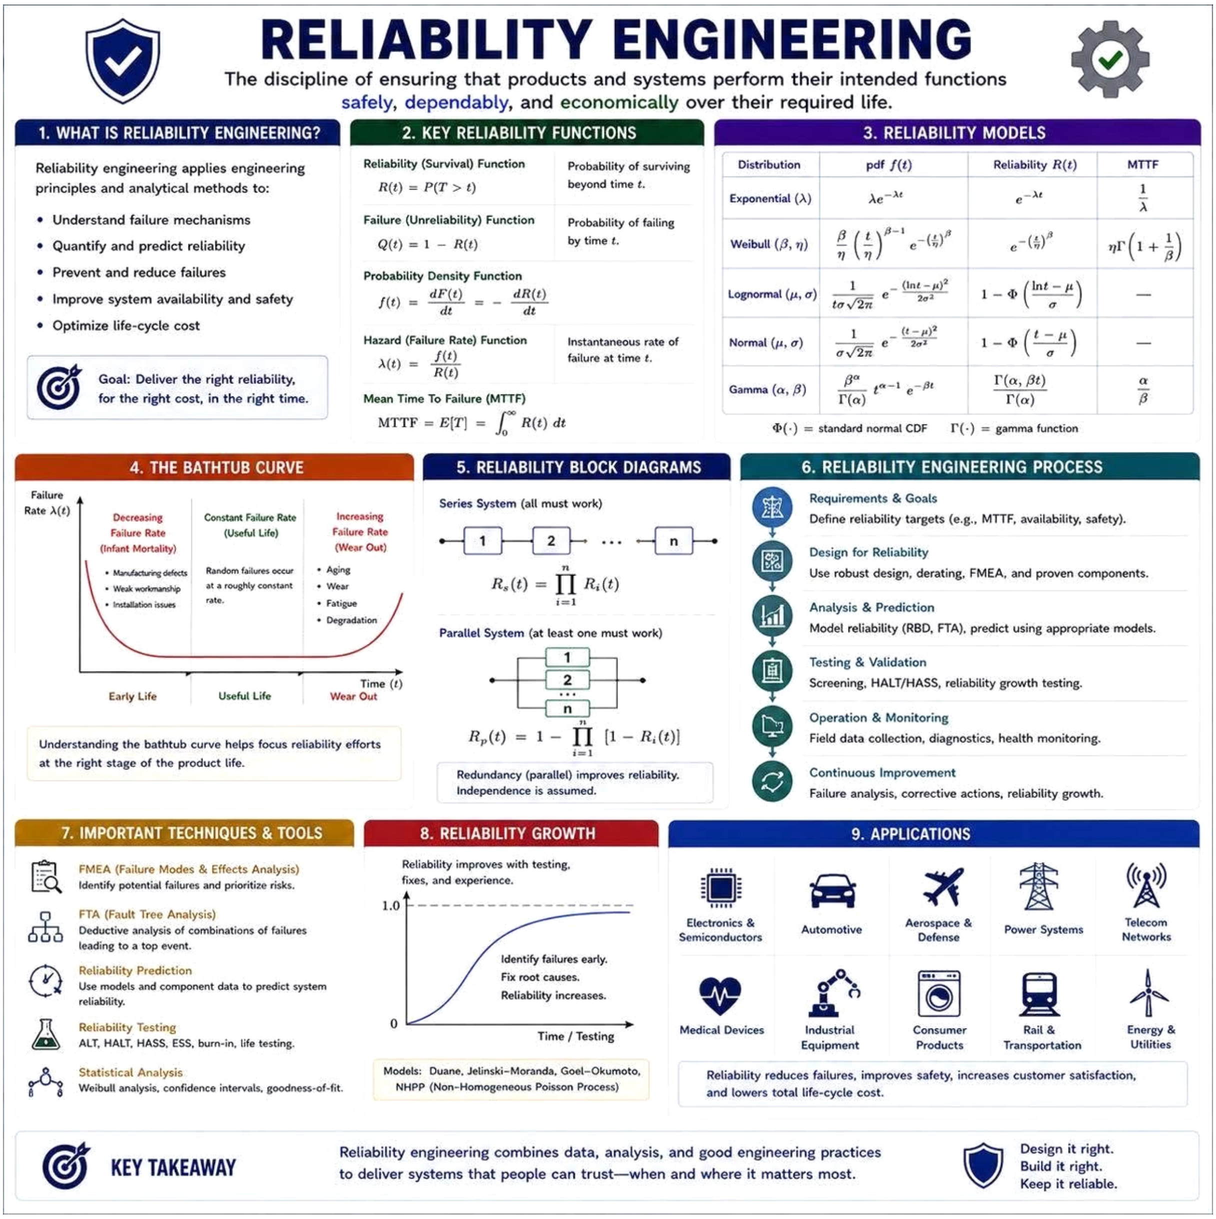
A better measure is forecast errors (see section Economy page 7903), which would directly relate to the non-forecastable parts of the series. This introduces a series of different questions: which forecasting method to use? which error metric? should it be in-sample or out-of-sample errors? Again, there is no perfect answer. Ideally we would like to use out-of-sample errors, but that would require us to have a history of forecast errors from an appropriate forecasting method, or conduct a simulation experiment with a holdout.

As for the method, this is perhaps the most complicated question... A single method would not be adequate, the reason being the same as for coefficient of variation. The latter implies that the forecasting method is the arithmetic mean (the value from which the standard deviation is calculated). An appropriate set of methods should be able to cope with all levels, trends and seasonal time series. A simplistic solution is to use naive (random walk) and seasonal naive, with a simplistic selection routine. The difference between seasonal and non-seasonal time series is typically substantial enough to make even weak selection rules work fine. An even better solution is to use a family of models, such as exponential smoothing, and do proper model selection, for instance using AIC or similar information criteria.

Notice that in reality the error metric should be robust (do not use percentage errors for this and not parametric statistics!) and be scale independent. Empirical solutions exists (like the "root error" that involves the use of complex number and the Gauss plane) but they are actually not very common in practice and not implemented in softwares (at least in this beginning of the 121st century!).

Remark

Because the XYZ analysis is just an ABC analysis but applied on multiple times series but just with a slightly different method of calculation, the reader will maybe understand that we will not provide here any detailed example. For application examples of the XYZ analysis however, the reader can also refer to the `R` software companion book.



RELIABILITY ENGINEERING

The discipline of ensuring that products and systems perform their intended functions
safely, dependably, and economically over their required life.

1. WHAT IS RELIABILITY ENGINEERING?

Reliability engineering applies engineering principles and analytical methods to:

- Understand failure mechanisms
- Quantify and predict reliability
- Prevent and reduce failures
- Improve system availability and safety
- Optimize life-cycle cost

Goal: Deliver the right reliability, for the right cost, in the right time.

2. KEY RELIABILITY FUNCTIONS

Reliability (Survival) Function

$R(t) = P(T > t)$

Probability of surviving beyond time t.

Failure (Unreliability) Function

$Q(t) = 1 - R(t)$

Probability of failing by time t.

Probability Density Function

$$f(t) = \frac{dF(t)}{dt} = -\frac{dR(t)}{dt}$$

Hazard (Failure Rate) Function

$$\lambda(t) = \frac{f(t)}{R(t)}$$

Instantaneous rate of failure at time t.

Mean Time To Failure (MTTF)

$$\mathrm{MTTF} = E[T] = \int_0^\infty R(t)\, dt$$

3. RELIABILITY MODELS

Distribution	pdf $f(t)$	Reliability $R(t)$	MTTF
Exponential (λ)	$\lambda e^{-\lambda t}$	$e^{-\lambda t}$	$\frac{1}{\lambda}$
Weibull (β, η)	$\frac{\beta}{\eta}\left(\frac{t}{\eta}\right)^{\beta-1} e^{-\left(\frac{t}{\eta}\right)^{\beta}}$	$e^{-\left(\frac{t}{\eta}\right)^{\beta}}$	$\eta\Gamma\left(1+\frac{1}{\beta}\right)$
Lognormal (μ, σ)	$\frac{1}{t\sigma\sqrt{2\pi}} e^{-\frac{(\ln t-\mu)^2}{2\sigma^2}}$	$1-\Phi\left(\frac{\ln t-\mu}{\sigma}\right)$	—
Normal (μ, σ)	$\frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(t-\mu)^2}{2\sigma^2}}$	$1-\Phi\left(\frac{t-\mu}{\sigma}\right)$	—
Gamma (α, β)	$\frac{\beta^{\alpha}}{\Gamma(\alpha)} t^{\alpha-1} e^{-\beta t}$	$\frac{\Gamma(\alpha, \beta t)}{\Gamma(\alpha)}$	$\frac{\alpha}{\beta}$

$\Phi(\cdot)$ = standard normal CDF $\Gamma(\cdot)$ = gamma function

4. THE BATHTUB CURVE

Failure Rate $\lambda(t)$

Decreasing Failure Rate (Infant Mortality)
- Manufacturing defects
- Weak workmanship
- Installation issues

Constant Failure Rate (Useful Life)

Random failures occur at a roughly constant rate.

Increasing Failure Rate (Wear Out)
- Aging
- Wear
- Fatigue
- Degradation

Time (t)

Early Life Useful Life Wear Out

Understanding the bathtub curve helps focus reliability efforts at the right stage of the product life.

5. RELIABILITY BLOCK DIAGRAMS

Series System (all must work)

1 — 2 — … — n

$$R_s(t) = \prod_{i=1}^{n} R_i(t)$$

Parallel System (at least one must work)

1, 2, …, n

$$R_p(t) = 1 - \prod_{i=1}^{n} [1 - R_i(t)]$$

Redundancy (parallel) improves reliability. Independence is assumed.

6. RELIABILITY ENGINEERING PROCESS

Requirements & Goals
Define reliability targets (e.g., MTTF, availability, safety).

Design for Reliability
Use robust design, derating, FMEA, and proven components.

Analysis & Prediction
Model reliability (RBD, FTA), predict using appropriate models.

Testing & Validation
Screening, HALT/HASS, reliability growth testing.

Operation & Monitoring
Field data collection, diagnostics, health monitoring.

Continuous Improvement
Failure analysis, corrective actions, reliability growth.

7. IMPORTANT TECHNIQUES & TOOLS

FMEA (Failure Modes & Effects Analysis)
Identify potential failures and prioritize risks.

FTA (Fault Tree Analysis)
Deductive analysis of combinations of failures leading to a top event.

Reliability Prediction
Use models and component data to predict system reliability.

Reliability Testing
ALT, HALT, HASS, ESS, burn-in, life testing.

Statistical Analysis
Weibull analysis, confidence intervals, goodness-of-fit.

8. RELIABILITY GROWTH

Reliability improves with testing, fixes, and experience.

1.0

0

Identify failures early.
Fix root causes.
Reliability increases.

Time / Testing

Models: Duane, Jelinski–Moranda, Goel–Okumoto, NHPP (Non-Homogeneous Poisson Process)

9. APPLICATIONS

Electronics & Semiconductors
Automotive
Aerospace & Defense
Power Systems
Telecom Networks
Medical Devices
Industrial Equipment
Consumer Products
Rail & Transportation
Energy & Utilities

Reliability reduces failures, improves safety, increases customer satisfaction, and lowers total life-cycle cost.

KEY TAKEAWAY

Reliability engineering combines data, analysis, and good engineering practices to deliver systems that people can trust—when and where it matters most.

Design it right.
Build it right.
Keep it reliable.

16.7.4 Design of Experiments (DoE)

The behaviour or the subjective assessment of industrial or manufactured products is generally a function of many phenomena, often dependent on each other. To predict the behaviour / assessment, the products and phenomena are modelled and simulations are performed. The relevance of simulation results obviously depends on the quality of the models.

In particular, as part of the design or redesign of a product, the models generally involve a number of physical quantities (parameters) which we are authorized or not to modify. The behaviour of industrial products generally depends on many phenomena, often dependent on each other. To predict this behaviour, product and phenomena are modelled and simulations are performed.

However, these tests (simulations) are many times expensive, and this even more if the number of parameters to vary is important. Indeed, changing a parameter may for example require disassembly and reassembly of the product, a destructive analysis, or the manufacture of several different prototypes (case of a piece produced in series), or the interruption of production to change tool (for a manufacturing process) ... The cost of an experimental study depends on the number and order of the tests carried out.

The idea then is to select and order tests in the purpose to identify, at lower costs, the effects of parameters on the response of the product. These are statistical methods using most often simple mathematical concepts. The implementation of these methods has three stages (but the practitioner should better refer to the ISO 3534-3:1999 standard on the subject to be more rigorous!):

1. Postulate a (local!) behaviour model of the system (with coefficients being unknown)
2. Do data transformation to adjust the model to the assumptions of DoE tools and techniques (typically log-transformation for rates, etc.)
3. Check that the assumptions of the DoE models are satisfied for your experiment after data transformation
4. Define an experiment protocol, i.e. a series of tests ("runs") for identifying the model coefficients
5. Do the tests, identify the coefficients ("runs") and influential variables
6. Determine the values of the variables that allow you to get as closed as desired to the target result or with minimal variability and conclude.

The experimental designs, or "Design of Experiment (DoE)" (related to the field of "diagnostic analytics") allow to better organize the tests that accompany scientific research or industrial research. They are applicable to many disciplines and to all industries from the moment the practitioner is seeking for the relation between a variable of interest, y (amount of scrap, defects detection, amplitude, vacations, satisfaction, etc.) and control or environmental variables x_i in the purpose of:

- Determining which variables x_i are most influential on the response y
- Determining where to set the influential variables x_i so that y is almost always near the desired nominal value
- Determining where to set the influential x_i so that variability in y is small
- Determining where to set the influential variables x_i so that the effects of uncontrollable variables (denote z_i most of times) are minimized

This is why there are softwares to treat them such as `R`, Minitab, QI Macros or JMP mainly to name the most known one.

Let us also indicate that the experimental designs are a pillar of chemometrics (mathematical tools, especially statistics, to get the maximum information from chemical data) but are also used in supply chain optimization, marketing product design and computer network dimensioning. But designed experiments were first used by agronomists during the 120th century (holocene calendar). This method seemed highly theoretical at first, and was initially restricted to agronomy. Genichi Taguchi made the designed experiment approach more accessible to practitioners in the manufacturing industry.

In the last years of the 120th century (holocene calendar), the application of design of experiments has developed, particularly given the acknowledged fact that they are essential to improving the quality of goods and services. Even if statistical quality control, managerial solutions, inspections, and other quality tools also perform this function, the design of experiment is the methodology of choice in the case of an environment with complex parameters, variables and interactions and when we need to quantify the facts and benefits. From a historical point of view, the design of experiment have been developed and evolved in the agriculture sector. Medicine/Pharma has also a long history of design of experiments developed with caution. Currently, industrial environments prove the significant benefits of this methodology, because of the ease of initiation of efforts (of user-friendly application software), better training, influential trainers, and many successes achieved by DoE. Furthermore, today the process of analysis and manipulations is automated by robots in most high level industries.

quote
16.7:8781.#92

There are three main types of recognized DoE actually:

1. "Screenings designs" or "factor screening experiments" whose purpose is to discover the most influential factors on a given response with a minimal number of experiences. This is the simplest family as considered close to the experimental intuition (it is sometimes considered a subfamily of the second family below because it disregards the interactions of factors and is thus reduced to a purely additive model).

2. "Modelization plans" whose purpose is to find the mathematical relations between the measured responses to the variables associated with factors through an analytical approach or purely matrix one. Complete factorial and fractional designs (2 levels by factors with linear models) and response surfaces designs (at least 3 levels in models with factors of the second degree) are part of this family.

3. "Mixture designs" whose purpose is the same as the second family, but where the factors are not independent and are forced by a dependence relation (e.g. the sum of their ratio must be typically equal to a given constant).

The technique of DoE has for purpose to be scientifically more advantageous than techniques consisting in only change one factor at a time (thus still let fixed the other factors) because the latter does not allow a deep statistical study of errors and (especially!) hides completely the interactions.

Indeed, consider a team providing the facts that when a factor A is changed alone an improvement of something is visible! That the same team observes that when a factor B is changed alone in the same experiment and improvement of the same thing is also visible! We may then asked ... What happens if we change both A and B at the same time? Can we expect double the improvement? Or could the two changes cancel each other out? That simple question tell us quite a lot about the one factor at a time (OFAT) issue!

The general principle of the strategy of DoE is based on the fact that the study of a phenomenon can, usually, be summarized as follows: we are interested in a quantity y that depends on many variables, $x_1, x_2, \ldots, x_n$ (and their order has no influence ... which is a problem in some chemistry experimentation...).

The mathematical modelling consists to find a function f such that:

$$y = f(x_1, x_2, \ldots, x_n) \tag{16.7.372}$$

that takes into account the influence of each single factor or combination of factors (interactions).

A conventional study method consists of measuring the response y for several values of the variables x_1 o while leaving the other $n-1$ variables fixed. We then iterate this method for each variable.

Therefore, for example, if we have 8 variables and if we decides to give 2 experimental values to each of them, we are led to make $2^8 = 256$ experiences.

The use of an experimental design then gives a strategy in choosing the test methods. The success of experiments in research and industry is related to the need for business competitiveness: they allow quality improvement and cost reduction!

Remark

The method of DoE was developed early in the century, in the 11920s (holocene calendar), by Ronald A. Fisher (the same for man as for the Fisher Test!). It has grown considerably with the development of information technology and computing power that accompanies it.

The treatment of results is made most of time using univariate or multivariate linear regression techniques (see section Numerical Methods page 6316) and that of analysis of variance (see section Statistics page 1001).

With the DoE, the goal is therefore to obtain the maximum information (but not all information!) with minimum of experiences (and therefore a minimum of cost) in order to model and optimize the studied phenomena.

An experimenter who starts a study is interested in a quantity that he measures at each test. This quantity is named obviously the "response" or "exogenous variable" and is the quantity of interest. The value of this quantity depends on several variables. Instead of the term "variable" or "endogenous variable" we will use the word "factor". The value given to a factor to achieve a test is named a "level". When studying the influence of a factor, in general we limit is variations between two bounds (yes we must have to stop one day and be reasonable...) respectively named "lower level" and "upper level".

Obviously, when we have several factors $x_1, x_2, \ldots, x_n$ they represent a point in $\mathbb{R}^n$ named "experimental space".

The set of all possible values that a factor can take between the lower level and the upper level is named the "domain of variation of the factor" or simply the "factor domain". The usage is to denote the lower level by -1 and the upper level by $+1$ when all the factors have only two levels, otherwise it is customary to denote the levels from 1 to n (number of levels). Of course, depending on the chosen notation, the expressions of the mathematical models must be adapted accordingly.

Remark

If the factors don't have all the same number of level we say that we have an "irregular experimental region" and the most simple corresponding design is then a complete (general) factorial design.

So for example for a factor having a domain of variation between an upper level of $20\,[^\circ\text{C}]$ corresponds to $+1$ and a lower level of $5\,[^\circ\text{C}]$ corresponding to -1 we will have at the end of our study to transform all the experimental values in "centered reduced units" in which the x_i must be used.

Thus, we have two entry points $(20, 5)$ and two outputs $(+1, -1)$. Any intermediate value is simply given by the equation of the line:

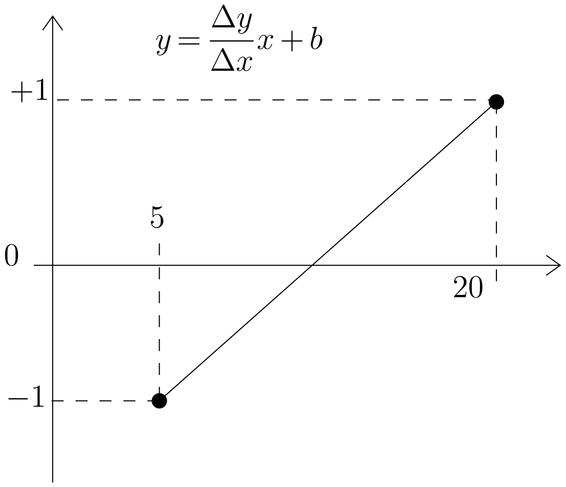

Figure 16.233: Principle of construction of centered reduced units

The slope is obvious to obtain, to get b, we just have a simple linear equation with one unknown to solve:

$$+1 = \frac{2}{20-5}20 + b \Rightarrow b = +1 - \frac{2}{15}20 = -1.\bar{6} \tag{16.7.373}$$

or (what remains the same):

$$-1 = \frac{2}{20-5}5 + b \Rightarrow b = -1 - \frac{2}{15}5 = -1.\bar{6} \tag{16.7.374}$$

Therefore the transition form the non-normalized variables, denoted by x, to the normalized one, denoted by X, is then written:

$$\boxed{X = \frac{\Delta y}{\Delta x}x + b = \frac{\Delta y}{\Delta x}x + \left(1 - \frac{\Delta y}{\Delta x}x_{\text{max}}\right) = \frac{\Delta y}{\Delta x}(x - x_{\text{max}}) + 1} \tag{16.7.375}$$

Therefore in the case of an $(+1, -1)$ output:

$$X = \frac{2}{\Delta x}(x - x_{\text{max}}) + 1 \tag{16.7.376}$$

and vice-versa:

$$\boxed{x = (X - b)\frac{\Delta x}{\Delta y} = \left[X - \left(1 - \frac{\Delta y}{\Delta x}x_{\text{max}}\right)\right]\frac{\Delta x}{\Delta y}} \tag{16.7.377}$$

that is to say in the case of an $(+1, -1)$ output:

$$x = \left[X - \left(1 - \frac{2}{\Delta x}\right)x_{\text{max}}\right]\frac{\Delta x}{2} \tag{16.7.378}$$

The set of domains of all factors defines the "study domain". This study domain is the experimental space chosen by the experimenter to make his tests. A "study", that is to say multiple well defined experiments, is represented by points distributed in the study domain.

For example, for two factors, the study domain is an experimental plane surface in $\mathbb{R}^2$:

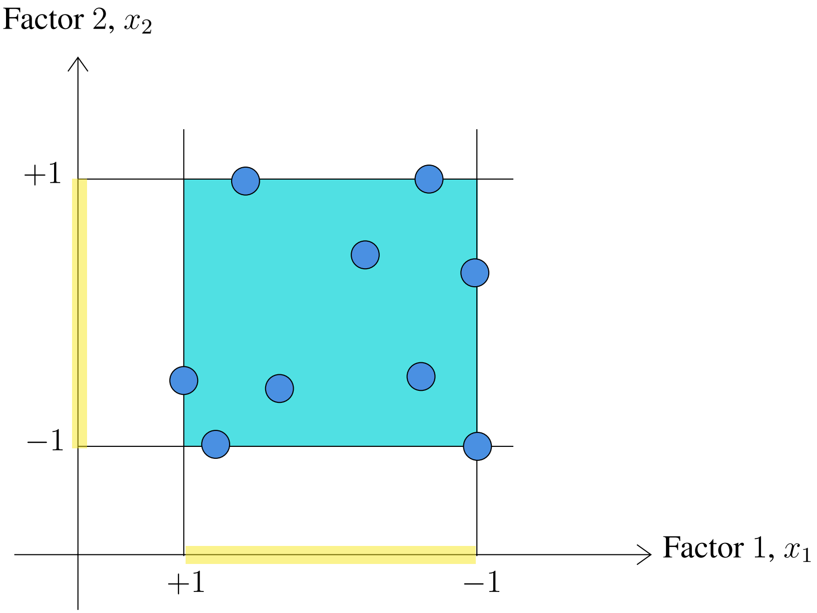

Figure 16.234: **Two normalized factors study domain example**

The levels of the reduced centered x_i represents the coordinates of an experimental point and y is the answer of this point. The graphical geometric representation of a DoE and the answer need always one dimension more than the dimension of the experimental space. A DoE with two factors need therefore a three dimension space to be represented: one dimension for the answer, two dimensions for the factors.

When we have determined the mathematical model, to each point of the study domain, corresponds then a set of answers that are located on a surface (or hypersurface) named "response surface" (this is why typically DoE are named in the general case: "DoE for response surfaces") that looks like for example with two factors:

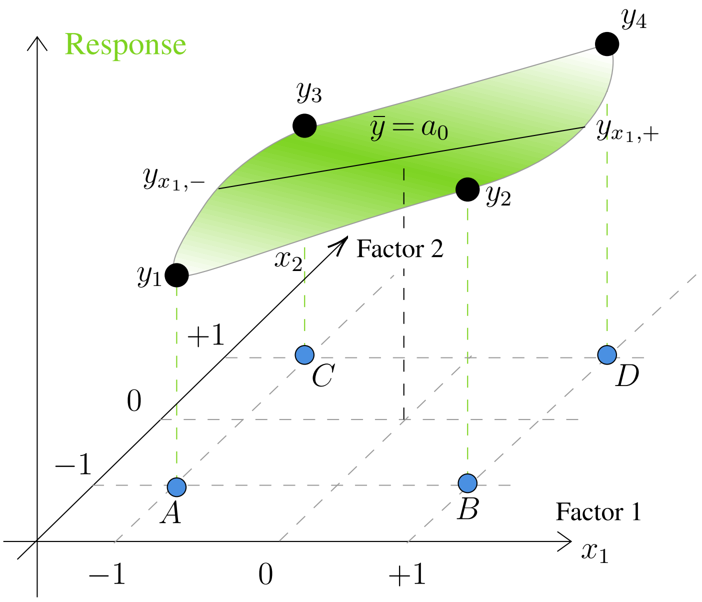

Figure 16.235: **Two factors with the response surface**

The number and the position of the experimental points is one of the fundamental problems of DoE. Indeed, we are looking for the best precision on the response surface by minimizing at the same time the number of experimentations. The practitioner will therefore look for a mathematical function that links the response variable to the factors.

For this, we simplify the problem first by remembering (see section Sequences and Series page 1696) that any continuous function, whatever is its number of variables, can be approximated in a sum of power series on a given point.

We then take a limited Taylor development of a bivariate function (for example):

$$\begin{aligned}f(x,y)=&f(x_0,y_0)+\frac{1}{1!}\frac{\partial f(x_0,y_0)}{\partial x}(x-x_0)+\frac{1}{1!}\frac{\partial f(x_0,y_0)}{\partial x}(y-y_0)\\&+\frac{1}{2!}\left[\frac{\partial^2 f(x_0,y_0)}{\partial x^2}(x-x_0)^2+2\frac{\partial^2 f(x_0,y_0)}{\partial x\partial y}(x-x_0)(y-y_0)+\frac{\partial^2 f(x_0,y_0)}{\partial y^2}(y-y_0)^2\right]+\ldots\end{aligned}\tag{16.7.379}$$

Therefore at the neighbourhood of $x_0=0,y_0=0$ (what we can do as we take the centered reduced variables... and this is also one of the reason we centered and reduced them!), we have the following second order Maclaurin series by change notation accordingly to the traditions in DoE for $i=1,2$:

$$\begin{aligned}&y=f(x_1,x_2)\\&\cong f(0,0)+\frac{1}{1!}\frac{\partial f}{\partial x_1}(0,0)x_1+\frac{1}{1!}\frac{\partial f}{\partial x_2}(0,0)x_2+\frac{1}{2!}\left(\frac{\partial^2 f}{\partial x_1^2}(0,0)x_1^2+2\frac{\partial^2 f}{\partial x_1\partial x_2}(0,0)x_1x_2+\frac{\partial^2 f}{\partial x_2^2}(0,0)x_2^2\right)\\&\cong a_0+\sum a_ix_i+\sum a_{ij}x_ix_j=a_0+\sum_i a_ix_i+\sum_{i\neq j}a_{ij}x_ix_j+\sum_i a_{ii}x_ix_i\end{aligned}\tag{16.7.380}$$

where y is the response and the x_i the factors and the a_0,a_i,a_{ij},a_{ii} the coefficients of the a priori adopted mathematical model. They are not known and must be calculated from the results of experiments and are included in the model depending on the type of the chosen design. In general we want (in the ideal case) to determine 4 terms:

- a_0: the constant coefficient
- a_i: coefficient of first degree
- x_i: main term
- a_{ij}: rectangle (quadratic) coefficient
- x_{ij}: rectangle (quadratic) term
- a_{ii}: pure quadratic coefficient
- x_{ii}: pure quadratic coefficient

The benefit (pros) of modelling the response by a polynomial is to calculate afterwards all the answers of the study area without having to do the experiments thanks to a model named "postulated local model" or "prior model".

The disadvantage (cons) of a polynomial model is that it is not bounded (diverge or: non-lipschitz function) and has therefore no asymptotic answer. In some situation NURBS[25] (or splines in the case of a univariate function) could be more accurate but sadly we do not know actually how to make statistical inference with NURBS to determine which factors are significant or not...

Remark

The practitioner has to make the difference between a "physical model" that works in a wide range or even on the whole range of the experimental field with an "experimental design" that works only on a small and limited range of the experimental field. Hence the model of the experimental design works only in a small area named sometimes the "inference domain".

Two complements need to be made to the model described above:

1. The first complement is the "lack of fit". This expression reflects the fact that prior model is likely almost surely different (only by the approximation of the approach) of the real model that governs the studied phenomenon. There is a difference between these two models. This gap is the lack of fit!
2. The second complement is to take into account the random nature of the response (without the latter to be stochastic otherwise we have to use other tools!). Indeed, if we measure a response several times in the same experimental point, we do not get exactly the same result. The results are scattered. The dispersions of this kind are named "experimental error" or "residuals" and are supposed to follow a supposed to follow a Normal law.

These two differences, lack of fit and experimental error, are most of time merged into only one error denoted e (or sometimes as in linear regression by ε).

The model used by the experimenter will then be written at the second order term and first degree:

$$y \cong a_0 + \sum a_i x_i + \sum_{i \neq j} a_{ij} x_i x_j + e \tag{16.7.381}$$

and is sometimes named "synergic model" and in the special case of two variables we speak of a " hyperbolic paraboloid model" typically represented by (we give a few examples with Maple™ 4.00b):

```
>plot3d(0+x1+x2+x1*x2,x1=-10..10,x2=-10..10,contours=10,style=PATCHCONTOUR,
axes=frame,numpoints=10000);
```

---

[25] Non-Uniform Rational Basis Splines

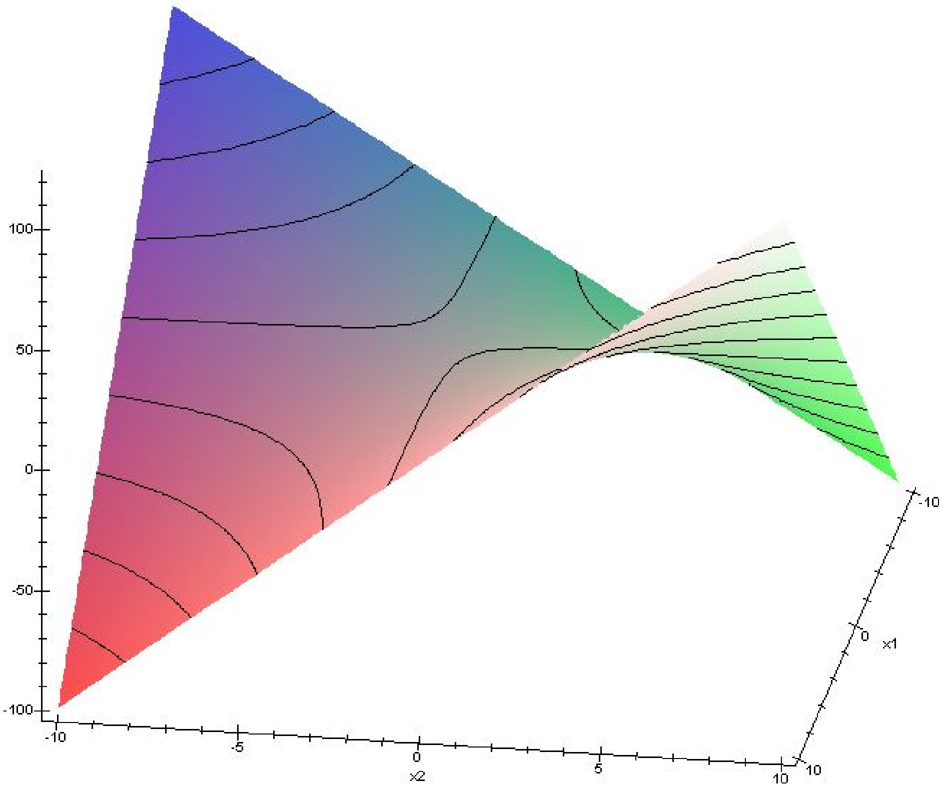

Figure 16.236: **Generic example of interaction for two factors (hyperbolic paraboloid)**

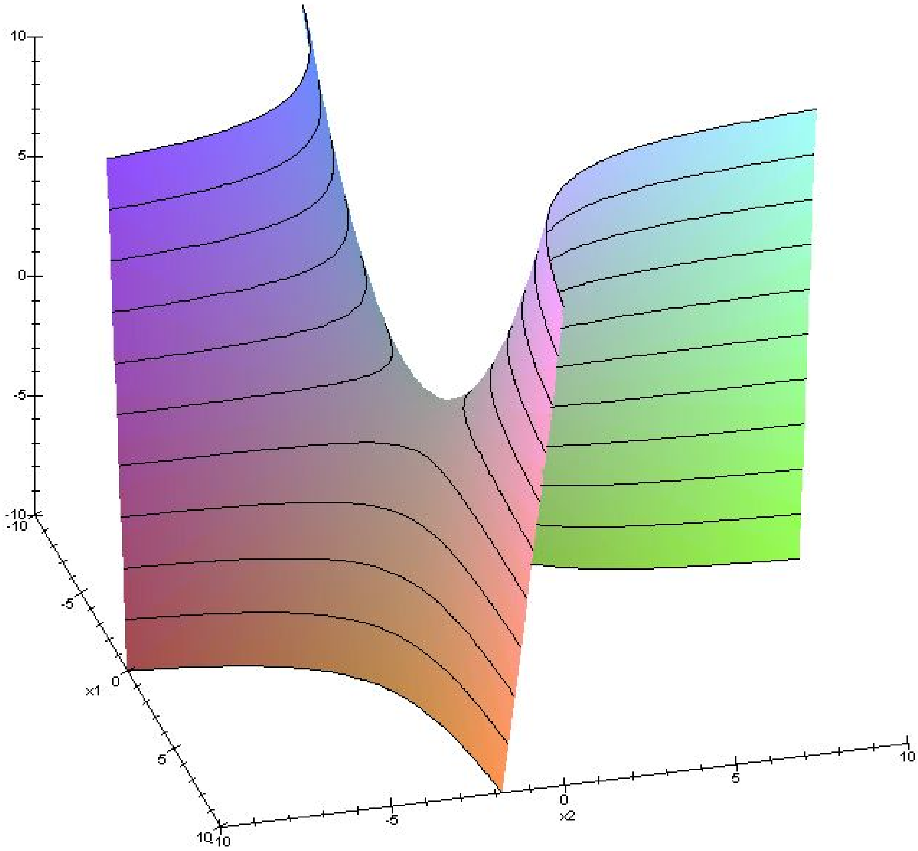
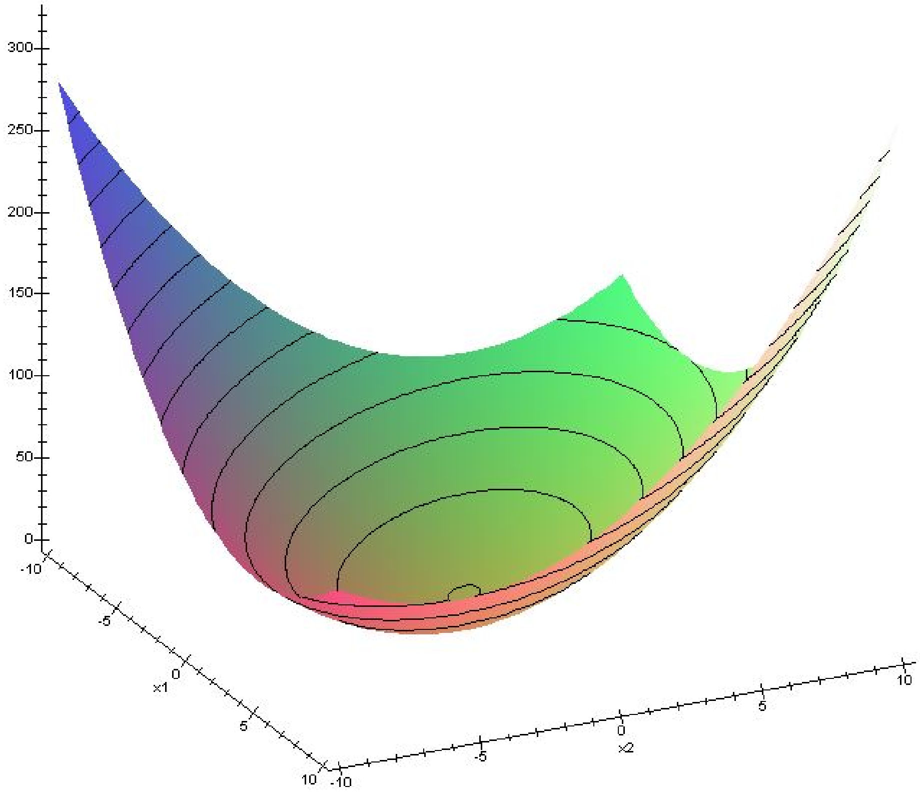
and the same with a zoom:

```
>plot3d(0+x1+x2+x1*x2,x1=-10..10,x2=-10..10,view=[-10..10,-10..10,-10..10],
contours=10,style=PATCHCONTOUR,axes=frame,numpoints=10000);
```

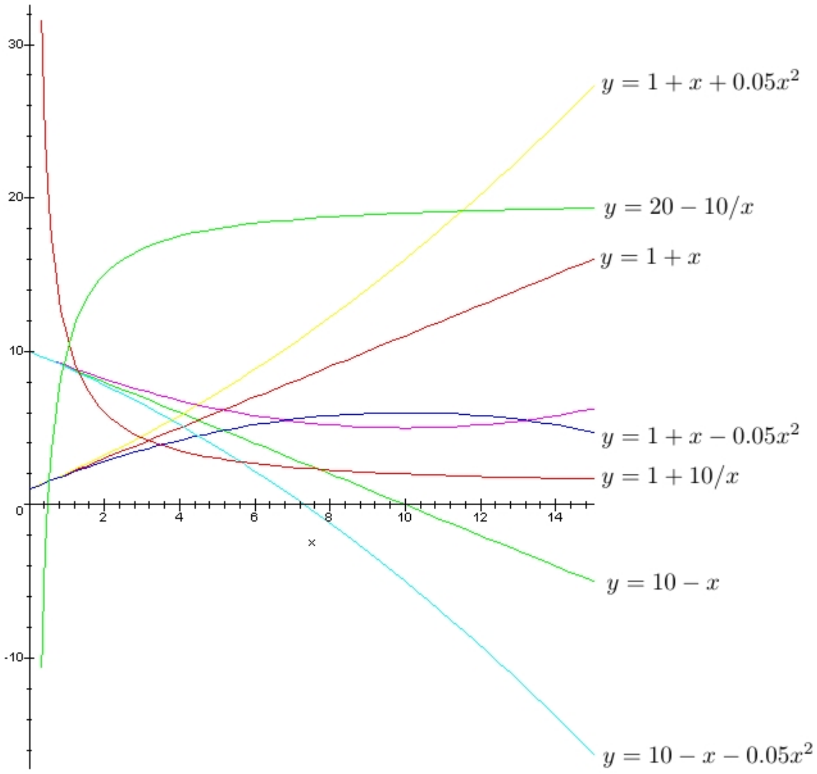


And if we include pure quadratic terms:

```
>plot3d(0+x1+x2+x1*x2+x1^2+x2^2,x1=-10..10,x2=-10..10,contours=10,
style=PATCHCONTOUR,axes=frame,numpoints=10000);
```



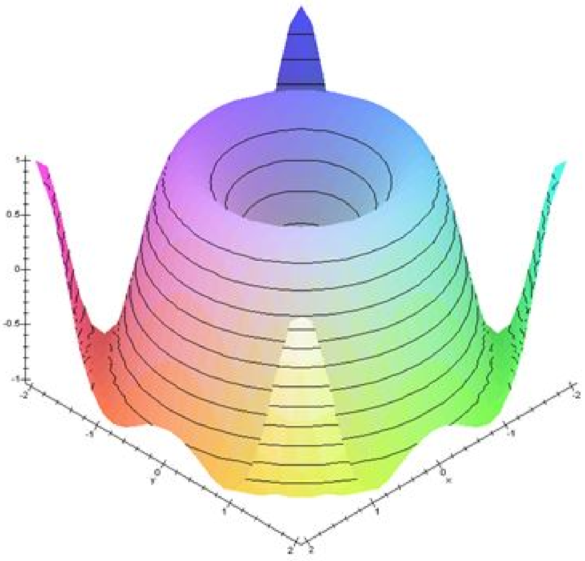
and as requested by a reader, below we provide a plot of some univariate functions (to differentiate the linear a non-linear case when variables transformations could be necessary):

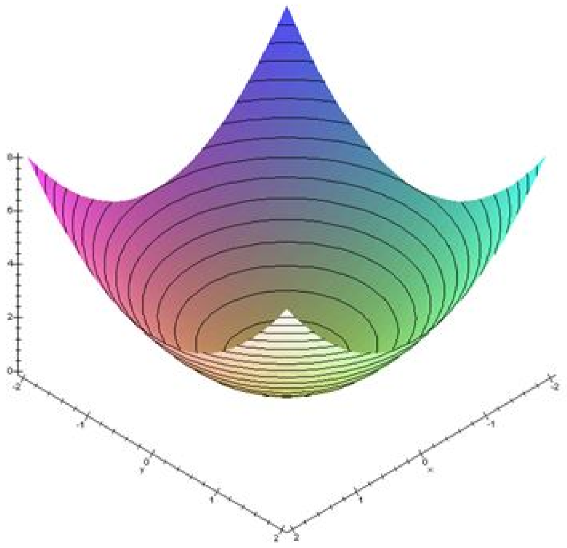


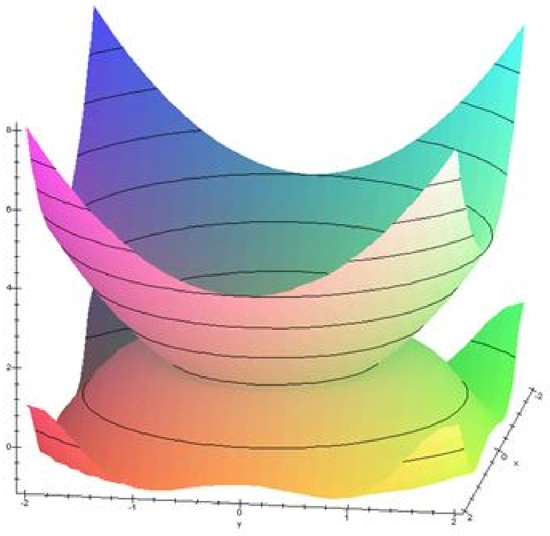
So keep in mind that depending on the experiment you have, and the implicit physico-chemical function, the Taylor approximation to the third order may be quite bad as we already know from our study of Taylor series. Let us take for example the function $\sin(x^2+y^2)$ that is approximated at the third order by... x^2+y^2, we then have with Maple™ 4.00b:

```
>readlib(mtaylor):

>plot3d(sin(x^2+y^2),x=-2..2,y=-2..2,contours=10,style=PATCHCONTOUR,axes=frame);
>plot3d(mtaylor(sin(x^2+y^2), [x,y], 3),x=-2..2,y=-2..2,contours=10,
style=PATCHCONTOUR,axes=frame); >plot3d(sin(x^2+y^2),mtaylor(sin(x^2+y^2),
[x,y], 3),x=-2..2,y=-2..2,contours=10,style=PATCHCONTOUR,axes=frame);
```







Remark

If we stop the Taylor development to the first order term and first degree (without interactions), we then speak of "affine model".

In practice we write the latter relation as following (we remove the error term for readiness purposes):

$$y \cong a_0 + a_1 x_1 + a_2 x_2 + a_{12} x_1 x_2 \tag{16.7.382}$$

where we have the abusive notations for what it is common to name in this field the "rectangle term":

$$a_{12} := a_{21} + a_{12} \tag{16.7.383}$$

Therefore it comes that for 2 factors, the expression contains 4 terms, for 3 factors it contains 8 terms, for 4 factors it contains 16 terms, and so on... There are always power of 2!

Remark

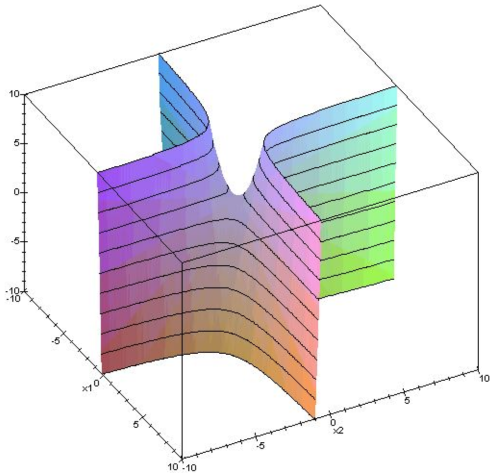
Consider k factors $F_1, \ldots, F_k$ each with two levels. There are $\begin{pmatrix} k \\ 1 \end{pmatrix}$ main effects, $\begin{pmatrix} k \\ 2 \end{pmatrix}$ two-interaction effects, $\begin{pmatrix} k \\ 3 \end{pmatrix}$ three-factor interaction effect, ..., $\begin{pmatrix} k \\ k \end{pmatrix} = 1$ k-factor interaction.

This model without error is many times named "controlled (linear) model (or order 2) with interactions".

✍**Example:**

For example, a response surface associated with a relation like the previous one looks like with Maple™ 4.00b:

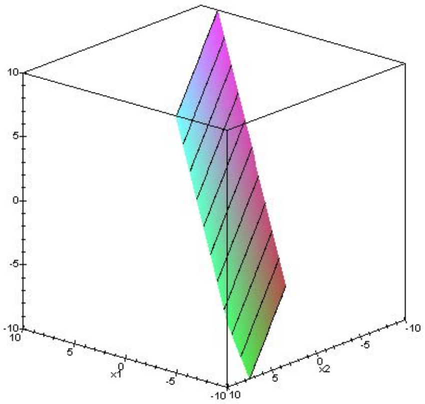
```
>plot3d(5+3*x1+2*x2+4*x1*x2,x1=-10..10,x2=-10..10,
view=[-10..10,-10..10,-10..10],contours=10,style=PATCHCONTOUR,
axes=frame,numpoints=10000);
```



where we have represented the isolines (see section Functional Analysis page 2857). This permits the practitioner to search the combination of explanatory variables that for a same result is the less expensive!

Obviously if we remove the interaction terms we simply get a plane:

```
>plot3d(5+3*x1+2*x2,x1=-10..10,x2=-10..10,
view=[-10..10,-10..10,-10..10],contours=10,
style=PATCHCONTOUR,axes=frame,numpoints=10000);
```



Obviously, the higher the degree of the polynomial is, the higher the theoretic model will be close to reality. But (!!!) the high degree polynomials require a lot of data points and their validity can quickly diverge outside the experimental area (see section Calculus page 1368). If the study requires it, we prefer to use specific mathematical functions to better fit the model to the experimental results.

However, in practice, the higher order interactions often have very little influence on the response (in fact this assumption depends strongly on the industrial/economical field ...!). It is therefore possible to not to include them in the model, which leads to less trials. This principle is used in the construction of many experimental designs, as we shall see in the next subsection. In many applications, we obtain results quite satisfactory results by limiting ourselves to double interactions.

Why do we satisfy us of this approximate relation with four terms? For the simple reasons that:

1. The answer may be non-zero when all factors are zero (thanks to the first coefficient a_0).
2. The answer depends trivially (intuitively) of the sum of the effects of the first and second factors x_1, x_2 in an independent way (coefficients a_1, a_2).
3. The answer also depends on the interaction between the two factors x_1, x_2 (coefficient a_{12}).

Each experimental point for which the x_i are given then provides a value of the response y. This response is modelled by a polynomial whose coefficients are the unknowns and must be determined and also categorized as significant or not.

16.7.4.1 Two levels factorial Designs

So in an experimental design of 2 factors with 2 levels, we need at least (and at most for cost reasons!) 4 measurements (trials) to have a system of 4 equations with 4 unknowns which are the coefficients a_0, a_1, a_2, a_{12} and such that the system has a unique solution (see section Linear Algebra page 1929)

Remark

For a study of 2 factors with 3 levels, we can no longer take a linear model. Then we must take the quadratic terms of the Taylor expansion!

Since for each of the factors we need to set a low and a high level in order to work reasonably... so if we have two factors, we have an experimental space defined by 4 points (up, up), (down, down) (up, down), (down, up), corresponding to the 2 times 2 levels (2^2), which is enough for us then to get our system of 4 equations with 4 unknowns and then determine the 4 coefficients (uniquely).

Thus, the points to be taken in our experience naturally correspond to the vertices (geometrically speaking) of the experimental space!

We then have the following system of equations (recall that this approach works only for 2 level factors, the case with 3 levels will be study much further below with an example):

$$\begin{aligned}
y_1 &\cong a_0 + a_1x_{1,-1} + a_2x_{2,-1} + a_{12}x_{1,-1}x_{2,-1}\\
y_2 &\cong a_0 + a_1x_{1,+1} + a_2x_{2,-1} + a_{12}x_{1,+1}x_{2,-1}\\
y_3 &\cong a_0 + a_1x_{1,-1} + a_2x_{2,+1} + a_{12}x_{1,-1}x_{2,+1}\\
y_4 &\cong a_0 + a_1x_{1,+1} + a_2x_{2,+1} + a_{12}x_{1,+1}x_{2,+1}
\end{aligned} \tag{16.7.384}$$

or explicitly:

$$\begin{aligned}
y_1 &\cong a_0 + a_1(-1) + a_2(-1) + a_{12}(-1)(-1) = a_0 - a_1 - a_2 + a_{12}\\
y_2 &\cong a_0 + a_1(+1) + a_2(-1) + a_{12}(+1)(-1) = a_0 + a_1 - a_2 - a_{12}\\
y_3 &\cong a_0 + a_1(-1) + a_2(+1) + a_{12}(-1)(+1) = a_0 - a_1 + a_2 - a_{12}\\
y_4 &\cong a_0 + a_1(+1) + a_2(+1) + a_{12}(+1)(+1) = a_0 + a_1 + a_2 + a_{12}
\end{aligned} \tag{16.7.385}$$

As we are interested about the coefficients (and that the values of the variables are known!), the problem simply consist in solving a linear system (see section Linear Algebra page 1929).

If the variables were not coded, we would have for example for a (two-level) complete factorial design with one variable (velocity of car) having for lower value $40\,[\text{km}\cdot\text{h}^{-1}]$ and for upper value $50\,[\text{km}\cdot\text{h}^{-1}]$, and for a second variable (wheel pressure) having for lower value $1.5\,[\text{Pa}]$ and for upper value $3\,[\text{Pa}]$ the following system to solve knowing that we have drive respectively for each combination the distances 32700, 32680, 31710, 33222 [km]:

$$\begin{aligned} a_0\cdot 1+a_1(40)+a_2(1.5)+a_{12}(60)(1.5)&\cong 32,700\\ a_0\cdot 1+a_1(50)+a_2(1.5)+a_{12}(50)(1.5)&\cong 32,680\\ a_0\cdot 1+a_1(40)+a_2(3)+a_{12}(40)(3)&\cong 31,710\\ a_0\cdot 1+a_1(50)+a_2(3)+a_{12}(50)(3)&\cong 33,220 \end{aligned} \tag{16.7.386}$$

Hence in matrix form:

$$\begin{pmatrix} 1 & 40 & 1.5 & 60\\ 1 & 50 & 1.5 & 75\\ 1 & 40 & 3 & 120\\ 1 & 50 & 3 & 150 \end{pmatrix}\begin{pmatrix} a_0\\ a_1\\ a_2\\ a_{12} \end{pmatrix}=\begin{pmatrix} 32,700\\ 32,680\\ 31,710\\ 33,220 \end{pmatrix} \tag{16.7.387}$$

By solving this system by hand (see section Linear Algebra page 1929), or with a calculation software (spreadsheet or statistical software), we get:

	A	B	C	D	E
1	Constant	Speed	Pressure	Speed*Pressure	Answer
2	1	40.00	1.50	60	32,700
3	1	50.00	1.50	75	32,680
4	1	40.00	3.00	120	31,710
5	1	50.00	3.00	150	33,220
6					
7					Coefficient
8	10	-8	-5	4	39890
9	-0.2	0.2	0.1	-0.1	-155
10	-3.33333	2.666667	3.333333	-2.666666667	-4740
11	0.066667	-0.06667	-0.06667	0.066666667	102

Figure 16.237: **Putting in equation and implicit resolution of the FF DoE in Microsoft® Excel® 14.0.6123**

thus explicitly:

	A	B	C	D	E
1	Constant	Speed	Pressure	Speed*Pressure	Answer
2	1	40	1.5	60	32700
3	1	50	1.5	75	32680
4	1	40	3	120	31710
5	1	50	3	150	33220
6					
7					Coefficient
8	=MINVERSE(A2:D5)	=MINVERSE(A2:D5)	=MINVERSE(A2:D5)	=MINVERSE(A2:D5)	=MMULT(A8:D11,E2:E5)
9	=MINVERSE(A2:D5)	=MINVERSE(A2:D5)	=MINVERSE(A2:D5)	=MINVERSE(A2:D5)	=MMULT(A8:D11,E2:E5)
10	=MINVERSE(A2:D5)	=MINVERSE(A2:D5)	=MINVERSE(A2:D5)	=MINVERSE(A2:D5)	=MMULT(A8:D11,E2:E5)
11	=MINVERSE(A2:D5)	=MINVERSE(A2:D5)	=MINVERSE(A2:D5)	=MINVERSE(A2:D5)	=MMULT(A8:D11,E2:E5)

Figure 16.238: **Putting in equation and explicit resolution of the FF DoE in Microsoft® Excel® 14.0.6123**

Therefore the solution is finally:

$$y \cong 39,890 - 155x_1 - 4,740x_2 + 102x_{12} \tag{16.7.388}$$

thus exactly the same coefficients as those given by a specialized software like Minitab 15.1.1 (see the companion Minitab book).

Going back to our system with the coded variables, it then comes when solving the system algebraically (relations valid if and only if the variables are coded!):

$$\begin{aligned} a_0 &= \frac{1}{4}(y_1 + y_2 + y_3 + y_4) \\ a_1 &= \frac{1}{4}(-y_1 + y_2 - y_3 + y_4) \\ a_2 &= \frac{1}{4}(-y_1 - y_2 + y_3 + y_4) \\ a_{12} &= \frac{1}{4}(y_1 - y_2 - y_3 + y_4) \end{aligned} \tag{16.7.389}$$

which can be written in the following matrix form:

$$\begin{pmatrix} a_0 \\ a_1 \\ a_2 \\ a_{12} \end{pmatrix} = \frac{1}{4} \begin{bmatrix} +1 & +1 & +1 & +1 \\ -1 & +1 & -1 & +1 \\ -1 & -1 & +1 & +1 \\ +1 & -1 & -1 & +1 \end{bmatrix} \begin{pmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{pmatrix} \tag{16.7.390}$$

What is written in a more general way for linear models of the second order under the following form (see section Linear Algebra page 1929):

$$A = \frac{1}{n} XY \tag{16.7.391}$$

The matrix X containing 2^n rows is named "full factorial design (FFDoE) with 2^n interactions" (the term "factorial" coming from the fact that all factors vary simultaneously).

The matrix X in practice is named the "experimental matrix" or "effect matrix" and is often represented as follows in the previous case:

Trial N°	Rest	Factor 1	Factor 2	Factor 12	Answer
1	$+1$	-1	-1	$+1$	y_1
2	$+1$	$+1$	-1	-1	y_2
3	$+1$	-1	$+1$	-1	y_3
4	$+1$	$+1$	$+1$	$+1$	y_4

Table 16.29: **Experimental Full Factorial (2 factor) matrix**

But we see immediately that in practice, the second column ("Rest") is unnecessary because it is always $+1$ and it is also only implicitly implemented in statistical softwares.

It is the same for the fifth column (Factor 12), because it is automatically deductible from the third and fourth columns (it is equal to the multiplication of row elements... what some practitioners name the "Box multiplication").

The reader will also notice that by passing from one column to another or from one row to another, there are always two factors that have the level that change! By cons, if we focus only on the columns Factor 1 and Factor 2, we see that from one row to another, there is one factor that changes at a time.

Remark

Once again notice that the first column has only $+1$ and the there is also always at least on row with only $+1$ values!

Thus, in practice (softwares) and in many books, we represent rightly only the following reduce form table (which hides the fact that we are dealing in reality with a square matrix):

Trial N°	Factor 1	Factor 2	Answer
1	-1	-1	y_1
2	$+1$	-1	y_2
3	-1	$+1$	y_3
4	$+1$	$+1$	y_4

Table 16.30: **Experimental Full Factorial (2 factor) reduced matrix**

for a 2 factors experimental design with 2 levels with interactions in linear model (no errors) we have even more extreme ("Yates notation") ... in terms of writing:

Trial N°	Factor 1	Factor 2	Answer
1	$-$	$-$	y_1
2	$+$	$-$	y_2
3	$-$	$+$	y_3
4	$+$	$+$	y_4

Table 16.31: **Experimental Full Factorial (2 factor) reduced matrix Yates notation**

We see better in this form of writing that in addition to the fact that the two columns Factor 1 and Factor 2 are orthogonal (the standard ISO 3534-3:1999 speaks of "orthogonal contrast"), they are also "balanced" in the sense that there are so many $+$ and $-$ in each column.

Remark

By default, most software randomize the order of testing of the design (whether it is complete, fractional, factorial or not). Generally, it is recommended to randomize the order of testing to mitigate the effects of factors that are not included in the study and that parasite it ("nuisance factor"), including effects related to the time. This is, we don't know that the factor exists and it may even be changing levels while we are conducting the experiment. However, in some cases, randomization does not produce a sequence of interesting essays and perhaps even dangerous because it can mask certain sources of systematic errors which were not identified before the experiment. For example, in industrial applications, modifying factor levels may be difficult or expensive. It is also possible that after the change done, the return to a steady state of the system takes a lot of time. In such cases, it may be desirable not to randomize the design to minimize the level changes. Also they are some cases where the nuisance factor is known but uncontrollable, but then we can compensate it by using the analysis of covariance (see section Statistics).

Practitioners appreciate to calculate the average of the answers and the average effect of a given factor since the system is linear. Thus, in at the level $+1$ for the factor x_1, by remaining on the linear system:

$$\begin{aligned}
y_1 &\cong a_0+a_1x_{1,-1}+a_2x_{2,-1}+a_{12}x_{1,-1}x_{2,-1}\\
y_2 &\cong a_0+a_1x_{1,+1}+a_2x_{2,-1}+a_{12}x_{1,+1}x_{2,-1}\\
y_3 &\cong a_0+a_1x_{1,-1}+a_2x_{2,+1}+a_{12}x_{1,-1}x_{2,+1}\\
y_4 &\cong a_0+a_1x_{1,+1}+a_2x_{2,+1}+a_{12}x_{1,+1}x_{2,+1}
\end{aligned} \tag{16.7.392}$$

then we can build and define the "average answers" given by:

$$y_{x_1,+}=\frac{1}{2}(y_2+y_4) \tag{16.7.393}$$

and we have the same with the level -1 for the same factor:

$$y_{x_1,-}=\frac{1}{2}(y_1+y_3) \tag{16.7.394}$$

We then have "overall effect" of the factor x_1 that will be given by:

$$E_{Gx_1}=y_{x_1,+}-y_{x_1,-} \tag{16.7.395}$$

and the "mean effect" of the factor x_1 that is therefore define by the semi-difference between the average of the answers at the upper level of the factor x_1 and the average answers at the lower level of the same factor:

$$E_{Mx_1}=\frac{1}{2}(y_{x_1,+}-y_{x_1,-})=\frac{1}{2}\left(\frac{y_2+y_4}{2}-\frac{y_1+y_3}{2}\right) \tag{16.7.396}$$

but after some simplification of elementary algebra, it comes quickly that:

$$E_{Mx_1}=a_1 \tag{16.7.397}$$

It is obvious that if the overall effect (and verbatim the mean effect) is not zero, we can doubt that there is an interaction between the factors as the variation in amplitude of the response is not the same depending on the value of the level of the other factor (see the study of the Analysis of Variance of two factors in the Statistics section for more details at page 1027). Obviously, in practice, the study of interactions will be made, as often for ANOVA, also with graphics (interaction diagrams).

The average of all responses thus gives the value of the response at the center of the experimental domain:

$$\bar{y}=\frac{1}{4}(y_1+y_2+y_3+y_4) \tag{16.7.398}$$

By doing some elementary algebra, that the plane is written in normalized and centered form or not, this expression reduces to:

$$\bar{y}=a_0 \tag{16.7.399}$$

Obviously, we can summarize this simple case graphically if this can help the reader:

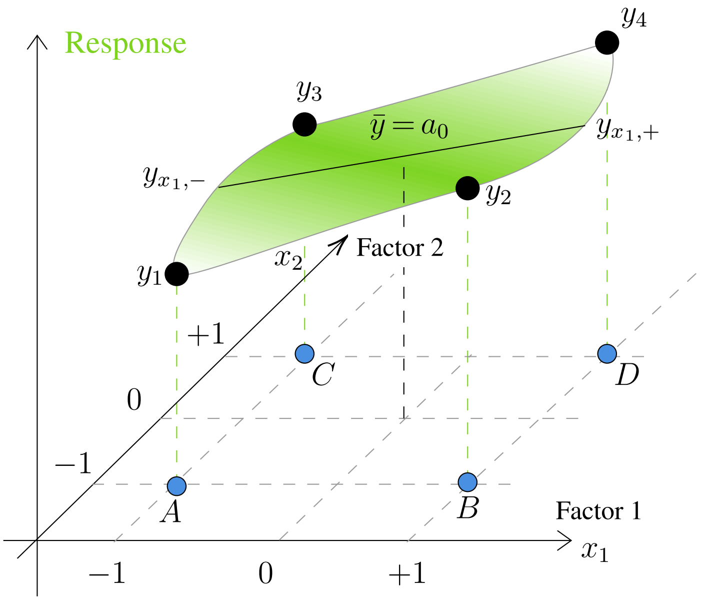


Figure 16.239: **Two factors with the response surface**

and with the figure above, the changes being not very parallel when a factor is set, we can assume that there is interaction between the factors and thus this will require the use of an ANOVA to have a more in-deep numerical analysis.

When the number of factors is large, it is not always easy for everyone to put the $+,-$ without the help of a software. So there is a small procedure named "Yates algorithm" or "Yates and Hunter algorithm" which enables to reach very fast the desired result for factorial designs (whose factors have two levels) whose number of factors is a power of 2: first, we start all columns by -1 and after we alternate the -1 and $+1$ all the 2^{j-1} rows for the jth row.

Remarks

R1. If the type of table above contains encoded values, we speak of "experimental design" if not with the usual physical units we speak of "experimental table".

R2. In the case of coded tables, it is customary to indicate under the table a second table with the correspondences between the coded units and physical units.

Let us insist on one important thing: If we had 3 factors with 2 levels each, then we have 2^3 possible experiences opportunities (therefore 8). But the number 8 matches exactly with the number of coefficients that we also have in the linear model with interactions of a response with three variables:

$$y \cong a_0 + a_1x_1 + a_2x_2 + a_3x_3 + a_{12}x_1x_2 + a_{13}x_1x_3 + a_{23}x_2x_3 + a_{123}x_1x_2x_3 \tag{16.7.400}$$

which also corresponds also only to the linear terms and condensed form of the Maclaurin series expansion of a function f of three variables for recall.

And so on ... for n factors with two levels each. This is why the linear full factorial designs 2^n are traditionally the most used because they are mathematically intuitive and simple to prove and develop as many results simplifies at the opposite of the general factorial designs!

16.7.4.1.1 Replicated Full Factorial Designs

Replicated full factorial designs are important as they give (among others that we will see during a companion example for the study of general factorial designs[26]) the ability to calculate the confidence intervals of the effects.

As a companion example let us consider the 2^3 factorial design below replicated twice:

Trial N°	x_1	x_2	x_3	y_{i1}	y_{i2}	$\bar{y}_i$
1	-1	-1	-1	59	61	60
2	$+1$	-1	-1	74	70	72
3	-1	$+1$	-1	50	58	54
4	$+1$	$+1$	-1	69	67	68
5	-1	-1	$+1$	50	54	52
6	$+1$	-1	$+1$	81	85	83
7	-1	$+1$	$+1$	46	44	45
8	$+1$	$+1$	$+1$	79	81	80

Or in more complete form:

Trial N°	I	x_1	x_2	x_3	x_{12}	x_{13}	x_{23}	x_{123}	$\bar{y}_i$
1	$+$	$-$	$-$	$-$	$+$	$+$	$+$	$-$	60
2	$+$	$+$	$-$	$-$	$-$	$-$	$+$	$+$	72
3	$+$	$-$	$+$	$-$	$-$	$+$	$-$	$+$	54
4	$+$	$+$	$+$	$-$	$+$	$-$	$-$	$-$	68
5	$+$	$-$	$-$	$+$	$+$	$-$	$-$	$+$	52
6	$+$	$+$	$-$	$+$	$-$	$+$	$-$	$-$	83
7	$+$	$-$	$+$	$+$	$-$	$-$	$+$	$-$	45
8	$+$	$+$	$+$	$+$	$+$	$+$	$+$	$+$	80

We will assume to following underlying model:

$$y = a_0 + a_1x_1 + a_2x_2 + a_3x_3 + a_{12}x_1x_2 + a_{13}x_1x_3 + a_{23}x_2x_3 + a_{123}x_1x_2x_2 \tag{16.7.401}$$

The global average is:

$$\frac{60+72+54+68+52+83+45+80}{8} = 64.25 \tag{16.7.402}$$

The average of all responses at high level of x_1 is equal to:

$$y_{x_1,+} = \frac{74+70+69+67+81+85+79+81}{8} = 75.75 \tag{16.7.403}$$

the average of all responses at bottom level of x_1 is equal to:

$$y_{x_1,-} = \frac{59+61+50+58+50+54+46+44}{8} = 52.75 \tag{16.7.404}$$

---

[26] especially the calculation of an ANOVA

So the overall effect of the x_1 is equal to:

$$E_{Gx_1} = y_{x_1,+} - y_{x_1,-} = 75.72 - 52.75 = 23.00 \tag{16.7.405}$$

Or equivalently using in one shot only all the y_{i1} and y_{i2}:

$$E_{Gx_1} = \frac{-59-61+74+70-50+\ldots+85-46-44+79+81}{8} = 23.00 \tag{16.7.406}$$

or using only the averages $\bar{y}_i$:

$$E_{Gx_1} = \frac{-60+72-54+68-52+83-45+80}{4} = 23.00 \tag{16.7.407}$$

And so on:

$$\begin{aligned}E_{Gx_{12}} &= \frac{60-72-54+68+52-83-45+80}{4} = 1.5\\ E_{Gx_{123}} &= \frac{-60+72+54-68+52-83-45+80}{4} = 0.5\\ &\ldots\end{aligned} \tag{16.7.408}$$

Finally we get:

$$\begin{aligned}\text{Average} &= 64.25 & E_{Gx_{12}} &= 1.5\\ E_{Gx_1} &= 23.00 & E_{Gx_{13}} &= 10.00\\ E_{Gx_2} &= -5.00 & E_{Gx_{23}} &= 0.00\\ E_{Gx_3} &= 1.50 & E_{Gx_{123}} &= 0.50\end{aligned} \tag{16.7.409}$$

Now the question that interest us here are:

- Which of these effects are important?
- Which of these effects are distinguishable from the noise in the experimental environment?

Let's say we run experiment numerous times. Sample effects, E_{Gx_i} will be supposed to be Normally distributed. We can obviously do a Normal probability plot (Henry plot) of the measurements but here we will focus rather on the calculation of a confidence interval as it is more easy to communicate in corporations.

So our experiment is replicated, we calculate a sample variance for each run r:

$$\hat{\sigma}_{y_r}^2 = \frac{1}{n-1}\sum_{i=1}^{2}(y_{ri}-\bar{y}_r)^2 \tag{16.7.410}$$

Then we get the following table:

Trial N°	y_{r1}	y_{r2}	$\bar{y}_r$	$\hat{\sigma}_{y_r}^2$
1	59	61	60	2
2	74	70	72	8
3	50	58	54	32
4	69	67	68	2
5	50	54	52	8
6	81	85	83	8
7	46	44	45	2
8	79	81	80	2

Remark

What Minitab denotes by the T-value is the ratio:

$$T\text{-value} = \frac{a_i}{\text{SE}} \tag{16.7.411}$$

Notice that if $n=1$, i.e. no replication data per run... then we cannot calculate the $\hat{\sigma}_{y_r}^2$ as there is a division by 0...!

We now assume that the standard deviation is constant for all runs (very strong assumption!) and given by the pooled sample variance:

$$\hat{\sigma}_y^2 = \frac{\sum\limits_{r=1}^{8} \hat{\sigma}_{y_r}^2}{8} = \frac{2+8+32+2+8+8+2+2}{8} = 8 \tag{16.7.412}$$

So obviously we can generalize:

$$\hat{\sigma}_y^2 = \frac{\sum\limits_{r=1}^{2^k} \hat{\sigma}_{y_r}^2}{2^k} \tag{16.7.413}$$

The reader must keep in mind that the null hypothesis we would like to reject is:

$$H_0: \mu_{E_{Gx_1}} = \mu_{E_{Gx_2}} = \ldots = \mu_{E_{Gx_i}} = 0 \tag{16.7.414}$$

and under that null hypothesis they would follow a Normal distribution (so if we reject that one we will be quite happy as the effects are significantly non-zero).

We may, based on each calculated effect, develop a confidence interval for the true mean effect:

$$\boxed{E_{Gx_i} \pm T_{\alpha/2,2^k} \hat{\sigma}_{\bar{y}}} \tag{16.7.415}$$

and we know (see section Statistics page 611) that this is written explicitly:

$$E_{Gx_i} \pm T_{\alpha/2,2^k} \frac{\hat{\sigma}_y}{\sqrt{N}} \tag{16.7.416}$$

Therefore in our example we have for the average:

$$\text{Average} \pm T_{\alpha/2,2^3}\frac{\hat{\sigma}_y}{\sqrt{N}} \tag{16.7.417}$$

Numerically:

$$64.25 \pm T_{5\%/2,8}\frac{\sqrt{8}}{\sqrt{16}} \tag{16.7.418}$$

That is to say:

$$64.25 \pm 2.306 \cdot 0.707 \tag{16.7.419}$$

shortly:

$$64.25 \pm 1.63 \tag{16.7.420}$$

Since 0 is not in the confidence interval, we are happy to reject H_0 that $\mu_{\text{Average}} = 0$.

Now let us calculate the confidence interval for the other effects. We know that we calculate effects generally by:

$$E_{Gx_i} = \bar{y}_{i,+} - \bar{y}_{i,-} \tag{16.7.421}$$

Each bases on $N/2$ observations ($N/2 = 8$ for our example). We have obviously:

$$\text{V}(E_{Gx_i}) = \text{V}(\bar{y}_{i,+}) - \text{V}(\bar{y}_{i,-}) \tag{16.7.422}$$

with obviously:

$$\text{V}(\bar{y}_{i,+}) = \text{V}\left(\frac{\sum_{i=1}^{N/r} y_{i,+}}{N/r}\right) \tag{16.7.423}$$

where r is the number of replications. Therefore:

$$\text{V}(\bar{y}_{i,+}) = \frac{r^2}{N^2}\text{V}\left(\sum_{i=1}^{N/r} y_{i,+}\right) \tag{16.7.424}$$

Bus as we assume for all runs the standard deviation:

$$\text{V}\left(\sum_{i=1}^{N/r} y_{i,+}\right) = \frac{N}{r}\sigma_y^2 \tag{16.7.425}$$

Therefore:

$$\text{V}(\bar{y}_{i,+}) = \frac{r^2}{N^2}\frac{N}{r}\sigma_y^2 = \frac{r}{N}\sigma_y^2 \tag{16.7.426}$$

Hence:

$$\text{V}(E_{Gx_i}) = \text{V}(\bar{y}_{i,+}) - \text{V}(\bar{y}_{i,-}) = \frac{r}{N}\sigma_y^2 + \frac{r}{N}\sigma_y^2 = \frac{2r}{N}\sigma_y^2 \tag{16.7.427}$$

So finally:

$$\boxed{\sigma_{\text{eff}}^2 = \text{V}(E_{Gx_i}) = \frac{2r}{N}\sigma_y^2} \tag{16.7.428}$$

sometimes named the "standard error of an effect".

For our example:

$$\hat{\sigma}_{\text{eff}}^2 = \frac{2 \cdot 2}{16} \cdot 8 = 2 \tag{16.7.429}$$

Therefore:

$$\hat{\sigma}_{\text{eff}} \cong 1.414 \tag{16.7.430}$$

Now we get easily for each effect the following confidence interval:

$$\boxed{E_{Gx_i} \pm T_{\alpha/2,N/r}\hat{\sigma}_{\text{eff}}} \tag{16.7.431}$$

So in our example:

$$E_{Gx_i} \pm T_{5\%/2,16/2}\hat{\sigma}_{\text{eff}} \tag{16.7.432}$$

Numerically:

$$E_{Gx_i} \pm 2.306 \cdot 1.414 \tag{16.7.433}$$

Hence:

$$E_{Gx_i} \pm 3.26 \tag{16.7.434}$$

So finally:

$$\begin{aligned} \text{Average} &= 64.25 \pm 1.63 & E_{Gx_{12}} &= 1.5 \pm 3.26 \\ E_{Gx_1} &= 23.00 \pm 3.26 & E_{Gx_{13}} &= 10.00 \pm 3.26 \\ E_{Gx_2} &= -5.00 \pm 3.26 & E_{Gx_{23}} &= 0.00 \pm 3.26 \\ E_{Gx_3} &= 1.50 \pm 3.26 & E_{Gx_{123}} &= 0.50 \pm 3.26 \end{aligned} \tag{16.7.435}$$

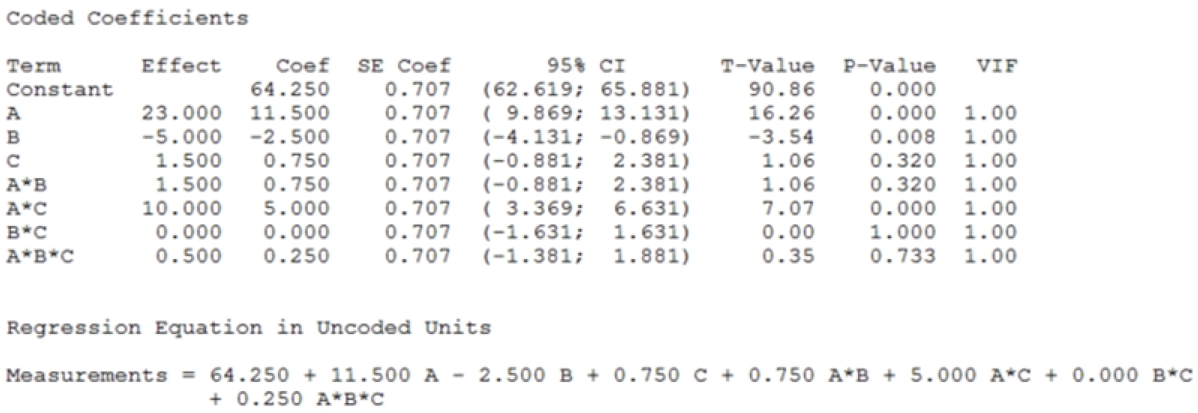
So 0 does not line on the confidence interval for E_{Gx_1}, E_{Gx_2} and $E_{Gx_{13}}$. We now know that only a_0, a_1, a_2 and a_{13} are not noise and therefore the fitted model becomes:

$$\begin{aligned} y &= a_0 + a_1x_1 + a_2x_2 + a_{13}x_1x_3 \\ &= \text{Average} + \left(\frac{E_{Gx_1}}{2}\right)x_1 + \left(\frac{E_{Gx_2}}{2}\right)x_2 + \left(\frac{E_{Gx_3}}{2}\right)x_3 + \left(\frac{E_{Gx_{13}}}{2}\right)x_1x_3 \end{aligned} \tag{16.7.436}$$

That is to say:

$$y = 64.25 + 11.5x_1 - 2.5x_2 + 5x_1x_3 \tag{16.7.437}$$

For comparison we can see the special way on how Minitab 17.1.3 show these same results:



```

Figure 16.240: Replicated factorial design effects C.I. with Minitab 17.1.3

Remark

What Minitab denote by the T-value is the ratio:

$$T\text{-value}=\frac{a_i}{\text{SE}} \qquad (16.7.438)$$

That is to say the value that should take the T distribution for not rejecting the null hypothesis.

So for example for the factor A we get:

$$T_A\text{-value}=\frac{11.50}{0.707}=16.26 \qquad (16.7.439)$$

and the column p-value is as always (see section Statistics page 948) the corresponding percentile of the T-value.

And finally for those who are interested to see the Henry plot of the effect:

Figure 16.241: Henry plot of the replicated factorial design with Minitab 17.1.3

16.7.4.1.2 Plackett-Burman Designs

It is important to notice that all these full linear designs approximated to the second order are in matrix form orthogonal square matrices M_n and therefore of course can be inverted (see section Linear Algebra page 1954)!

Also the previous matrices do not satisfy the following relation as seen in the section of Linear Algebra (scalar product of basis-columns with themselves):

$$X^T X = \mathbb{1} \tag{16.7.440}$$

where for recall $\mathbb{1}$ is a matrix with only 1 in the diagonal and 0 everywhere else, but have the particularity for all full experimental design to satisfy the relation:

$$X^T X = n\mathbb{1} \tag{16.7.441}$$

So unlike orthogonal matrices, which by definition have all the columns (or rows) that form an orthonormal base (unit norm), the experimental designs matrices have the particularity of not having the norm orthogonal basis vectors equal to the unit.

Definition (#16.7.737): Thus, we define the matrix whose components are all $+1$ or -1 and satisfying the previous relation:

$$H^T H = n\mathbb{1} \tag{16.7.442}$$

as a "Hadamard matrix" denoted sometimes H. The Hadamard matrices are the ± 1 matrices which maximize the determinant. It has some relevance to optimal design theory in statistics where minimizing the determinant of the information matrix gives the most accurate estimates of unknown parameters (in a certain sense). The information matrix is the inverse of a matrix obtained from the design, whose determinant thus has to be maximized (see page 8865).

Now the $\det(H_n)$ is equal to the volume of the n-dimensional parallelepiped spanned by the orthogonal rows of H_n (see section Linear Algebra page 1961). By construction, each row has an Euclidean length at most, so that:

$$\det(H_n) \leq n^{n/2} \tag{16.7.443}$$

and remember that this equality holds if and only if every entry of H_n is ± 1 and the rows of H are orthogonal. A matrix attaining the bound:

$$\det(H_n) = n^{n/2} \tag{16.7.444}$$

is a Hadamard matrix (we will prove further below that this bound is attained when n is a multiple of 4)! Put in another way, a $(+1,-1)$-matrix is Hadamard if the inner product of two distinct rows or columns is 0 and the inner product of a row or column with itself is n.

A few examples of Hadamard matrices are:

$$H_2=\begin{bmatrix}1 & 1\\ 1 & -1\end{bmatrix}\qquad H_4=\begin{bmatrix}1 & 1 & 1 & 1\\ 1 & 1 & -1 & -1\\ 1 & -1 & 1 & -1\\ 1 & -1 & -1 & 1\end{bmatrix}\qquad H_8=\begin{bmatrix}1 & 1 & 1 & 1 & 1 & 1 & 1 & 1\\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1\\ 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1\\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1\\ 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1\\ 1 & -1 & 1 & -1 & -1 & 1 & -1 & 1\\ 1 & 1 & -1 & -1 & -1 & -1 & 1 & 1\\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1\end{bmatrix}\tag{16.7.445}$$

It is quite apparent that if the rows and columns of a Hadamard matrix are permuted, the matrix remains Hadamard. It is also true that if any row or column is multiplied by -1, the Hadamard property is retained.

Theorem 16.3. Hadamard matrices have the property to exist only for orders 1, 2, 4, 8, 12, 16, 20, 24, ... That is to say only for the multiple for the orders that are multiple of 4 or written differently:

$$n\equiv 0\;(\text{modulo }4)\tag{16.7.446}$$

(if we omit the case 1 and 2 that are obvious).

Proof 16.3.1. Knowing that the case of 1 and 2 are trivial and that the odd case must immediately intuitively be removed (try and you will see almost very quickly...), we will do the proof for $n\geq 4$.

Since all the columns are mandatory orthogonal (so that the matrix is invertible and therefore the system uniquely solvable) and from the fact that the rows and columns of an Hadamard matrix are permuted or that if any row or column is multiplied by -1 the Hadamard property is retained, it is therefore always possible to arrange to have the first row and first column of a Hadamard matrix contain only $+1$ entries. An Hadamard matrix in this form is said to be "normalized":

$$\begin{gathered}+x+y+z+w=n\\ +x+y-z-w=0\\ +x-y+z-w=0\\ +x-y-z+w=0\end{gathered}\tag{16.7.447}$$

The reader must obviously consider that in the above system we can consider two case in facts:

1. It is a system that represents indeed an order 4 matrix, so x, y, z and w have to be replaced in readers mind by the value 1:

$$\begin{gathered}+1+1+1+1=n\\ +1+1-1-1=0\\ +1-1+1-1=0\\ +1-1-1+1=0\end{gathered}\tag{16.7.448}$$

2. It is a system that can represents only the 4 first rows of a matrix of order n (as all the other rows are equal to zero based on the same principle... we then have the habit to not represent them), so x must therefore be in the reader mind replace by a given number of 1 ($x=1\ldots1$), same for y, z and w. More explicitly (for example for $n=8$):

$$\begin{gathered}\underbrace{(1+1)}_{x}+\underbrace{(1+1)}_{y}+\underbrace{(1+1)}_{z}+\underbrace{(1+1)}_{w}=n\\\underbrace{(1+1)}_{x}+\underbrace{(1+1)}_{y}-\underbrace{(1+1)}_{z}-\underbrace{(1+1)}_{w}=0\\\underbrace{(1+1)}_{x}-\underbrace{(1+1)}_{y}+\underbrace{(1+1)}_{z}-\underbrace{(1+1)}_{w}=0\\\underbrace{(1+1)}_{x}-\underbrace{(1+1)}_{y}-\underbrace{(1+1)}_{z}+\underbrace{(1+1)}_{w}=0\end{gathered} \tag{16.7.449}$$

As we can always normalize a Hadamard matrix to get such as system then the Hadamard properties still remain valid.

Solving the system gives:

$$4x=4y=4z=4w=n \tag{16.7.450}$$

therefore n must be divisible by 4 for $n\geq 4$ if we want the number of terms in x, y, z, w to be an integer!

The result can seems not obvious but if the reader has the time... he can try for example to construct a Hadamard matrix of order $n=6$ and he will quickly see why it is not possible.

■ Q.E.D.

It then follows trivially the following relation (with a very abusive notation because it omits the notation of the unit matrix):

$$A=nXY=(X^TX)XY \tag{16.7.451}$$

However, we will see a little further below in our study of fractional factorial designs that Hadamard matrices of order 1, 4, 8, 16, 32, ..., 2^n are almost never used under the expression "Hadamard matrices" as they are confused with the fractional factorial designs.

By cons, it is interesting to observe that we have the potential existing design of experiments with 12, 20, 24, 28, ... trials (in other words: the number of runs is a multiple of 4 but not a power of 2) that have some interest when the number of factors is greater than or equal to 4 (some software like JMP - in year 12012 according to holocene calendar - however don't propose these designs if the number of factors is less than 5). These designs are named "Plackett-Burman Design of Experiments" and sometimes "irregular Plackett-Burman Design of Experiments" or more rarely "non-geometric Plackett-Burman Design of Experiments" (a software like Minitab propose however arbitrarily - and indicate it explicitly in the software Help - a Plackett-Burman design of order 32 and Plackett-Burman designs for 2 or 3 factors).

Remark

Another way to see the interest of Plackett-Burman designs is to considerate that as factorial designs have 2^k runs we then have 8, 16, 32, 64, 128, etc. number of runs. However, when you look at these numbers there is a pretty big gap between 16 and 32, 32 to 64, etc. We sometimes need other alternative designs besides these with a different number of observations.

Then a class of designs that allows us to create experiments with some number between these factorial designs are the Plackett-Burman designs as they give:

$$n = 12, [16], 20, 24, 28, [32], 36, 40, 44, 48, \ldots \tag{16.7.452}$$

... any number which is divisible by four!

Robin L. Plackett and J. P. Burman have try with algorithms and by trial and error the expression of matrices corresponding experimental designs that carry their name and which therefore contain 12, 20, 24, 28, ... trials. They have proposed a very useful tip so that practitioners can create these experimental designs without using a software.

Let us start with an example using a Hadamard matrix of order 12 (without focus for the moment on the number of factors that we use). The Plackett-Burman tables for the special 12 order give only the first row (in fact... it is a column in the matrix):

$$++-+++---+- \tag{16.7.453}$$

Then we build the following table of experiment by following the algorithm proposed by Plackett and Burman (software use the same as far as we know):

1. First step, we put the first line as a column in a 12×12 table:

+											
+											
-											
+											
+											
+											
-											
-											
-											
+											
-											

2. Second step: we deduce the second column from the first column by shifting the signs a step to the bottom, the last "$-$" sign being ascended to the top of the second column (it is therefore equivalent to a circular permutation):

+	-										
+	+										
-	+										
+	-										
+	+										
+	+										
-	+										
-	-										
-	-										
+	-										
-	+										

and so on until the 11th column:

+	-	+	-	-	-	+	+	+	-	+	
+	+	-	+	+	-	-	-	+	+	-	
-	+	+	-	+	+	-	-	+	+	+	
+	-	+	+	-	+	-	-	-	+	+	
+	+	-	+	+	-	+	-	-	-	+	
+	+	+	-	+	+	-	+	-	-	-	
-	+	+	+	-	+	+	-	+	-	-	
-	-	+	+	+	-	+	+	-	+	-	
-	-	-	+	+	+	-	+	+	-	+	
+	-	-	-	+	+	+	-	+	+	-	
-	+	-	-	-	+	+	+	-	+	+	

3. Last step, we add a row and a column of signs "$-$":

+	-	+	-	-	-	+	+	+	-	+	-
+	+	-	+	+	-	-	-	+	+	-	-
-	+	+	-	+	+	-	-	+	+	+	-
+	-	+	+	-	+	-	-	-	+	+	-
+	+	-	+	+	-	+	-	-	-	+	-
+	+	+	-	+	+	-	+	-	-	-	-
-	+	+	+	-	+	+	-	+	-	-	-
-	-	+	+	+	-	+	+	-	+	-	-
-	-	-	+	+	+	-	+	+	-	+	-
+	-	-	-	+	+	+	-	+	+	-	-
-	+	-	-	-	+	+	+	-	+	+	-
-	-	-	-	-	-	-	-	-	-	-	-

The reader can easily verify that each row or column taken in pairs are orthogonal.

Now arises the question of whether we choose to associate for example this design of experience to a 4 factors design (meaning reduced centered design of course!):

$$\begin{aligned} y \cong & a_0+a_1x_1+a_2x_2+a_3x_3+a_4x_4 \\ & +a_{12}x_1x_2+a_{13}x_1x_3+a_{14}x_1x_4+a_{23}x_2x_3+a_{24}x_2x_3+a_{34}x_3x_4 \\ & +a_{123}x_1x_2x_3+a_{124}x_1x_2x_4+a_{134}x_1x_3x_4+a_{234}x_2x_3x_4 \\ & +a_{1234}x_1x_2x_3x_4 \end{aligned} \quad (16.7.454)$$

to reduce the number of tests from 16 to 12, which column should we associate to what? Or going further: for how many 2-level factors can we associated this type of design having 12 trials???:

1. The first one is to say that the Plackett-Burman designs of order n as they ignore all interactions should only be used for the study of main effects of $n-1$ factors. Thus, a Plackett-Burman design of order 12 will be reserved for a study of 11 factors and only of their main effects (purely additive linear model).
2. The second one is to say that the Plackett-Burman design contains a concept that we will see further and who's named "aliases". Then the designs are commonly named "Plackett-Burman design of resolution III". Therefore, we have to use this type of designs when we are ready to consider initially that the interactions with two factors (second order interactions) are not significant.

The complexity of the alias with the Plackett-Burman design makes that in practice they are rather used in the first religion release... by beginners and in the second by consultants.

Remark

A software like Minitab 15.1.1 does not display all the aliases used in the implementation of Plackett-Burman designs.

To conclude this section, let us summarize with simple observation:

Plan	Factors	Interactions	Sum
2^2	2	1	3
2^3	3	4	7
2^4	4	11	15
2^5	5	26	31
2^6	6	57	63
2^7	7	120	127
...	...	...	...

Table 16.32: **Types of plans and factors & interactions**

So using full factorial designs, the user is sure to have the optimal experimental procedure since these plans are based on Hadamard matrices and we have proved that we could not do better.

16.7.4.1.3 Fractional Factorial Designs

In practice, full factorial designs can only be used on systems with very few factors, or when each test takes very little time. When n is greater than or equal 3 then experiences costs can quickly become expensive.

The smallest case where it is interesting to optimize the number of tests is the one consisting of 3 factors with 2 levels each. We then have the following equation and experience table:

$$y \cong a_0 + a_1x_1 + a_2x_2 + a_3x_3 + a_{12}x_1x_2 + a_{13}x_1x_3 + a_{23}x_2x_2 + a_{123}x_1x_2x_3 \qquad (16.7.455)$$

Trial N°	Factor 1	Factor 2	Factor 3	Answer
1	−	−	−	y_1
2	+	−	−	y_2
3	−	+	−	y_3
4	+	+	−	y_5
5	−	−	+	y_5
6	+	−	+	y_6
7	−	+	+	y_7
8	+	+	+	y_8

Table 16.33: **Experimental Full Factorial (2 factor) matrix**

Either as full experiment table:

Trial N°	Rest	F1	F2	F3	F12	F13	F23	F123	Answers
1	+	−	−	−	+	+	+	−	y_1
2	+	+	−	−	−	−	+	+	y_2
3	+	−	+	−	−	+	−	+	y_3
4	+	+	+	−	+	−	−	−	y_4
5	+	−	−	+	+	−	−	+	y_5
6	+	+	−	+	−	+	−	−	y_6
7	+	−	+	+	−	−	+	−	y_7
8	+	+	+	+	+	+	+	+	y_8

Table 16.34: **Full Design of experiment with 3 factors and interactions under Yates form**

or in matrix form:

$$\begin{bmatrix} +1 & -1 & -1 & -1 & +1 & +1 & +1 & -1 \\ +1 & +1 & -1 & -1 & -1 & -1 & +1 & +1 \\ +1 & -1 & +1 & -1 & -1 & +1 & -1 & +1 \\ +1 & +1 & +1 & -1 & +1 & -1 & -1 & -1 \\ +1 & -1 & -1 & +1 & +1 & -1 & -1 & +1 \\ +1 & +1 & -1 & +1 & -1 & +1 & -1 & -1 \\ +1 & -1 & +1 & +1 & -1 & -1 & +1 & -1 \\ +1 & +1 & +1 & +1 & +1 & +1 & +1 & +1 \end{bmatrix} \qquad (16.7.456)$$

where once again it is easy to control that all columns are orthogonal and balanced (same number of $+$ or $-$ in each column, or in other words the sum of each column - excepted the first one - is equal to zero) and that the matrix is a Hadamard matrix. Therefore the full factorial design for 3 factors needs 8 trials.

We can also represent this in the following form:

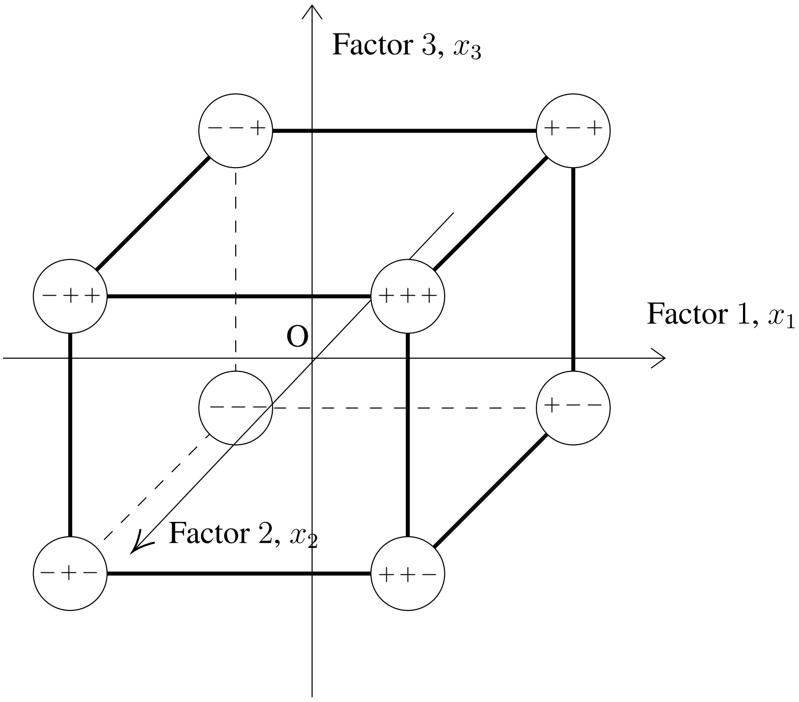

Figure 16.242: Traditional representation of a full factorial design with 3 factors

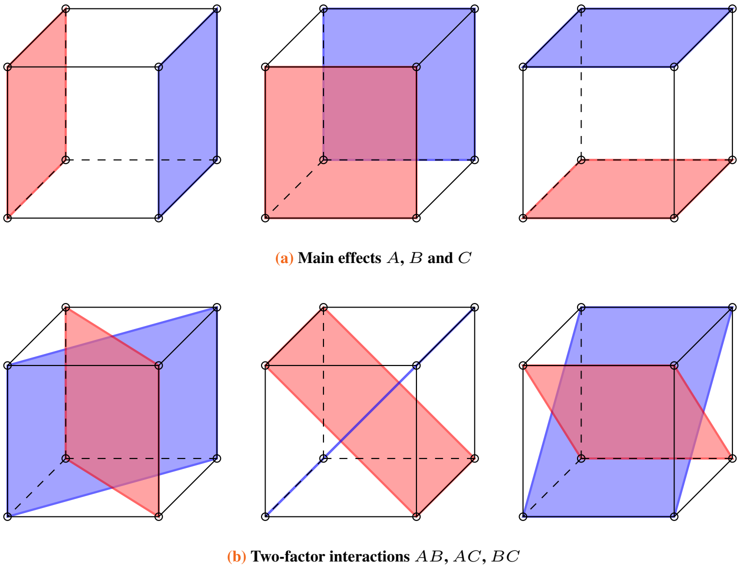
and the corresponding 2-way interactions in the following form (typical of ANOVA studies):



(a) Main effects A, B and C

(b) Two-factor interactions AB, AC, BC

Figure 16.243: Geometric representation of contrasts (in each case, high levels are highlighted in blue, low levels in red)

A "reduced design", more commonly named "fractional factorial designs (FF)" or "screening plans" (following the standard ISO 3534-3:1999), that consist in selecting some combinations, has therefore been proposed. They naturally gives the opportunity to reduce the experimental costs, but also decrease the information available on the system! We must therefore be sure of the adequate choice relatively to the model to identify!

A first elementary method is to do the hypothesis that there are no interactions. Therefore our function is reduce to a purely additive mode:

$$y \cong a_0 + a_1 x_1 + a_2 x_2 + a_3 x_3 \tag{16.7.457}$$

and to resolve thy system, 4 trials are enough. We therefore go from a 8 trial design to a 4 trial design just by supposing that there are no interactions and therefore we fall back on a simple target design.

To reduce the experimental costs by keeping the interactions implicitly, we can play with mathematics stuff. First let us take the actual problem with a full factorial design of 3 factors into explicit form:

$$\begin{aligned}
+a_0 - a_1 - a_2 - a_3 + a_{12} + a_{13} + a_{23} - a_{123} &= y_1\\
+a_0 + a_1 - a_2 - a_3 - a_{12} - a_{13} + a_{23} + a_{123} &= y_2\\
+a_0 - a_1 + a_2 - a_3 - a_{12} + a_{13} - a_{23} + a_{123} &= y_3\\
+a_0 + a_1 + a_2 - a_3 + a_{12} - a_{13} - a_{23} - a_{123} &= y_4\\
+a_0 - a_1 - a_2 + a_3 + a_{12} - a_{13} - a_{23} + a_{123} &= y_5\\
+a_0 + a_1 - a_2 + a_3 - a_{12} + a_{13} - a_{23} - a_{123} &= y_6\\
+a_0 - a_1 + a_2 + a_3 - a_{12} - a_{13} + a_{23} - a_{123} &= y_7\\
+a_0 + a_1 + a_2 + a_3 + a_{12} + a_{13} + a_{23} + a_{123} &= y_8
\end{aligned} \tag{16.7.458}$$

Can we reduce the writing of this system to reduce the trials to do? The answer is: Yes! But in counterpart we will lost the measurement of pure effects (we therefore sometimes speak of "confusion" or of "confounding").

The inferior nearest writing is the Hadamard matrix of order 4. This means obviously that we need to conserve 4 rows on the 8 and that these 4 rows must remain orthogonal, balanced and must satisfy the relation:

$$X^T X = n\mathbb{1} \tag{16.7.459}$$

The idea, named the "Box and Hunter method" and that works only for design with two level factors, is in a first time to merge together the influential factors (in indices) such that (the developments are similar for any n):

$$\begin{aligned}
&+(a_0 - a_{123}) + (-a_1 + a_{23}) + (-a_2 + a_{13}) + (-a_3 + a_{12}) = y_1\\
&+(a_0 + a_{123}) + (+a_1 + a_{23}) + (-a_2 - a_{13}) + (-a_3 - a_{12}) = y_2\\
&+(a_0 + a_{123}) + (-a_1 - a_{23}) + (+a_2 + a_{13}) + (-a_3 - a_{12}) = y_3\\
&+(a_0 - a_{123}) + (+a_1 - a_{23}) + (+a_2 - a_{13}) + (-a_3 + a_{12}) = y_4\\
&+(a_0 + a_{123}) + (-a_1 - a_{23}) + (-a_2 - a_{13}) + (+a_3 + a_{12}) = y_5\\
&+(a_0 - a_{123}) + (+a_1 - a_{23}) + (-a_2 + a_{13}) + (+a_3 - a_{12}) = y_6\\
&+(a_0 - a_{123}) + (-a_1 - a_{23}) + (+a_2 - a_{13}) + (+a_3 - a_{12}) = y_7\\
&+(a_0 + a_{123}) + (+a_1 + a_{23}) + (+a_2 + a_{13}) + (+a_3 + a_{12}) = y_8
\end{aligned} \tag{16.7.460}$$

The grouping choice is also made so that the interaction terms that are supposed to be negligible by the centered reduce normalisation are merged ("confused") with a coefficient of a main factor supposed as not negligible!! Therefore it is also logic that in each grouping we never found indices with a number of a main factor (as merging two main factors that are not negligible will be very bad!).

We then say that we have an "alias structure" (the standard ISO 3534-3:1999 name this a "concomitance" when it is the practitioner that force the choice of the regroupement and "alias" if the regroupement choice is due to the nature of the experience) of the type:

```
0+123;1+23;2+13;3+12
```

and if we write this in the same way as many statistical software, this give (this is exactly the alias given by a software like Minitab 15.1.1):

```
I+ABC;A+BC;B+AC;C+AB
```

Also some practitioner write this (as `I` must always have a positive sign):

```
I=ABC;A+BC;B+AC;C+AB
```

Let us write the previous system as following:

$$\begin{aligned}
(a_0-a_{123})-(a_1-a_{23})-(a_2-a_{13})-(a_3-a_{12})&=y_1\\
(a_0+a_{123})+(a_1+a_{23})-(a_2+a_{13})-(a_3+a_{12})&=y_2\\
(a_0+a_{123})-(a_1+a_{23})+(a_2+a_{13})-(a_3+a_{12})&=y_3\\
(a_0-a_{123})+(a_1-a_{23})+(a_2-a_{13})-(a_3-a_{12})&=y_4\\
(a_0+a_{123})-(a_1+a_{23})-(a_2+a_{13})+(a_3+a_{12})&=y_5\\
(a_0-a_{123})+(a_1-a_{23})-(a_2-a_{13})+(a_3-a_{12})&=y_6\\
(a_0-a_{123})-(a_1-a_{23})+(a_2-a_{13})+(a_3-a_{12})&=y_7\\
(a_0+a_{123})+(a_1+a_{23})+(a_2+a_{13})+(a_3+a_{12})&=y_8
\end{aligned} \tag{16.7.461}$$

Let us change our notations:

$$\begin{aligned}
l_0^- - l_1^- - l_2^- - l_3^- &= y_1\\
l_0^+ + l_1^+ - l_2^+ - l_3^+ &= y_2\\
l_0^+ - l_1^+ + l_2^+ - l_3^+ &= y_3\\
l_0^- + l_1^- + l_2^- - l_3^- &= y_4\\
l_0^+ - l_1^+ - l_2^+ + l_3^+ &= y_5\\
l_0^- + l_1^- - l_2^- + l_3^- &= y_6\\
l_0^- - l_1^- + l_2^- + l_3^- &= y_7\\
l_0^+ + l_1^+ + l_2^+ + l_3^+ &= y_8
\end{aligned} \tag{16.7.462}$$

Naturally, if we consider this new notation as new variables, this unique system can now be splitted into two sub-systems (the grouping being named "contrasts" in this field but this is not corresponding to the vocabulary of the standard ISO 3534-3) to be solvable:

$$\begin{aligned}
l_0^- - l_1^- - l_2^- - l_3^- &= y_1\\
l_0^- + l_1^- + l_2^- - l_3^- &= y_4\\
l_0^- + l_1^- - l_2^- + l_3^- &= y_6\\
l_0^- - l_1^- + l_2^- + l_3^- &= y_7
\end{aligned}
\quad\text{and}\quad
\begin{aligned}
l_0^+ + l_1^+ - l_2^+ - l_3^+ &= y_2\\
l_0^+ - l_1^+ + l_2^+ - l_3^+ &= y_3\\
l_0^+ - l_1^+ - l_2^+ + l_3^+ &= y_5\\
l_0^+ + l_1^+ + l_2^+ + l_3^+ &= y_8
\end{aligned} \tag{16.7.463}$$

which gives the possibility to divide the number of trials by 2 relatively to the initial full factorial design!!!!

By solving these two systems, we say that the interactions are "aliased" (also said in "confusion") with the pure effects in negative or in positive (in the present case, some main effects are aliased with two factors interactions).

It is afterwards the tradition to keep only the positive aliased system:

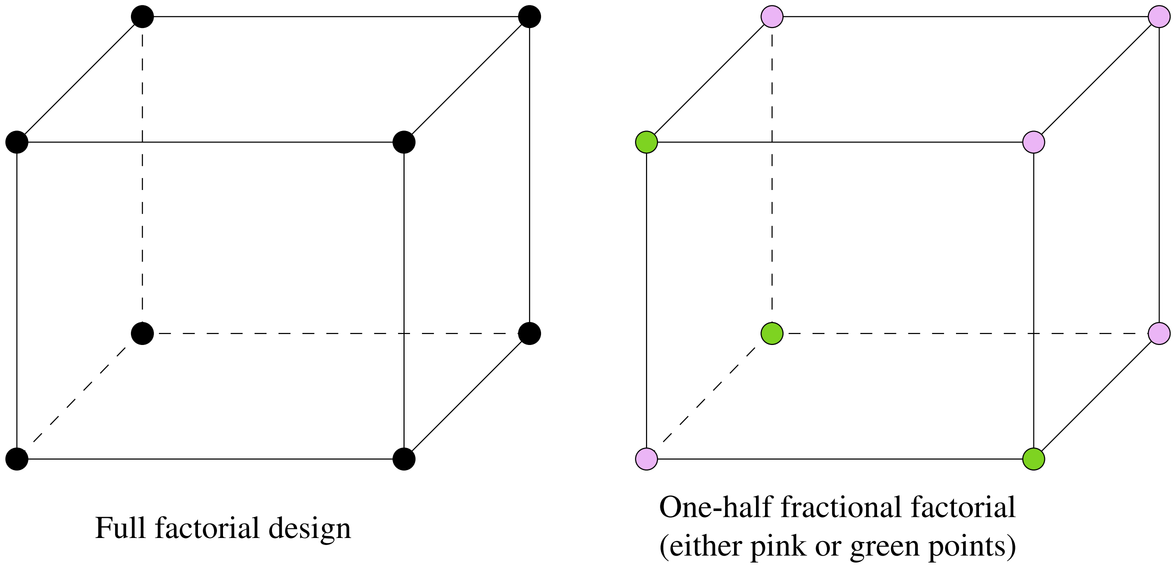
$$\begin{matrix} l_0^+ + l_1^+ - l_2^+ - l_3^+ = y_2 \\ l_0^+ - l_1^+ + l_2^+ - l_3^+ = y_3 \\ l_0^+ - l_1^+ - l_2^+ + l_3^+ = y_5 \\ l_0^+ + l_1^+ + l_2^+ + l_3^+ = y_8 \end{matrix} \tag{16.7.464}$$

because if the interactions are zero, we fall back on the same experience of the matrix of a full 2^2 factorial design! The approach therefore leads to select only the runs 2, 3, 5 and 8, which give the possibility to divide the number of tests by two compared to a full factorial design. Thus, the fractional factorial design of an experiment with three factors may be reduced to 4 runs with this method. The fractional factorial design above will naturally be represented by the following experimental matrix:

Trial N°	Factor 1	Factor 2	Factor 3	Answer
2	+	−	−	y_2
3	−	+	−	y_3
5	−	−	+	y_5
8	+	+	+	y_8

Table 16.35: **Fractional design with 3 factors into Yates form**

Or more visually:



Full factorial design

One-half fractional factorial
(either pink or green points)

Figure 16.244: **Visual 2^2 factorial design and fractional factorial design**

Remark

We have seen that the 8 runs (2^3 experiments) above is splitted into 2×4 fractional experiments. In a software like Minitab (see companion book) the practitioner can choose if he wants to use the first fraction or the second one in the options of the design builder.

For a fractional DoE splitted for example into 4 parts the practitioner can therefore choose in Minitab 4 possible fractions (but they are obviously equivalent!!!).

There is however a problem: Even if the triple interaction is really equal to zero, it can remain up to 7 other coefficients in the model, while we have only 4 trial results to identify them. In other words, unless we know a priori that at least 3 of these coefficients are equal to zero (to reduce the problem to 4 equations with 4 unknowns), we will get at best only relations between the coefficients and the rigorous identification will therefore be impossible. Thus, it is not possible to indefinitely reduce the cost of an experimental design without degrading its robustness (information it provides).

It is important to notice that in the fractional factorial design above, the third factor is confused (is aliased) with the interaction 12 of factors 1 and 2. We name this the "initial alias" or "alias generator" and we can notice by reiterating the calculations for factorial designs with 4, 5, 6... factors that the generators helps us to immediately identify the trials (runs) to preserve (you can control when using softwares like JMP or Minitab that they don't let you choose the alias generator, these softwares take by default the theoretical one). For example, the generator ("alias" or "confusion") of the above experimental table will be written by the tradition:

```
C=AB
```

This does not mean that the coefficient of the model are equal but simply that the design is unable to separate the analysis of these two entities. We must therefore pay a particular attention to the interpretation of the respective coefficients!

We have just seen that a $2^{(3-1)}$ design (resolution `III`) has the serious drawback of confusing a main factor with an interaction of order 2. A $2^{(4-1)}$ (resolution `IV`) design has the only disadvantage of confusing (aliasing) a main factor with an interaction of order 3 and two interactions of order 2. A $2^{(5-1)}$ design has even lower drawbacks. It is for this reason that the factorial theory uses the concept of "resolution". The higher the resolution, the greater the design is accurate.

Definitions (#16.7.738):

D1. When no main effect is aliased with another main effect, but the main effects have aliases with interactions of 2 factors, we speak then of "resolution III designs". From a practical point of view, resolution III designs are mainly intended to allow exploratory research because they allow to explore a number of factors with a certain economy. Even if the fail to obtain a sufficiently accurate model they possibly can eliminate a lot of factors in first time and then reduce the number of trials (runs).

D2. When no main effect has alias with another main effect or another 2 factors interaction, but some of the 2 factors interactions have aliases with other 2 factor interactions and some main effects have aliases wither 3 factor interactions, we speak of "resolution IV designs".

D3. When no main effect or interaction of 2 factors have alias with another different main effect or another 2 factors interaction, but 2 factors interactions have alias with 3 factors interactions and main effects have alias interactions with 4 factors interactions we speak of "resolution V designs".

and so on... Here is a table that summarize a bit the situation:

Resolution	**Ability**
`I`	• Not useful: an experiment of exactly one run only tests one level of a factor and hence can't even distinguish between the high and low levels of that factor
`II`	• Not useful: main effects are confounded with other main effects
`III`	• Estimate main effects, but these may be confounded with two-factor interactions
`IV`	• Estimate main effects unconfounded with two-factor interaction but confounded with three-factor interactions • Estimate two-factor interaction effects, but these may be confounded with other two-factor interactions
`V`	• Estimate main effects unconfounded by three-factor (or less) interactions but confounded with four-factor interactions • Estimate two-factor interactions effects unconfounded with other two-factor interactions but confounded with three-factor interactions
`VI`	• Estimate main effects unconfounded by four-factor (or less) interactions • Estimate two-factor interaction effects unconfounded by three-factor (or less) interactions • Estimate three-factor interaction effects, but these may be confounded with other three-factor interactions

Table 16.36: **Fractional factorial designs resolution summary table**

Remark

The reader must keep in mind that when you have a factorial design with n factors, and hence with n columns, there is $n!$ way to represent on a paper or on a screen the columns using different ordering of the columns. For example, for a design with 7 factors, most textbooks and softwares will present on the screen 7 columns (the columns corresponding to the main factors) and there is therefore $7!=5040$ possible order to represent the 7 columns on a display (paper or screen)!

This concept of resolution is important. We find it in programs like Minitab 15.1.1 in the selection of fractional factorial designs with the most common alias known under the name "minimum aberration designs":

	Factors													
Runs	2	3	4	5	6	7	8	9	10	11	12	13	14	15
4	Full	III												
8		Full	IV	III	III	III								
16			Full	V	IV	IV	IV	III	III	III	III	III	III	III
32				Full	VI	IV	IV	IV	IV	IV	IV	IV	IV	IV
64					Full	VII	V	IV	IV	IV	IV	IV	IV	IV
128						Full	VIII	VI	V	V	IV	IV	IV	IV

Figure 16.245: **Display of fractional factorial designs resolutions selector with Minitab 15.1.1**

or with the Design Expert software (part of the picture but is more explicit than Minitab 15.1.1):

	3	4	5	6	7
4	2^{3-1}_{III}				
8	2^{3}	2^{4-1}_{IV}	2^{5-2}_{III}	2^{6-3}_{III}	2^{7-4}_{III}
16		2^{4}	2^{5-1}_{V}	2^{6-2}_{IV}	2^{7-3}_{IV}

Figure 16.246: **Display of fractional factorial designs resolutions selector in Design Expert**

Thus, the reader will observe that a full factorial design of 5 factors with 32 trials (runs) can be reduced to 16 trials by bringing together the influential factors in pairs or 2-tuples (hence the division by 2 of the number of tests) , or 8 tests by bringing together the influential factors by 4-tuples.

Then it's the job of the experimenter to know well its analysis and whether:

1. Among the aliased factors if there are interactions or not!
2. In the aliased factor, the strong influence on the answer comes from the interaction or from the pure effect alone!

Once determined coefficients, assuming that each of the factors or interactions is independent (acceptable limit hypothesis ...) some engineers are analysing the variance of the regression line obtained final or determine the correlation coefficient to whether the linear approximation of the model is acceptable in the field of study and application.

Regarding the generators of fractional factorial designs here is a non-exhaustive summary table:

Factors	Trials	Resolution	Reduction	Generators	Aliases
3	4	III	$2^{(3-1)}$	C=AB	I+ABC,A+BC,B+AC,C+AB
4	8	IV	$2^{(4-1)}$	D=ABC	I+ABCD,A+BCD,B+ACD C+ABD,D+ABC,AB+CD AC+BD,AD+BC
5	8	III	$2^{(5-2)}$	D=AB E=AC	I+ABD+ACE+BCDE A+BD+CE+ABCDE B+AD+CDE+ABCE C+AE+BDE+ABCD D+AB+BCE+ACDE E+AC+BCD+ABDE BC+DE+ABE+ACD BE+CD+ABC+ADE
6	16	V	$2^{(5-1)}$	E=ABCD	A+BCDE B+ACDE C+ABDE D+ABCE E+ABCD AB+CDE AC+BDE AD+BCE AE+BCD BC+ADE BD+ACE BE+ACD CD+ABE CE+ABD DE+ABC
...	...	...	...	...	...

Table 16.37: **Some fractional factorial designs with generators and alias**

Of course, use of fractional design is an economic (and temporal) bet. If the conclusions are clear, then we have saved time and reduced our effort. But sometimes we lose the bet. We can therefore use a "complementary design" that consists of adding in a pertinent way enough lines to the initial design to unaliased some desired coefficients based on the choice of the alias generator.

Before moving on to another type of design, let us come back on to the fractional factorial design with 3 factors and therefore with 4 trials for educational reasons. Consider that we have done these 4 trials, and for each, we got a measurement as given in the figure below:

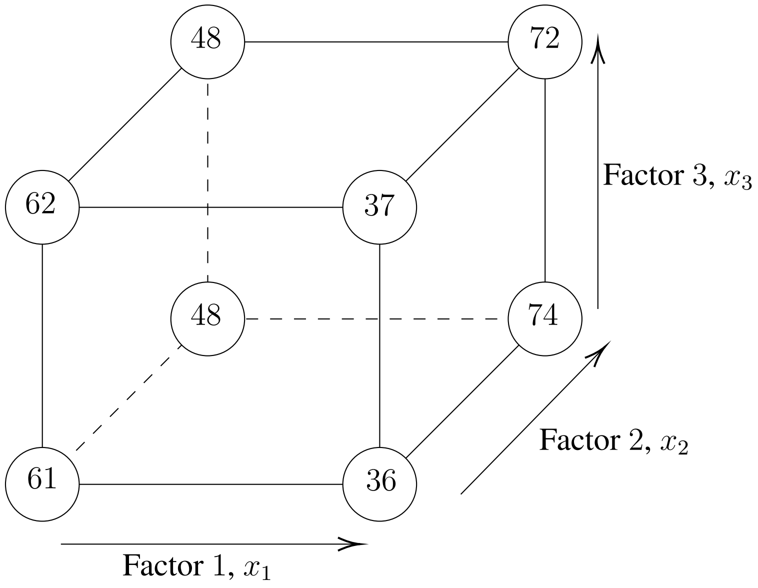


Figure 16.247: Representation of a real fractional factorial design with 3 factors

We want to show to the reader not how to determine the coefficients by calculations (its all about solving a simple linear system and then there will be an example about its it a little further below) but how to calculate the effects in the context of this special case!

Indeed, the effect of x_1 is:

$$\frac{72+37+74+36}{4}-\frac{48+62+48+61}{4}=\frac{(24)+(-25)+26+(-25)}{4}=0 \tag{16.7.465}$$

and this of x_2 is:

$$\frac{48+72+48+74}{4}-\frac{62+37+61+36}{4}=\frac{(-14)+35+(-13)+38}{4}=11.5 \tag{16.7.466}$$

and this of x_3 is:

$$\frac{48+72+62+37}{4}-\frac{48+74+61+36}{4}=\frac{0+(-2)+1+1}{4}=0 \tag{16.7.467}$$

The effect of interaction is somewhat subtle in the case of 3 factors using the figure above (we will see in the example further below with a picture that with a table it is much more intuitive). Thus, we have for the interaction x_1x_2:

$$\frac{72+74+62+61}{4}-\frac{48+37+48+36}{4}=25 \tag{16.7.468}$$

and for x_1x_3:

$$\frac{37+72+48+61}{4}-\frac{48+62+74+36}{4}=-0.5 \tag{16.7.469}$$

and for x_2x_3:

$$\frac{48+72+61+36}{4}-\frac{62+37+48+74}{4}=-1 \tag{16.7.470}$$

For the triple interaction $x_1x_2x_3$ with the figure above it is also not obvious (it is a little more intuitive with a table as we will see in the example further below). We have:

$$\frac{72+62+48+36}{4}-\frac{48+37+74+61}{4}=-0.5 \tag{16.7.471}$$

16.7.4.2 General factorial Designs

In this textbook we name "general factorial design" designs that have a given quantity of factors but with more than 2 levels and that are not reduced.

Given n the number of factor, l_i the number of levels of each factor. The number of runs N of a general factorial design is given obviously by:

$$N=\prod_{i=1}^{n} l_i \qquad (16.7.472)$$

As we will see below, many of the techniques relatives to complete factorial design (designs with only 2 levels for recall) applies identically to general factorial design. The main differences that surprise people starting to work in the field of DoE are:

- The final regression model don't have a unique coefficient for each factor therefore we cannot do a statistical regression analysis.
- The calculation methods of the standard error of the coefficients we have seen for the 2 factorial design cannot be applied (we have to use other methods of calculations)

Rather than doing a long theoretical introduction to general factorial designs, let us use a companion example that will show us that in fact most concepts that we have learned so far also applies!

As part of the study of tires, the criterion retain by a company is the longevity (number of kilometres travelled before the tire blow up) and the chosen factors are the type of use (city or highway), average speed (40 [km/h] or 50 [km/h]) and the inflation pressure (1.5 or 2 or 2.5 [kg]).

Therefore we have a general factorial design with the following number of runs:

$$N=\prod_{i=1}^{3} l_i = 2\cdot 2\cdot 3 = 12 \qquad (16.7.473)$$

Furthermore, it is more healthy to repeat the experiments (to analyse the dispersion of the values in order to run an ANOVA), so to make 24, 36, etc. experiments or to make some central points measurements.

We will denote as usual y the variable of interest and in this case x_1,x_2,x_3 the variables factors. We are seeking a simple model in the form:

$$y=a_0+a_1x_1+a_2x_2+a_3x_3+\ldots \qquad (16.7.474)$$

As each factor can have several levels, we will have for example the value of y at the level 2 of factor 1 and at level 1 of factor 2 and at level 3 of factor 3 that will be denoted:

$$y=a_0+a_1x_{1,2}+a_2x_{2,1}+a_3x_{3,3} \qquad (16.7.475)$$

The full factorial design is the presentation of the various experiences (measurement) depending on the levels of the variables. For example, to study the tires we will have:

- For the factor 1, the place, denoted x_1: city$=1$, town $=2$
- For the factor 2, the speed, denoted x_2: $40\,[\mathrm{km}\cdot\mathrm{h}^{-1}]=1$, $50\,[\mathrm{km}\cdot\mathrm{h}^{-1}]=2$
- For the factor 3, the pressure, denoted x_3: 1.5 [kg] $=1$, 2 [kg] $=2$, 3 [kg] $=3$

The experimental matrix will then be (this is exactly the same as that generally obtained with the software Minitab: a full complete general design for 2 factors with 2 levels and 1 factor with 3 levels without randomization):

Trial N°	x_1	x_2	x_3
1	1	1	1
2	1	1	2
3	1	1	1
4	1	2	1
5	1	2	2
6	1	2	3
7	2	1	1
8	2	1	2
9	2	1	3
10	2	2	1
11	2	2	2
12	1	2	3

At this table, we can associate the results of the experiments. For example, for the tires, we did three tests (three "replication") for each of the levels and we got:

Trial N°	x_1	x_2	x_3	**Measured values of y**		
1	1	1	1	32700	32750	32960
2	1	1	2	33430	33360	32910
3	1	1	3	31710	32100	32220
4	1	2	1	32680	32270	33130
5	1	2	2	34070	33100	33610
6	1	2	3	33220	33700	33285
7	2	1	1	33180	32160	32640
8	2	1	2	34430	34380	34460
9	2	1	3	33570	33300	32570
10	2	2	1	33270	33080	32415
11	2	2	2	33440	33570	34204
12	1	2	3	32840	33210	32470

Thanks to these values we can calculate the effects of the various factors. For this we start with principle that their average (effect) is zero for a given factors. Therefore the global arithmetic average (that can be calculated as the arithmetic average if and only the variables are coded):

$$\bar{y}=33119.3 \tag{16.7.476}$$

is the constant coefficient of the model (intercept):

$$x_0 = 33119.3 \tag{16.7.477}$$

The effect of x_1 at the level 1 is the variation of this average when we consider only the cases where x_1 is at the level 1. The arithmetic average becomes 32955.8 and therefore the effect is:

$$32955.8 - x_0 = 32955.8 - 33119.3 = -163.4 \tag{16.7.478}$$

We will write this obviously as we already know:

$$x_{1,1} = -163.4 \tag{16.7.479}$$

At the level of x_1, the average becomes 33282.7, therefore the effect of x_1 at level 2 is equal to:

$$x_{1,2} = 33282.7 - x_0 = 33282.7 - 33119.3 = 163.4 \tag{16.7.480}$$

The difference:

$$x_{1,1} - x_{1,2} = 163.4 - (-163.4) = 326.8 \tag{16.7.481}$$

is named the "effect" of the factor.

We notice that as assumed, the sum of the effects x_1 is zero, as it is the sum of the deviations from the arithmetic average of the sub-populations of the same size (and thus the overall average is the arithmetic average of the levels).

Exactly in the same way, we get:

$$\begin{aligned} x_{2,1} &= -78.7 \quad & x_{2,2} &= 78.7 & & \\ x_{3,1} &= -349.7 \quad & x_{3,2} &= 619.4 \quad & x_{3,3} &= -269.7 \end{aligned} \tag{16.7.482}$$

and we also find that the sum of the effects of a variable (factor) is zero.

We modelize these results into the form using the average response (notice that the sum of each vector is zero):

$$y = 33119.31 + x_1 \begin{bmatrix} -163.4 \\ 163.4 \end{bmatrix} + x_2 \begin{bmatrix} -78.7 \\ 78.7 \end{bmatrix} + x_3 \begin{bmatrix} -349.7 \\ 619.4 \\ -269.7 \end{bmatrix} \tag{16.7.483}$$

giving the model found. Function that we can rewrite under the form of absolute average effects (the most interesting form mathematically speaking):

$$y = 33119.3 + 164.4x_1 + 78.7x_2 + 619.4x_3 \tag{16.7.484}$$

intermediate result to be compared with a simple linear regression that (perfectly identical result between Microsoft® Excel® 14.0.6117 and Minitab 15.1.1):

$$y = 32313.8 + 326.9x_1 + 157.4x_2 + 40x_3 \tag{16.7.485}$$

but that does not make sense since the linear regression is not built for factors over two levels (see section Numerical Methods page 6335).

From these results, we already derive the best tire usage policy: road, speed 50 [km/h] and pressure 2 [kg], we can expect to do:

$$y = x_0 + x_{1,2} + x_{2,2} + x_{3,2} = 33119.3 + 163.4 + 78.7 + 619.4 \cong 33981 \tag{16.7.486}$$

Let us notice immediately that in some cases, the experiment did better (see the values in the above table), even in town or at 40 $[\text{km} \cdot \text{h}^{-1}]$. This come for the obvious dispersion of the results. But then... did the effects found come perhaps only from this dispersion!? Furthermore we studied the effects independently of each other. But it may have some that reinforce some others. We will explore these issues further below!

Let us take back our 36 experiments, comparing the differences Δ between the values measured (denoted here $\hat{y}$) and the model predictions (denoted here y):

x_1	x_2	x_3	$\hat{y}$	y	Δ	x_1	x_2	x_3	$\hat{y}$	y	Δ
1	1	1	32700	32527.5	172.5	2	1	1	32160	32854.3	−694.3
1	1	2	33430	33496.6	−66	2	1	2	34280	33823.4	456.6
1	1	3	31710	32607.5	−897.5	2	1	3	33300	32943.3	365.7
1	2	1	32680	32684.9	−4.9	2	2	1	33080	33011.7	68.3
1	2	2	34070	33654	416	2	2	2	33570	33980.8	−410.8
1	2	3	33220	32764.9	455.1	2	2	3	33210	33091.7	118.3
2	1	1	33180	32854.3	325.7	1	1	1	32960	32527.5	432.5
2	1	2	34430	33823.4	606.6	1	1	2	32910	33496.6	−586.6
2	1	3	33570	32934.3	635.7	1	1	3	32220	32607.5	−387.5
2	2	1	33270	33011.7	258.3	1	2	1	33130	32684.9	445.1
2	2	2	33440	33980.8	−540.8	1	2	2	33610	33654	−44
2	2	3	33840	33091.7	−251.7	1	2	3	33285	32764.9	520.1
1	1	1	32750	32527.5	222.5	2	1	1	32640	32854.3	−214.3
1	1	2	33360	33496.6	−136.6	2	1	2	34460	33823.4	636.6
1	1	3	32100	32607.5	−507.5	2	1	3	32570	32934.3	−364.3
1	2	1	32270	32684.9	−414.9	2	2	1	32415	33011.7	−596.7
1	2	2	33100	33654	−554	2	2	2	34204	33980.8	223.2
1	2	3	33700	32764.9	935.1	2	2	3	32470	33091.7.8	−621.7

We see that the differences between the model and the predicted values are sometimes important. This may be a natural random dispersion of values, or an incorrect model or it could be due to the fact that combination of factors have more effect than separate. The positive or negative effects of two factors may do more than just add themselves (purely additive model may therefore be reject).

It is therefore probably interactions (chemists speak of "potentiation"). To see if there are second orders interactions, a good way is to study all the factors in pairs (and ignore the existence of others). So if we start with the factors (location) x_1 and (speed) x_2 by ignoring the tire pressure x_3, we get (the explanations of how the values in this table are calculated are given below the table):

Levels	Experimental average	Total effect	Sum of effects	Interaction effect
$x_{1,1}x_{2,1}$	32682.2	-437.1	-242.2	-194.9
$x_{1,1}x_{2,2}$	33229.4	110.2	-84.7	-194.9
$x_{1,2}x_{2,1}$	33398.9	279.6	84.7	194.9
$x_{1,2}x_{2,2}$	33166.6	47.3	242.2	-194.9

Table 16.38: **Table of interaction of factors 1 and 2**

So in the table above $32,682.2$ is the arithmetic average of the experiences done at level $x_{1,1}$ (City) and level $x_{2,1}$ (40 [km/h]). By subtracting the main average x_0 (always $33,119.3$), we get an effect of -437.1, while the effect of x_1 (-163.4) plus the effect of x_2 (-78.7) gives only -242.2.

So there a surplus off -194.9, largely due to the interaction $x_{1,1},x_{2,1}$ (notice that this is the same for $x_{1,2}x_{2,2}$, and the opposite for $x_{1,1}x_{2,2}$ and $x_{1,2}x_{2,1}$). We notice immediately that the interaction $x_{1,1}x_{2,1}$ has a much greater effect than the effects of x_1 and x_2!

Let us see the two other possible interactions of respectively factors 1 and 3 and 2 and 3:

Levels	Experimental average	Total effect	Sum of effects	Interaction effect
$x_{1,1}x_{3,1}$	32748.3	-370.9	-513.1	142.2
$x_{1,1}x_{3,2}$	33143.3	294.1	455.9	-161.9
$x_{1,1}x_{3,3}$	32705.8	-413.4	-433.1	19.7
$x_{1,2}x_{3,1}$	32790.8	-328.4	-186.3	-142.2
$x_{1,2}x_{3,3}$	34064.0	944.7	782.8	161.9
$x_{1,2}x_{3,3}$	32993.3	-125.9	-106.3	-19.7

Levels	Experimental average	Total effect	Sum of effects	Interaction effect
$x_{2,1}x_{3,1}$	32731.7	-387.6	-428.4	40.8
$x_{2,1}x_{3,2}$	33811.7	629.4	540.7	151.7
$x_{2,1}x_{3,2}$	33811.7	692.4	540.7	151.7
$x_{2,1}x_{3,3}$	32578.3	-540.9	-348.4	-192.5
$x_{2,2}x_{3,1}$	32807.5	-311.8	-271.0	-40.8
$x_{2,2}x_{3,2}$	33665.7	546.5	698.1	-151.7
$x_{2,2}x_{3,3}$	33120.8	1.6	-191.0	192.5

We can represent the interactions differently by crossing the factors:

	$x_{2,1}$	$x_{2,2}$
$x_{1,1}$	-194.9	194.9
$x_{1,2}$	194.9	-194.9

	$x_{3,1}$	$x_{3,2}$	$x_{3,3}$
$x_{1,1}$	142.2	-161.9	19.7
$x_{1,2}$	-142.2	161.9	-19.7

	$x_{3,1}$	$x_{3,2}$	$x_{3,3}$
$x_{2,1}$	40.8	151.7	−192.5
$x_{2,2}$	−40.8	−151.7	192.5

We notice then that each line or each column has a total of zero. We also see that in this case, it is difficult to neglect the interactions, and that x_2 (for example) influence the results more by its interactions than that its own effect!

We can still try to check if the interaction of the three factors has a significant effect. As the experiment has been repeated 3 times at each level (we then speak of "three-blocks"), we can calculate the mean of y, and subtract to it the model with the interactions calculated above (notice that the sum of each vector is zero!):

$$\begin{aligned} y = 33119.31 &+ x_1\begin{bmatrix}-163.4\\163.4\end{bmatrix} + x_2\begin{bmatrix}-78.7\\78.7\end{bmatrix} + x_3\begin{bmatrix}-349.7\\619.4\\-269.7\end{bmatrix} + x_1x_2\begin{bmatrix}-194.9\\194.9\\194.9\\-194.9\end{bmatrix}\\ &+ x_1x_3\begin{bmatrix}142.2\\-161.9\\19.7\\-142.2\\161.9\\-19.7\end{bmatrix} + x_2x_3\begin{bmatrix}40.8\\151.7\\-192.5\\-40.8\\-151.7\\192.5\end{bmatrix} \end{aligned} \tag{16.7.487}$$

that it is customary to write for simplification purposes (notice that the sum of each vector is still zero):

$$\begin{aligned} y = 33119.31 &+ x_1\begin{bmatrix}-163.4\\163.4\end{bmatrix} + x_2\begin{bmatrix}-78.7\\78.7\end{bmatrix} + x_3\begin{bmatrix}-349.7\\619.4\\-269.7\end{bmatrix} + x_1x_2\begin{bmatrix}-194.9\\194.9\end{bmatrix}\\ &+ x_1x_3\begin{bmatrix}142.2\\-161.9\\19.7\end{bmatrix} + x_2x_3\begin{bmatrix}40.8\\151.7\\-192.5\end{bmatrix} \end{aligned} \tag{16.7.488}$$

Remark

It suffices to know that for the coefficients of interaction terms the missing effects (not written) are of opposed sign.

Some statistical software go further in the simplification of notation by writing (still in the same idea that the other coefficients are of opposed sign):

$$\begin{aligned} y = 33119.31 &+ x_1\begin{bmatrix}-163.4\end{bmatrix} + x_2\begin{bmatrix}-78.7\end{bmatrix} + x_3\begin{bmatrix}-349.7\\619.4\\-269.7\end{bmatrix} + x_1x_2\begin{bmatrix}-194.9\end{bmatrix}\\ &+ x_1x_3\begin{bmatrix}142.2\\-161.9\\19.7\end{bmatrix} + x_2x_3\begin{bmatrix}40.8\\151.7\\-192.5\end{bmatrix} \end{aligned} \tag{16.7.489}$$

and other softwares (such as Minitab 17.1.3 for example) give:

10	2	2	1	33270	33080	32415	32921.7	32633.8	287.9
11	2	2	2	33440	33570	34204	33738.0	33796.1	−58.1
12	1	2	3	32840	33210	32470	32840.3	33069.6	−229.6

We see then that the values of the model with interactions continues to diverge quite significantly for the average values, which can be interpreted either by the fact that the effects are not linear, either by an interaction between the three factors.

It would be necessary to redo the calculations above with the interaction of the three factors. But as it is always the same principle, we will do that if some readers explicitly request us to add it.

But there may still exist a source of error in the model, that is to take into account effects that do not occur in reality! To ensure that the effect calculated on a variable or interaction is real, we will use to start the one-way fixed factor analysis of variance (ANOVA) that we have studied in detail in the section Statistics. For this, it is important to have repeated the experiments in order to highlight the dispersion due to external and almost unknown uncontrolled factors.

For example, the factor x_2 has a rather small effect. Does he have a real influence? For this, we separate the 36 experiments in two samples (level $x_{2,1}$ and level $x_{2,2}$, and we calculate the sums of squares and the degrees of freedom (we can detail the following calculations on request) as we have seen it in the section of Statistics:

Source	Sum of squares	χ^2 df	Average of squares
Inter-Class	$Q_A=\sum_i n_i\left(\bar{x}_i-\bar{\bar{x}}\right)^2=170019$	$k-1=1$	$\text{MSk}=\dfrac{Q_A}{k-1}=170019$
Intra-Class	$Q_R=\sum_{ij}\left(x_{ij}-\bar{x}_i\right)^2=16025448$	$N-k=34$	$\text{MSE}=\dfrac{Q_R}{k-1}=471337$
Total	$Q_T=\sum_{ij}\left(x_{ij}-\bar{\bar{x}}\right)^2=16195467$	$N-1=35$	

And we get from this table:

$$F=\frac{\text{MSk}}{\text{MSE}}=0.36\Rightarrow p\text{-value}=0.552 \tag{16.7.490}$$

What gives with Minitab 17.3.1 (we can see also that the model is probably not linear) as detailed in the Minitab companion book:

and visually:

As we can see here we reject the null hypothesis H_0 of this ANOVA at a threshold of 5%.

Therefore this factor has a significant impact on our experience.

Let us recall that the fact we reject the null hypothesis H_0 highlight an influential factor, the one who is controlled. So the basic model to consider (leaving aside the interactions) is not:

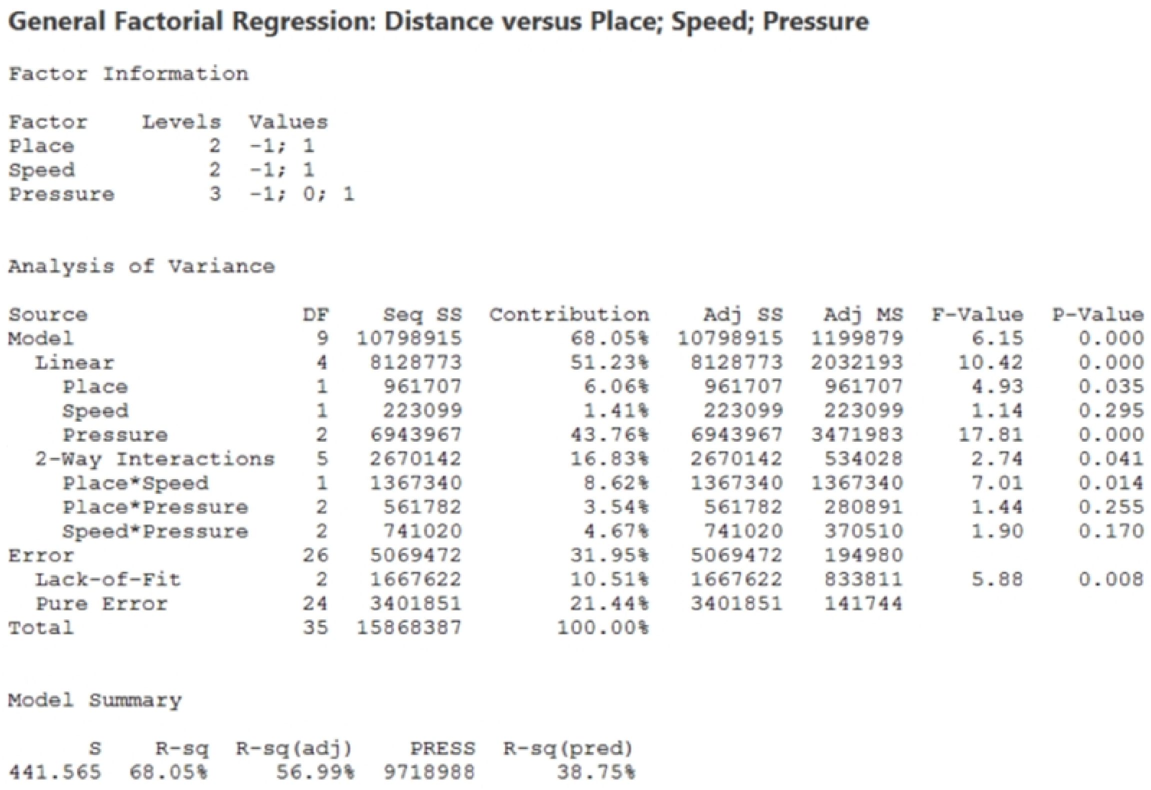
$$y = 33119.3 + x_1 \begin{bmatrix} -163.4 \\ 163.4 \end{bmatrix} + x_2 \begin{bmatrix} -78.7 \\ 78.7 \end{bmatrix} + x_3 \begin{bmatrix} -349.7 \\ 619.4 \\ -269.7 \end{bmatrix} \tag{16.7.493}$$

but (the sum of the vectors still being equal to zero):

$$y \cong 33119.3 + x_3 \begin{bmatrix} -349.7 \\ 619.4 \\ -269.7 \end{bmatrix} \tag{16.7.494}$$

Caution!!! That fact that x_1 (speed) and x_2 (place) have no significant influence does not result that the interactions between x_1 and x_2, or x_2 and x_3, or even x_1x_2 and x_3 are not. For example, here, x_2x_3 has no significant influence (the Fischer-Snedecor test succeeds), but at the level 1 of x_3, the interaction x_1x_2 has a significant influence (in the sense $x_1 = x_2$ against $x_1 \neq x_2$).

Let us see this again with Minitab 17.3.1 (the calculations below can be detailed on request):



General Factorial Regression: Distance versus Place; Speed; Pressure

```

```

We see that by doing a multifactorial ANOVA, that finally the factor *Place* is statistically significant (p-value less than 5%), the factor *Speed* is not (p-value greater than 5%), the pressure has a very significant influence (almost zero p-value). The interaction *Place * Speed* is significant (p-value less than 5%). By cons, the interactions *Speed * Pressure* and *Place * Pressure* are not significant (p-value greater than 5%). The triple interaction *Place * Speed * Pressure* is significant!

So as we can see it, its not because a single given factor is not significant in the model without interactions that it will remain not significant when we take into account the interactions!!!

Remarks

R1. All the results that we have obtained above and also the charts can be obtained with a simple spreadsheet software like Microsoft® Excel®. So if the reader wants we can add the corresponding screenshots he must not hesitate, as always, to contact us.

R2. We can notice above that each factor F_i having n_i levels, has (obviously) $n_i - 1$ degrees of freedom, then we have a total of $(\prod_i F_i) - 1$ (including all type of interactions I), the degrees of freedom or residuals (error) will be $(n-1)\prod_i F_i$, where n is the number of replications, and the total degrees of freedom will be $(n\prod_i F_i) - 1$. Such that we have indeed:

$$\underbrace{\left[(n-1)\prod_i F_i\right]}_{\text{df errors (residuals)}} + \underbrace{\left[\left(\prod_i F_i\right) - 1\right]}_{\text{df due to factor and \underline{all} interactions}} = \underbrace{\left(n\prod_i F_i\right) - 1}_{\text{total df}} \tag{16.7.495}$$

To close this subject, remember that we talked earlier about the interest to randomize the order of the measurement to eliminate unknown confounders. In reality, we must consider three important cases of harmful factors in practice and which will only change a little bit the used ANOVA and that most modern statistical software implement nowadays:

1. We have "unknown harmful and uncontrollable factors". Therefore we make a usual ANOVA but simply where the order of measurement were randomized.
2. We have "known harmful factors but still uncontrollable". We speak then of "covariates" or "cofactors" and we use an ANCOVA (see section Statistics) instead of a simple ANOVA
3. We have "known harmful factors and that under control" that we want to eliminate from the ANOVA. The idea is to use a technique named "blocking" it is simply a hierarchical ANOVA (see section Statistics page 1065).

16.7.4.3 Taguchi Designs and Nomenclature (robust designs)

"Taguchi designs" also named "robust designs" or "Taguchi Orthogonal Array Designs" (abbreviated "Taguchi OA designs" in some softwares) are only a particular technique to find factorial or multifactorial fractional or full designs (from a matrix, a triangular table or from graph). In other words: Taguchi designs are a type of general fractional factorial design!

Definition (#16.7.739): An "orthogonal array" of s elements, denoted $\text{OA}_N(s^m)$, is a $N \times m$ matrix whose columns have the property that in every pair of columns each of the possible ordered pairs of elements appears the same number of time. Taguchi refers to $\text{OA}_N(s^m)$ by the notation $L_n(s^m)$ where L stands for "Level".

Below for example are given $\text{OA}_4(2^3)$ and $\text{OA}_8(2^7)$ respectively:

	Column number		
Row number	**1**	**2**	**3**
1	0	0	0
2	0	1	1
3	1	0	1
4	1	1	0

Table 16.39: $\text{OA}_4(2^3)$ Orthogonal array

	Column number						
Row number	**1**	**2**	**3**	**4**	**5**	**6**	**7**
1	0	0	0	0	0	0	0
2	0	0	0	1	1	1	1
3	0	1	1	0	0	1	1
4	0	1	1	1	1	0	0
5	1	0	1	0	1	0	1
6	1	0	1	1	0	1	0
7	1	1	0	0	1	1	0
8	1	1	0	1	0	0	1

Table 16.40: $\text{OA}_8(2^7)$ Orthogonal array

With softwares that automatically generate the corresponding designs, this technique has become a bit old fashioned but it had the advantage at the time of its use to provide a list of over a hundred of tables with factors at 2 or more levels with or without interactions. Let us see some classics examples for the general culture (as it is something good to know and plus it's nice and still used in practice and in some softwares!!!!).

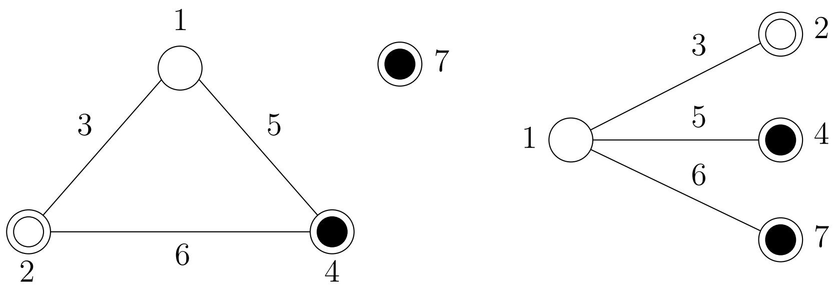
Dr. Genichi Taguchi has proposed to organize experiences following tables and graphs to identify interactions (the Taguchi tables include some Plackett-Burman designs) and afterwards to be able to find the settings for the controllable variables that minimize the variability transmitted to the response from the uncontrollable variable.

In the Taguchi OA design, only the main effects and two-factor interactions are considered, and higher-order interactions are assumed to be non-existent!!!! In addition, designers are asked to identify (based on their knowledge of the subject matter) which interactions might be significant before conducting the design.

Let us start with an example of table that we know well, the L_8 table. By Taguchi this table can be read as the table of a fractional factorial design of 7 factors (thus without interactions) or as the table of a full factorial design for 3 factors (hence with interactions!). This is why it is denoted $L_8(2^7)$ or $L_8(2^3)$ and represented by:

Trial N°	1	2	3	4	5	6	7
1	1	1	1	1	1	1	1
2	1	1	1	2	2	2	2
3	1	2	2	1	1	2	2
4	1	2	2	2	2	1	1
5	2	1	2	1	2	1	2
6	2	1	2	2	1	2	1
7	2	2	1	1	2	2	1
8	2	2	1	2	1	1	2

Table 16.41: L_8 **table with common factorial notation by Taguchi and associated graph**



We'll see if this table really differs from what we already know. First, each factor also takes two levels in this table, we can replace the Taguchi notation with our usage notation for the factorial replacing 1 by "$+$" and "2" by "$-$":

Trial N°	1	2	3	4	5	6	7
1	$+$	$+$	$+$	$+$	$+$	$+$	$+$
2	$+$	$+$	$+$	$-$	$-$	$-$	$-$
3	$+$	$-$	$-$	$+$	$+$	$-$	$-$
4	$+$	$-$	$-$	$-$	$-$	$+$	$+$
5	$-$	$+$	$-$	$+$	$-$	$+$	$-$
6	$-$	$+$	$-$	$-$	$+$	$-$	$+$
7	$-$	$-$	$+$	$+$	$-$	$-$	$+$
8	$-$	$-$	$+$	$-$	$+$	$+$	$-$

Table 16.42: L_8 **table with common notation**

We see already much better that all the rows and columns are orthogonal taken in pairs (Hadamard matrix). We add a column of "$+$":

Trial N°	1	2	3	4	5	6	7	**Rest**
1	$+$	$+$	$+$	$+$	$+$	$+$	$+$	$+$
2	$+$	$+$	$+$	$-$	$-$	$-$	$-$	$+$
3	$+$	$-$	$-$	$+$	$+$	$-$	$-$	$+$
4	$+$	$-$	$-$	$-$	$-$	$+$	$+$	$+$
5	$-$	$+$	$-$	$+$	$-$	$+$	$-$	$+$
6	$-$	$+$	$-$	$-$	$+$	$-$	$+$	$+$
7	$-$	$-$	$+$	$+$	$-$	$-$	$+$	$+$
8	$-$	$-$	$+$	$-$	$+$	$+$	$-$	$+$

Table 16.43: L_8 table with common notation

and we notice that we fall back on the full factorial design with 3 factors at 2 levels if we rewrite the title row of the columns as follows:

Trial N°	$F3$	$F2$	$F23$	$F1$	$F13$	$F12$	$F123$	**Rest**
1	$+$	$+$	$+$	$+$	$+$	$+$	$+$	$+$
2	$+$	$+$	$+$	$-$	$-$	$-$	$-$	$+$
3	$+$	$-$	$-$	$+$	$+$	$-$	$-$	$+$
4	$+$	$-$	$-$	$-$	$-$	$+$	$+$	$+$
5	$-$	$+$	$-$	$+$	$-$	$+$	$-$	$+$
6	$-$	$+$	$-$	$-$	$+$	$-$	$+$	$+$
7	$-$	$-$	$+$	$+$	$-$	$-$	$+$	$+$
8	$-$	$-$	$+$	$-$	$+$	$+$	$-$	$+$

Table 16.44: Previous table with traditional notation for the title row

and that this also corresponds to the fractional factorial design of a 7-factor experimental design at 2 levels (without interactions).

The question that will obviously ask the reader to himself is how we would have identify what factor belonged to which column in the context of a full factorial design with 3 factors if we did not know the table was prepared with the techniques view previously? Well in fact just by using the following linear graph:

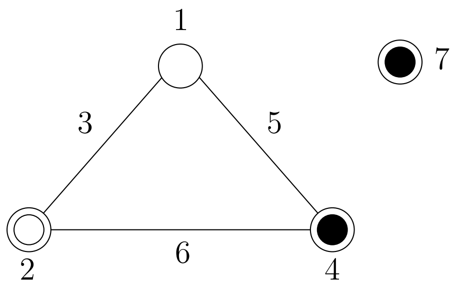


Figure 16.248: Taguchi L8 linear graph

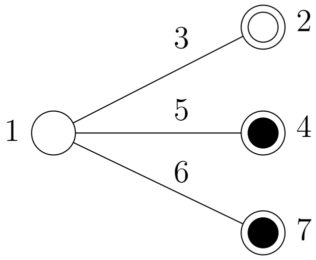
that indicates the main factors in the vertices of the graph (therefore the columns 1, 2 and 4 are the main factors). The column 3 is the interaction between the columns 1 and 2 (hence the fact that it is on the edge between the two vertices), the column 5 is the interaction between the columns 1 and 4 (hence the fact that it is on the edge between the two vertices), and column 6 is the interaction between the columns 2 and 4 (hence the fact that it is on the edge between the two vertices). The fact that 7 is outside the linear graph outside is because a triple interaction can not be represented with the technique of planar graph. We then used the symbols of vertices to signify that this is the superposition of the vertices 1, 2 and 4 (circle + ring + disc).

The second linear graph associated with this table permits to highlight another potential use:



That is to say, we make use of it for an analysis of 4 factors (always with two modality in this case) represented by columns 1, 2, 4, 7 (the reader can indeed check that these four columns correspond to a fractional factorial design with for generator **12** for 4 factors either by hand or with software) with 3 interactions (1 and 2; 1 and 4, 1 and 7).

And what about the different shapes of the symbols on the linear graph??? There are given here:

Symbol	Description
○	Difficult, so the number of level changes in the runs order must be low.
◎	Quite difficult, so the number of changes in the runs order must be also quite low.
◉	Quite easy.
●	Easy, so frequent changes of the level of the factor are not a problem.

Remark

The practitioner must be careful because there are therefore two Taguchi tables denoted L_8: one that is a full table for 3 factors to 2 levels and one for 7 factors at 2 levels without interactions as we have just seen (so with 7 columns), but there also tables L_8 for 5 factors splitted into 4 factors at 3 levels and 1 factor to 4 levels (without interactions) but only with 5 columns. This is why books listing the tables Taguchi normally explicitly specify the scope of application of the given tables.

Let's see some other tables (a small part of the complete list):

- Table $L_4(2^3)$:

Trial N°	$F1$	$F2$	$F3$
1	1	1	1
2	1	2	2
3	2	1	2
4	2	2	1

- etc.

The Taguchi tables together with their graphs are therefore full or fractional factorial designs with all their advantages. Taguchi's merit is to have tried to simplify the use of factorial designs to make them accessible to a large number of experimenters.

Taguchi's designs are usually highly fractionated, which makes them very attractive to practitioners. Doing a half-fraction, quarter-fraction or eighth-fraction of a full factorial design greatly reduces costs and time needed for a designed experiment. As we know, the drawback of a fractionated design is that some interactions may be confounded with other effects. It is important to consider carefully the role of potential confounders and aliases. Failure to take account of such confounded effects can result in erroneous conclusions and misunderstandings.

So, some Taguchi designs are primarily intended to study main effects of factors. Occasionally, you might want to study some of the two-way interactions. Some of the Taguchi designs (orthogonal arrays) let you study a limited number of two-way interactions. This usually requires that you leave some columns out of the array by not assigning factors to them. Some of the array columns are confounded with interactions between other array columns[27].

Taguchi interaction tables show confounded columns, which can help you assign factors to array columns. The columns and rows represent the column numbers of the Taguchi design

---

[27] Most DOE softwares choose automatically how to assign factors to array columns in a way that avoids confounding by default! Or, if you know exactly what design you want and know the columns of the entire array that correspond to the design, you can assign factors to array columns yourself. Assigning factors to columns of the array does not change in most softwares how the design looks in the on the computer screen.

(orthogonal array). Each table cell contains the interactions confounded for the two columns of the orthogonal array.

For example, the entry in cell below $(1,2)$ is 3. This means that the interaction between columns 1 and 2 is confounded with column 3. Thus, if you assigned factors A, B, and C to columns 1, 2, and 3, you could not study the AB interaction independently of factor C. If you suspect that there is a substantial interaction between A and B, you should not assign any factors to column 3 (hence you can assign factors A, B and C respectively to columns 1, 2 and 4). Similarly, the column 1 and 3 interaction is confounded with column 2, and the column 2 and 3 interaction is confounded with column 1.

	1	**2**	**3**	**4**	**5**	**6**	**7**
1		3	2	5	4	7	6
2			1	6	7	4	5
3				7	6	5	4
4					1	2	3
5						3	2
6							1

Table 16.50: $L_8(2^7)$ **Taguchi interaction table**

When using a Taguchi design, one needs to guess which interactions are most likely to be significant - even before any experiment is performed.

The Taguchi methodology is say to have generated considerable debate and controversy. Part of the controversy arose because Taguchi's methodology was advocated in the West initially (and primarily) by entrepreneurs, and the underlying statistical science had not been adequately peer-reviewed. By the late 11980s (holocene calendar) the results of a very comprehensive peer review indicated that although Taguchi's engineering concepts and the overall objective Taguchi's robust parameter design were well-founded [103], there were substantial problems with his experimental strategy (maximizing signal to noise does not necessarily minimize variability...) and methods of data analysis [301].

Remark

For example to see how this is vicious... Taguchi's catalogue contains 20 arrays. However, only 18 of these arrays are in reality orthogonal arrays...

Finally let summarize what we have seen so far with the respective names (this list is to take with precaution as there is a priori no clear international standard to our knowledge regarding these definitions) in the order of mathematical generalization:

- Designs that contain only factors at two levels, are referred to as "factorial design" that they are based on a linear or non-linear model, additive or not.
- Designs that have the column of the experimental matrix that have a zero dot product are named "orthogonal designs" (hence it exists designs that are named "non-orthogonal designs" but that are less easy to manipulate).
- The factorial designs that allow only to determine the coefficients of the main factors (i.e. additive model: without interactions) are referred to as "Koshal designs" or "screening

designs" (also named "one shot at a time designs" because as the technique of "one at a time" it can't analyse any interaction but the comparison stops there!).

- The factorial designs where all the interactions of three and higher order are neglected are referred to as "Rechtschaffner designs".
- The factorial designs where the coefficients are aliased while keeping interactions are referred to as "fractional factorial designs" or of "Box and Hunter designs" or even under the name of "matrix Hadamard based designs". With fractional factorial designs, it should also be specify the method of resolution.
- The factorial designs whose order is a multiple of 4 but not a power of 2 (i.e. 12, 16, 20, 24, etc.) are designated under the name of "Plackett-Burman designs"
- The designs with any number of factors, of interactions of any order and any number of levels are referred to as "Fisher designs" or "general full factorial designs" (in honour of to the original creator of the concept of experimental design).
- The designs where all factors have three levels and are based on the conferences matrices and permits to determine main factors without alias and at the same time with quadratic terms are named "definitive screening designs".
- The designs which contain as many tests (runs) as the number of coefficients to be determined are designated under the name of "saturated designs[28]".
- The fractional designs which are made to determine only main effects are named "saturated main effect designs" (typical of resolution III designs).
- The fractional designs which are made to determine only main effects and 2-way interactions are named "unsaturated designs" (typical of resolution V designs or greater).
- The designs which contain fewer tests than the number of coefficients to be determined are referred to as "oversaturated designs" or "supersaturated designs" (typical of A/D/G "optimal designs").
- There are other more exotic designs like α-designs, search designs (also named "resolution V.1 designs, or "resolution III.1 designs" depending on the case) and so on....

One aspect still needs to be clarified: it is the verification of the validity of the mathematical model of the first degree. None of these designs provides, as far as we know, such a validity test using elaborated statistics. This is why it is recommended to always add at least one test point at the center of the experimental range. The value of the response at this point will be compared to the deduced value of the other data points through mathematical model. If both values are similar, the mathematical model will be adopted if they are not we will have to reject this model and complete the results already obtained by experiments by going through a model of the second degree.

Finally if we have one response variable for the problem to take up for DOE then we have the following situations (options):

---

[28] This is quite a problem as then the model fits perfectly the data and we can therefore not make statistical adjustment tests.

1. The multiple responses are independent. Then we do our job as usually (as optimizing one under the independence assumption must not change the other responses)
2. The multiple responses are not independent. Then we add each model as a weighted sum and we optimize that latter (Overall Evaluation Criterion method as suggested in Taguchi designs) with any solver.
3. We use 2 stage least squares regression techniques (see section Numerical Methods) and after we optimize the whole with a solver.

16.7.4.3.1 Signal Factor

When we add a "signal factor" to an existing Taguchi design, the Taguchi design without the signal factor is named "static design" and that with the signal factor is named "dynamic design".

For example, if we add a signal factor with 2 levels to an existing $L_4(2^3)$ array, 4 rows (1 replicate of 4 runs) are added to the worksheet. If we add a signal factor with 3 levels, 8 rows (2 replicates of 4 runs) are added to the worksheet. A replicate is the entire set of runs from the static design as illustrated below:

Trial N°	1	2
1	$-$	$-$
2	$-$	$+$
3	$+$	$-$
4	$+$	$+$

Table 16.51: $L_4(2^3)$ **Taguchi static design**

Trial N°	1	2	Signal Factor
1	$-$	$-$	$-$
2	$-$	$+$	$-$
3	$+$	$-$	$-$
4	$+$	$+$	$-$
5	$-$	$-$	$+$
6	$-$	$+$	$+$
7	$+$	$-$	$+$
8	$+$	$+$	$+$

7	$+$	$-$	2
8	$+$	$+$	2
5	$-$	$-$	3
6	$-$	$+$	3
7	$+$	$-$	3
8	$+$	$+$	3

Table 16.53: $L_4(2^3)$ **Taguchi dynamic design with** 3**-level signal factor**

16.7.4.4 Response Surface Methodology (Box Domains)

In statistics, "response surface methodology (RSM)" explores the relationships between several explanatory variables and one or more response variables. The method was introduced by G. E. P. Box and K. B. Wilson in 11951 (holocene calendar). The main idea of RSM is to use a sequence of designed experiments to obtain an optimal response. Box and Wilson suggest using a second-degree polynomial model to do this. They acknowledge that this model is only an approximation, but use it because such a model is easy to estimate and apply, even when little is known about the process.

An easy way to estimate a first-degree polynomial model is as we have seen to use a factorial experiment or a fractional factorial design based in the two variables case for recall by:

$$y \cong a_0 + \sum a_i x_i + \sum_{i \neq j} a_{ij} x_i x_j + e \tag{16.7.496}$$

This is sufficient to determine which explanatory variables affect the response variable(s) of interest. Once it is suspected that only significant explanatory variables are left, then a more complicated design, such as a central composite design can be implemented to estimate a second-degree polynomial model, which is still only an approximation at best given by:

$$y \cong a_0 + \sum a_i x_i + \sum a_{ij} x_i x_j + e = a_0 \sum a_i x_i \sum_{i \neq j} a_{ij} x_i x_j + \sum_i a_{ii} x_i x_i + e \tag{16.7.497}$$

However the second-degree model can be used to optimize the process (maximize, minimize, or attain a specific target for).

Obviously in the case of two variables, we speak of "response surface" (beyond we speak of a "volume" or "hypervolume") and then the previous relation will be written:

$$y = a_0 + a_1 x_2 + a_{12} x_1 x_2 + \underbrace{a_{11} x_1^2 + a_{22} x_2^2}_{\text{curvature}} \tag{16.7.498}$$

The designs including the following three terms:

$$a_{12} x_1 x_2 + \underbrace{a_{11} x_1^2 + a_{22} x_2^2}_{\text{curvature}} \tag{16.7.499}$$

are named "Doehlert's composite designs". We will have then to determine 4 terms:

- a_0: the constant coefficient
- a_i: coefficient of first degree
- a_{ij}: rectangle (quadratic) coefficient
- a_{ii}: pure quadratic coefficient

We see that in the case of a 2-factor design, we need then to estimate 6 coefficients:

$$y = \underbrace{a_0}_{1} + \underbrace{a_1}_{2} x_2 + \underbrace{a_2}_{3} + \underbrace{a_{12}}_{4} x_1 x_2 + \underbrace{a_{11}}_{5} x_1^2 + \underbrace{a_{22}}_{6} x_2^2 \tag{16.7.500}$$

and for 3 factors we will have to estimate 10 coefficients:

$$y=a_0+a_1x_1+a_2x_2+a_3x_3+a_{12}x_1x_2+a_{13}x_1x_3+a_{23}x_1x_3+a_{23}x_2x_3+a_{11}x_1^2+a_{22}x_2^2+a_{33}x_3^2 \tag{16.7.501}$$

Therefore after trials and errors we found that a Doehlert design has a cost (number of runs) that can be simply written as:

$$\boxed{N_{\text{Do}}=k^2+2k+N_0} \tag{16.7.502}$$

where k is the number of factors and N_0 the number of additional points.

The idea often adopted to pass to a model of the second degree after a factorial study while retaining the tests already carried out is simply to complete the existing design by the tests for the estimation of the model of higher degree when possible.

✍**Example:**

For example, a response surface associated with a relation like the previous one looks like with Maple™ 4.00b:

```
>5+3*x1+2*x2+4*x1*x2+2.5*x1^2+3*x2^2,x1=-10..10,x2=-10..10,
view=[-10..10,-10..10,0..50],contours=10,style=PATCHCONTOUR,
axes=frame,numpoints=10000);
```

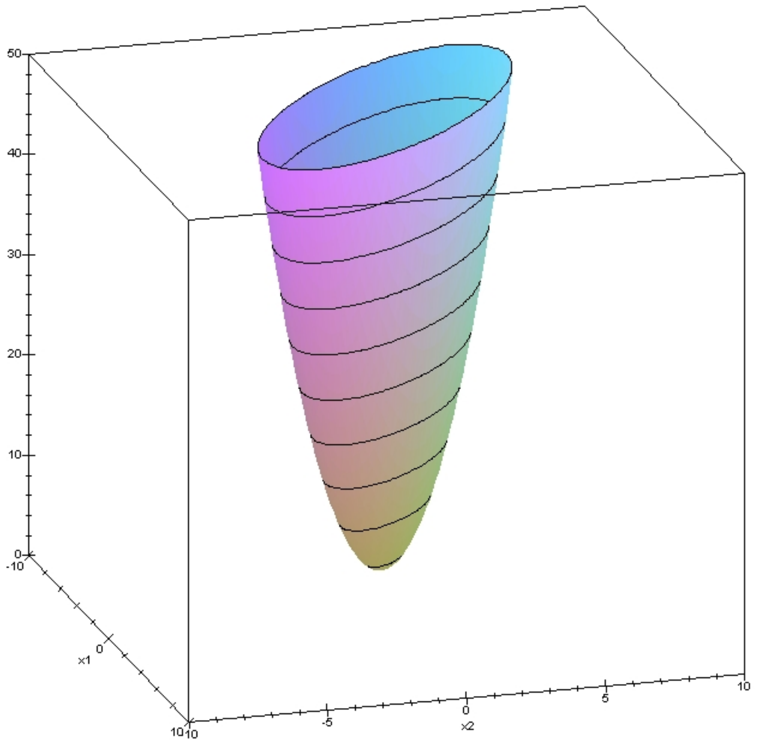

Figure 16.249: **Generic example of interaction for two factors quadratic polynomial**

16.7.4.4.1 Pure quadratic curvature test

In running a two-level factorial experiment, we usually anticipate fitting the first order model, but we should be alert to the possibility that the second order model (response surface methodology) is really more appropriate. Therefore before running response surface we should be aware of any curvature assumption!

There is a method for replicating certain points in a 2^k factorial that will provide protection against curvature from second-order effects as well as allow an independent estimate of error to be obtained. The method consist of adding center points to the 2^k design. These consist of n replicates run at the points $x_i = 0$. One important reason for adding the replicate runs at the design center is that center points do not affect the usual effect estimates in a 2^k design.

To illustrate the approach, consider 2^2 design, with one observation at each of the factorial points $(-,-)$, $(+,-)$, $(-,+)$, and $(+,+)$ and n_c observations at the center point $(0,0)$. Let $\bar{y}_F$ be the average of the four runs at the four factorial points and let $\bar{y}_C$ be the average of the n_c runs at the center point. If the difference:

$$\bar{y}_F - \bar{y}_C \tag{16.7.503}$$

is small then the center points lie on or near the plane passing through the factorial points, and there is no quadratic curvature. On the other hand, if this same difference is large, then quadratic curvature is present. A single-degree-of-freed sum of squares for pure quadratic curvature is given by (see proof just below):

$$\text{SS}_{\text{pure quadratic}} = \frac{n_F n_C (\bar{y}_F - \bar{y}_C)^2}{n_F + n_C} \tag{16.7.504}$$

where in general, n_F is the number of factorial design points. This quantity may be compared to the error mean square to test for pure quadratic curvature. More specifically, when point are added to the center of the 2^k design, then the test for curvature actually test the hypotheses the coefficients of the quadratic terms are all non zero):

$$\begin{aligned} H_0 :& \quad \sum_{j=1}^{k} \beta jj = 0 \\ H_1 :& \quad \sum_{j=1}^{k} \beta jj \neq 0 \end{aligned} \tag{16.7.505}$$

Or more explicitly:

$$\begin{aligned} H_0 :& \quad \beta_{11} + \beta_{22} + \ldots + \beta_{kk} = 0 \\ H_1 :& \quad \beta_{11} + \beta_{22} + \ldots + \beta_{kk} \neq 0 \end{aligned} \tag{16.7.506}$$

First let us prove that:

$$\text{E}(\bar{y}_F) = \beta_{11} + \beta_{22} + \ldots + \beta_{kk} \tag{16.7.507}$$

Indeed, let us recall the full model:

$$y_F=\beta_0+\beta_1x_1+\beta_2x_2+\beta_{12}x_1x_2+\beta_{11}x_1^2+\beta_{22}^2 \tag{16.7.508}$$

And let us rewrite if for the for the (x_1,x_2) combinations $(-1,+1)$, $(-1,-1)$, $(+1,+1)$, $(+1,-1)$:

$$\begin{aligned}y_{F_{(-1,+1)}}&=\beta_0-\beta_1+\beta_2-\beta_{12}+\beta_{11}+\beta_{22}\\y_{F_{(-1,-1)}}&=\beta_0-\beta_1-\beta_2+\beta_{12}+\beta_{11}+\beta_{22}\\y_{F_{(+1,-1)}}&=\beta_0+\beta_1-\beta_2-\beta_{12}+\beta_{11}+\beta_{22}\\y_{F_{(+1,+1)}}&=\beta_0+\beta_1+\beta_2-\beta_{12}+\beta_{11}+\beta_{22}\end{aligned} \tag{16.7.509}$$

We see immediately that the sum gives:

$$\sum y_F=4\beta_0+4\beta_{11}+4\beta_{22} \tag{16.7.510}$$

Therefore the average is (the sum divided by the number of corresponding measurement points):

$$\bar{y}_F=\beta_0+\beta_{11}+\beta_{22} \tag{16.7.511}$$

and in general:

$$\mathrm{E}(y_F)=\bar{y}_F=\beta_0+\beta_{11}+\beta_{22}+\ldots+\beta_{kk} \tag{16.7.512}$$

It is immediate that for the center point $(0,0)$ we have:

$$\mathrm{E}(y_C)=\bar{y}_C=\beta_0 \tag{16.7.513}$$

Therefore:

$$\mathrm{E}(\bar{y}_F-\bar{y}_C)=\beta_{11}+\beta_{22}+\ldots+\beta_{kk} \tag{16.7.514}$$

Now the variance of $\bar{y}_F-\bar{y}_C$ is under the assumption of equality of variances and independence:

$$\mathrm{V}(\bar{y}_F-\bar{y}_C)=\mathrm{V}(\bar{y}_F)+\mathrm{V}(\bar{y}_C)=\frac{\sigma^2}{n_F}+\frac{\sigma^2}{n_C}=\sigma^2\left(\frac{1}{n_F}+\frac{1}{n_C}\right) \tag{16.7.515}$$

Consequently a hypotheses can be conducted using the homoscedastic Student T-test (see section Statistics):

$$T_{n-2}=\frac{\bar{y}_F-\bar{y}_C}{\sqrt{\hat{\sigma}^2\left(\dfrac{1}{n_F}+\dfrac{1}{n_C}\right)}} \tag{16.7.516}$$

with $n=n_F+n_C$.

As we have proved in the section Statistics (see page 859), we have $T_{n-2}^2=F_{1,n-2}$ (it is convenient in statistical packages to put the curvature test in the ANOVA table where all other tests are based on Fisher distribution). Hence:

$$F_{1,n-2}=\frac{(\bar{y}_F-\bar{y}_C)^2}{\hat{\sigma}^2\left(\dfrac{1}{n_F}+\dfrac{1}{n_C}\right)} \tag{16.7.517}$$

and therefore:

$$\boxed{F_{1,n-2}=\text{SS}_{\text{pure quadtratic}}=\frac{n_F n_C(\bar{y}_F-\bar{y}_C)^2}{n_F+n_C}} \tag{16.7.518}$$

This finish our proof of the "pure quadratic curvature test" and notice that this doesn't give us the factors that are responsible of the curvature!

The reader can find an application example of this test in our Minitab companion book.

16.7.4.4.2 Box-Wilson Central Composite Designs

Let us recall that so far we have seen that according to the principle of analysis of factorial experimental designs that in the 1D case (a single explanatory variable), the interpolated point must have a left measurement point (-1) and a right measurement point $(+1)$. In the 2D case (two explanatory variables) it is natural to think then to have at least 3 points around the interpolated point such that we have a triangle whose barycenter is the point to be interpolated. Identically in the 3D case (three explanatory variables) it is natural to think of having at least 4 points surrounding the point to be interpolated and forming a cube or tetrahedron as needed. Thus, by generalizing the reasoning, in an n-dimensional space we will need at least $n+1$ points to construct a simplex around the point to be interpolated.

Now let us recall that we saw in the section of Theoretical Computing different techniques of linear regression (see page 6316) and we also studied the fact that a polynomial could be analysed with a simple linear regression (see page 6327). We obtained in the same section (during the study of the factor of inflation of the variance at page 6398) the following relation with its abusive notation ... dangerously confusing matrix of covariance and simple variance:

$$\text{cov}\left(\hat{\vec{\beta}}\right)=\text{V}\left(\hat{\vec{\beta}}\right)=\sigma_\varepsilon^2(X_c^TX_c)^{-1} \qquad (16.7.519)$$

with for recall:

$$\sigma_\varepsilon^2=\frac{1}{n-k}\sum(Y_i-y_i)^2 \qquad (16.7.520)$$

We have therefore to obtain a scalar from the explanatory values:

$$\text{V}(\hat{y})=\sigma_\varepsilon^2\vec{x}^T(X_c^TX_c)^{-1}\vec{x} \qquad (16.7.521)$$

And therefore:

$$\sigma_{\hat{y}}=\sigma_\varepsilon\sqrt{\vec{x}^T(X_c^TX_c)^{-1}\vec{x}} \qquad (16.7.522)$$

Experts in the field routinely write the latter relation in the following form and name it "variance function":

$$\text{V}(\hat{y})\frac{N}{\sigma_\varepsilon^2}=\frac{1}{N}\vec{x}^T(X_c^TX_c)^{-1}\vec{x} \qquad (16.7.523)$$

The idea now is to come back to our experimental designs is therefore to choose our measurement points which minimizes the standard deviation of the predictions introduced just previously!

Let us consider as an example the problem of finding a linear regression to the polynomial:

$$y=a_0+a_1x_1+a_2x_2 \qquad (16.7.524)$$

in the square $-1\leq x_1\leq 1,-1\leq x_2\leq 1$ and let us compare the maximum value of the predictive variance for the case of a complete factorial design (i.e. a square in the plane) and then for a fractional factorial design (i.e. a triangle in the plane) that omits the point $(1,1)$.

In the first case of the complete factorial design, we have therefore (see section Linear Algebra page 1951 and page 1967):

$$X=\begin{bmatrix}1&-1&-1\\1&-1&1\\1&1&-1\\1&1&1\end{bmatrix}\qquad X^TX=\begin{bmatrix}4&0&0\\0&4&0\\0&0&4\end{bmatrix}\qquad (X^TX)^{-1}=\frac{1}{4}\begin{bmatrix}1&0&0\\0&1&0\\0&0&1\end{bmatrix} \tag{16.7.525}$$

and therefore:

$$\vec{x}^T(X_c^TX_c)^{-1}\vec{x}=(1\,x_1\,x_2)\left(\frac{1}{4}\begin{bmatrix}1&0&0\\0&1&0\\0&0&1\end{bmatrix}\right)\begin{pmatrix}1\\x_1\\x_2\end{pmatrix}=\frac{1}{4}(1+x_1^2+x_2^2) \tag{16.7.526}$$

What is written more frequently:

$$\vec{x}^T(X_c^TX_c)^{-1}\vec{x}=\frac{1}{4}(1+R^2) \tag{16.7.527}$$

where R is the distance (radius) to the central point. When a predictive variance depends only on the distance R, we say that we have a "rotation invariant experimental design" or simply a "rotational experimental design" (the variance function is then say to be "spherical"). This type of plan is attractive to practitioners who do not know a priori where in the space of experimentation the most precise forecasts must be found!

Therefore:

$$\sigma_{\hat{y}}=\sigma_\varepsilon\sqrt{\frac{1}{4}(1+R^2)}=\frac{\sigma_\varepsilon}{2}\sqrt{1+R^2} \tag{16.7.528}$$

The variance has then for value at the point of origin $(0,0)$:

$$\sigma_{\hat{y}}=\frac{\sigma_\varepsilon}{2} \tag{16.7.529}$$

And:

$$\sigma_{\hat{y}}=\sigma_\varepsilon\frac{\sqrt{3}}{2} \tag{16.7.530}$$

at the ends. This case thus shows a small variation between the origin and the extremities (a variation exactly of $\sqrt{3}$).

In the second case of the fractional factorial design we have:

$$X=\begin{bmatrix}1&-1&-1\\1&-1&1\\1&1&-1\end{bmatrix}\qquad X^TX=\begin{bmatrix}3&-1&-1\\-1&3&-1\\-1&-1&3\end{bmatrix}\qquad (X^TX)^{-1}=\frac{1}{4}\begin{bmatrix}2&1&1\\1&2&1\\1&1&2\end{bmatrix} \tag{16.7.531}$$

and therefore:

$$\begin{aligned}\vec{x}^T(X_c^TX_c)^{-1}\vec{x}&=(1\,x_1\,x_2)\left(\frac{1}{4}\begin{bmatrix}2&1&1\\1&2&1\\1&1&2\end{bmatrix}\right)\begin{pmatrix}1\\x_1\\x_2\end{pmatrix}=\frac{1}{2}(1+x_1+x_2+x_1^2+x_2^2+x_1x_2)\\&=\frac{1}{2}(1+x_1+x_2+R^2+x_1x_2)\end{aligned} \tag{16.7.532}$$

Therefore:

$$\sigma_{\hat{y}} = \sigma_\varepsilon\sqrt{\frac{1}{2}(1+x_1+x_2+R^2+x_1x_2)} \tag{16.7.533}$$

So first this design is by definition not invariant by rotation since the variance does not depend only on R!

The variance corresponding to the point of origin $(0,0)$ is then:

$$\sigma_{\hat{y}} = \frac{\sigma_\varepsilon}{\sqrt{2}} \tag{16.7.534}$$

and at the end $(1,1)$ we have:

$$\sigma_{\hat{y}} = \sqrt{3}\sigma_\varepsilon \tag{16.7.535}$$

If we now compute by the partial derivatives the coordinates which minimizes the error such that:

$$\frac{\partial\sigma_{\hat{y}}}{\partial x_1} = \frac{\partial\sigma_\varepsilon\sqrt{\frac{1}{2}(1+x_1+x_2+R^2+x_1x_2)}}{\partial x_1} = 0 \tag{16.7.536}$$

We get:

$$\frac{1}{2}\frac{\frac{1}{2}\sigma_\varepsilon(1+2x_1+x_2)}{\sqrt{\frac{1}{2}(1+x_1+x_2+R^2+x_1x_2)}} \tag{16.7.537}$$

Hence:

$$x_1 = \frac{-x_2-1}{2} \tag{16.7.538}$$

and therefore:

$$\left.\begin{aligned} x_1 &= \frac{-x_2-1}{2} \\ x_2 &= \frac{-x_1-1}{2} \end{aligned}\right\} \Rightarrow x_1 = \frac{\frac{x_1+1}{2}-1}{2} = \frac{x_1-1}{4} \tag{16.7.539}$$

Therefore it comes:

$$(x_1,x_2) = \left(-\frac{1}{3},-\frac{1}{3}\right) \tag{16.7.540}$$

is the point of minimum variance and at this point (which coincides with the barycenter of the triangle, that is to say the center of the inscribed circle), we have:

$$\sigma_{\hat{y}} = \frac{\sigma_\varepsilon}{\sqrt{3}} \tag{16.7.541}$$

From this example, we can already easily conclude that for a complete factorial design, the variance of the predictive error is written:

$$\sigma_{\hat{y}} = \frac{\sigma_\varepsilon}{2^{n/2}}\sqrt{1+x_1^2+x_2^2+\ldots+x_n^2} = \frac{\sigma_\varepsilon}{2^{n/2}}\sqrt{1+R^2} \tag{16.7.542}$$

and as well as the maximum error is immediate and is equal in the case of a complete factorial design:

$$\sigma_{\hat{y},\max}=\sigma_\varepsilon\sqrt{\frac{1+n}{2^n}} \tag{16.7.543}$$

Thus, the quality of the fit (regression) becomes very good when n grows!

Let us now consider now the fractional factorial design based on three points in the plane forming an equilateral triangle:

$$X=\begin{bmatrix}1 & \sqrt{3/2} & -1/\sqrt{2}\\ 1 & -\sqrt{3/2} & -1/\sqrt{2}\\ 1 & 0 & \sqrt{2}\end{bmatrix} \tag{16.7.544}$$

Similar calculations to before give us (as always on readers request we can detail!):

$$\sigma_{\hat{y}}=\sigma_\varepsilon\sqrt{\frac{1}{3}(1+x_1^2+x_2^2)}=\sigma_\varepsilon\sqrt{\frac{1}{3}(1+R^3)} \tag{16.7.545}$$

Thus, we notice that, by judiciously choosing the points of the design, we may have a lower prediction error than with a complete factorial design both at the origin and at the points $(1,1)$, $(-1,1)$, $(1,-1)$ and $(-1,-1)$. However the price to pay is that we have to make measurements outside the unit square which complicates the task of the practitioner.

16.7.4.4.2.1 Circumscribed Center Designs

The "Composite Center Design (CCD)" is a two-level experimental design for surface planes. In the 2D case (two explanatory variables) this is equivalent to taking the usual points of the squares to which we add the points of intersection of the axes with the circumscribed circle (+ in practice one or more central control points):

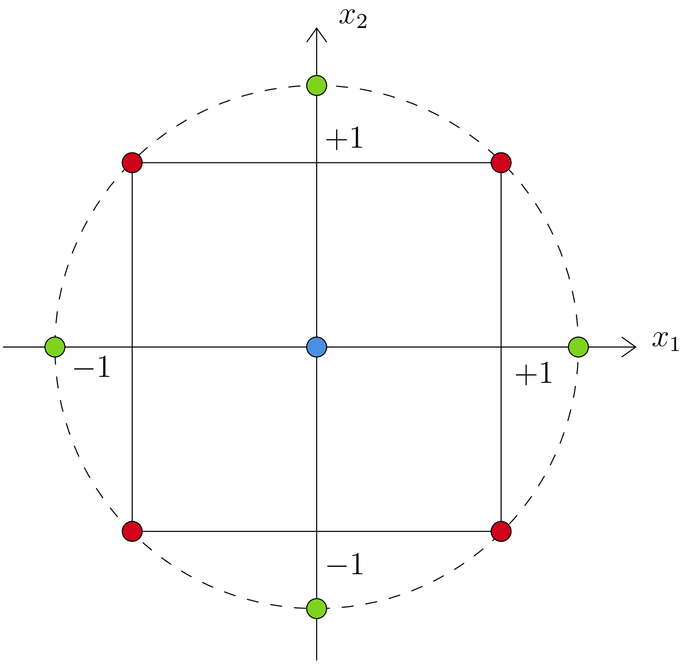

Figure 16.250: **2D Composite Center Design**

We thus have the following points, which are all at the same distance from the origin of the axes:

$$(1,1),(-1,1),(-1,1),(1,-1),(\sqrt{2},0),(0,\sqrt{2}),(-\sqrt{2},0),(0,-\sqrt{2}) \tag{16.7.546}$$

where of course the root of 2 comes from the fact that the radius of the circle is given by the vertices of the square and thus by stupidly applying Pythagoras:

$$R=\sqrt{1^2+1^2} \tag{16.7.547}$$

Due to the fact that in the above case the circle (in 2D) or the sphere (in 3D) is circumscribed to the square (or the cube in the 3D case) we also talk about CCC design for "Circumscribed Center Design (CCD)".

Let's take the example of the CCD case where the columns in the matrix below, the first is filled only with 1, the other columns corresponding respectively to the terms: x_1,x_2,x_1x_2, x_1^2, x_2^2 (notice that not all columns are orthogonal!):

$$X=\begin{bmatrix}1 & -1 & -1 & 1 & 1 & 1\\ 1 & -1 & 1 & -1 & 1 & 1\\ 1 & 1 & -1 & -1 & 1 & 1\\ 1 & 1 & 1 & 1 & 1 & 1\\ 1 & \sqrt{2} & 0 & 1 & 2 & 0\\ 1 & -\sqrt{2} & 0 & 0 & 2 & 0\\ 1 & 0 & \sqrt{2} & 0 & 0 & 2\\ 1 & 0 & -\sqrt{2} & 0 & 0 & 2\\ 1 & 0 & 0 & 0 & 0 & 0\end{bmatrix} \tag{16.7.548}$$

where the last row correspond to the fact of adding a control point a the center of the domain. This empirical matrix is sometimes named "composite equiradial matrix", it request as we see a strong symmetry and therefore implies what we named an "isovariance" (see plots with Maple™ further below of the variance).

The previous matrix is more commonly written in the following design matrix form (where the two columns are orthogonal):

$$D=\begin{bmatrix}-1 & -1\\ -1 & 1\\ 1 & -1\\ 1 & 1\\ \alpha & 0\\ -\alpha & 0\\ 0 & \alpha\\ 0 & -\alpha\\ 0 & 0\end{bmatrix} \tag{16.7.549}$$

So we can see that this design is such that for k factors we have:

- A factorial "cube" part consisting of 2^k points from a full factorial where the levels of each factor are coded as -1 and $+1$

- An "axial" or "star" part (named "star points") consisting of $2k$ points on the axis of each factor at a distance α from the center of the design
- At least one center point

We also see that the factors have 5 levels $(-1,1,-\sqrt{2},+\sqrt{2},0)$. This is a characteristic of CCD designs!

Therefore:

$$X^TX=\begin{bmatrix} 9 & 0 & 0 & 0 & 8 & 8 \\ 0 & 8 & 0 & 0 & 0 & 0 \\ 0 & 0 & 8 & 0 & 0 & 0 \\ 0 & 0 & 0 & 4 & 0 & 0 \\ 8 & 0 & 0 & 0 & 12 & 4 \\ 8 & 0 & 0 & 0 & 4 & 12 \end{bmatrix} \tag{16.7.550}$$

Using a CAD software we get:

$$(X^TX)^{-1}=\begin{bmatrix} 1 & 0 & 0 & 0 & -1/2 & -1/2 \\ 0 & 1/8 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1/8 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1/4 & 0 & 0 \\ -1/2 & 0 & 0 & 0 & 11/32 & 7/32 \\ -1/2 & 0 & 0 & 0 & 7/32 & 11/32 \end{bmatrix} \tag{16.7.551}$$

Then we have:

$$\begin{aligned}\sigma_{\hat{y}}&=\sigma_{\varepsilon}\sqrt{\vec{x}^T(X_c^TX_c)^{-1}\vec{x}}\\ &=\sigma_{\varepsilon}\sqrt{\begin{pmatrix}1 & x_1 & x_2 & x_1x_2 & x_1^2 & x_2^2\end{pmatrix}(X_c^TX_c)^{-1}\begin{pmatrix}1\\ x_1\\ x_2\\ x_1x_2\\ x_1^2\\ x_2^2\end{pmatrix}}\\ &=\sigma_{\varepsilon}\sqrt{\left(1-\frac{7}{8}x_1^2-\frac{7}{8}x_2^2+\frac{22}{32}x_1^2x_2^2+\frac{11}{32}x_1^4+\frac{11}{32}x_2^4\right)}\\ &=\sigma_{\varepsilon}\sqrt{1-\frac{7}{8}(x_1^2+x_2^2)+\frac{11}{32}(x_1^2+x_2^2)^2}\\ &=\sigma_{\varepsilon}\sqrt{1-\frac{7}{8}+\frac{11}{32}R^4}\end{aligned} \tag{16.7.552}$$

We therefore have here an experimental design whose variance depends indeed only on the distance R from the origin as many textbooks state but without proof.

Also at the opposite of 99% of textbooks we will give the Maple™ 4.00b code to plot the famous variance corresponding figure:

```
>contourplot3d(sqrt(1-7/8*(x^2+y^2)+11/32*(x^2+y^2)^2),
x=-sqrt(2)..sqrt(2),y=-sqrt(2)..sqrt(2),contours=10,filled=true);
```

We have:

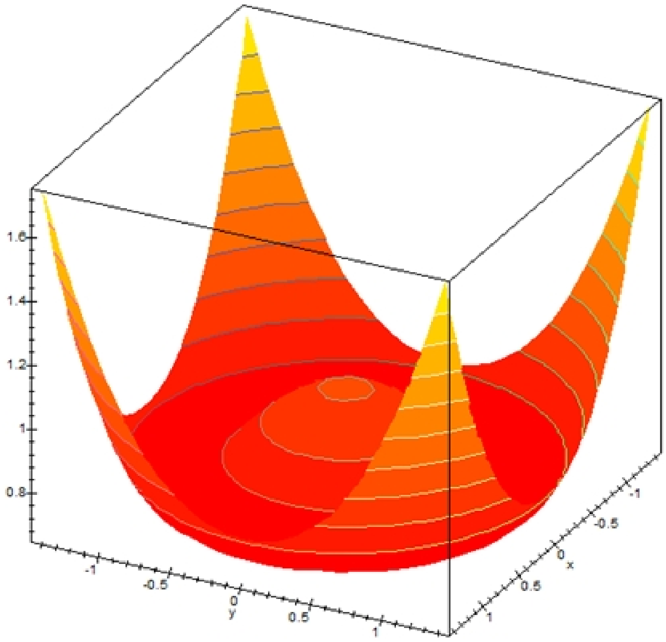

Figure 16.251: **2D Composite Center Design variance perspective plot in Maple™ 4.00b**

Either seen from above we get the corresponding famous chart available in many textbooks regarding to the rotational invariance property of surface design with two factors:

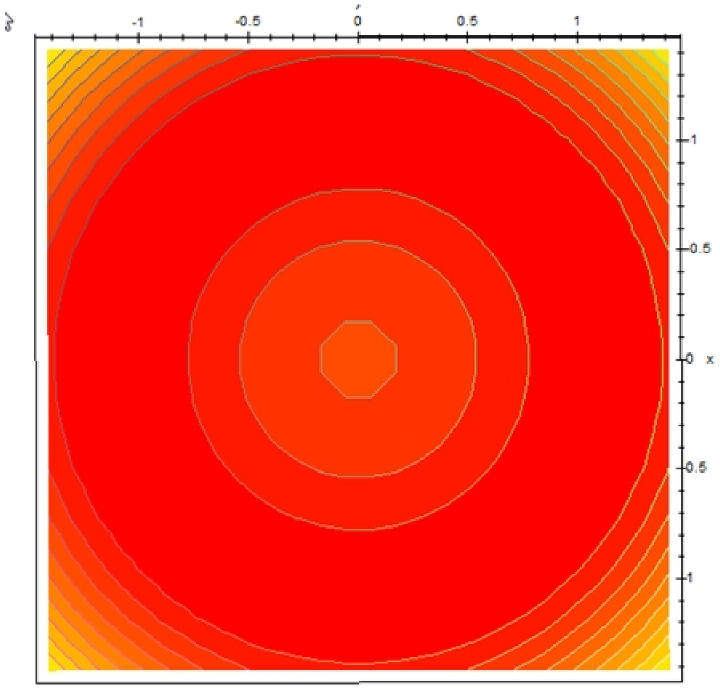

Figure 16.252: **2D Composite Center Design variance top plot in Maple™ 4.00b**

We can see that CCD have a number cost (run) of:

$$\boxed{N_{\text{CCD}}=2^{k-r}+2k+N_0} \tag{16.7.553}$$

where k is the number of factors, r the reduction integer and N_0 the number of center points. Therefore the three terms can be read as following:

- 2^{k-r}: Common full factorial of fraction factorial design of the composite equiradial matrix.
- $2k$: Number of star points
- N_0: Number of center points

Therefore for a typical two factors design with a full factorial subset we have:

$$N_{\text{CCD}}=2^{2-0}+2\cdot 2+N_0=2^2+4+N_0=8 \tag{16.7.554}$$

and as 5 is recommended for N_0, it comes that $N_{\text{CCD}}=13$ for a two factor response surface design with 5 center points.

16.7.4.4.2.2 Face Centered Designs

Repeating the same maneuver but with an experience design said to be "face-centered design" such as:

$$X=\begin{bmatrix}1&-1&-1&1&1&1\\1&-1&1&-1&1&1\\1&1&-1&-1&1&1\\1&1&1&1&1&1\\1&1&0&1&1&0\\1&-1&0&-1&1&0\\1&0&1&0&0&1\\1&0&-1&0&0&1\\1&1&0&0&1&0\end{bmatrix}\tag{16.7.555}$$

Then we have:

$$X^TX=\begin{bmatrix}10&1&1&0&7&7\\1&7&0&2&1&0\\1&0&7&0&0&1\\0&2&0&6&0&0\\7&1&0&0&7&4\\7&0&1&0&4&7\end{bmatrix}\tag{16.7.556}$$

And:

$$\left(X^TX\right)^{-1}=\begin{bmatrix}\frac{257}{270}&-\frac{1}{18}&-\frac{1}{20}&\frac{1}{54}&-\frac{3}{5}&-\frac{65}{108}\\-\frac{1}{18}&\frac{1}{6}&0&-\frac{1}{18}&0&\frac{1}{18}\\-\frac{1}{20}&0&\frac{3}{20}&0&\frac{1}{20}&0\\\frac{1}{54}&-\frac{1}{18}&0&\frac{5}{27}&0&-\frac{1}{54}\\-\frac{3}{5}&0&\frac{1}{20}&0&\frac{3}{5}&\frac{1}{4}\\-\frac{65}{108}&\frac{1}{18}&0&-\frac{1}{54}&\frac{1}{4}&\frac{65}{108}\end{bmatrix}\tag{16.7.557}$$

We then have after:

$$\begin{aligned}\sigma_{\hat{y}}&=\sigma_\varepsilon\sqrt{\vec{x}(X_c^TX_c)^{-1}\vec{x}}\\&=\sigma_\varepsilon\sqrt{\begin{gathered}\frac{257}{270}-\frac{1}{18}x_1-\frac{1}{20}x_2+\frac{1}{54}x_1x_2-\frac{3}{5}x_1^2-\frac{65}{108}x_2^2\\+x_1\left(-\frac{1}{18}+\frac{1}{6}x_1-\frac{1}{18}x_1x_2+\frac{1}{18}x_2^2\right)+x_2\left(-\frac{1}{20}+\frac{3}{20}x_2-\frac{1}{20}x_1^2\right)\\+x_1x_2\left(\frac{1}{54}-\frac{1}{18}x_1+\frac{5}{27}x_1x_2-\frac{1}{54}x_2^2\right)+x_1^2\left(-\frac{3}{5}+\frac{1}{20}x_2+\frac{3}{5}x_1^2+\frac{1}{4}x_2^2\right)\\+x_2^2\left(-\frac{65}{108}+\frac{1}{18}x_1-\frac{1}{54}x_1x_1+\frac{1}{4}x_1^2+\frac{65}{108}x_2^2\right)\end{gathered}}\end{aligned}\tag{16.7.558}$$

Notice that the Circumscribed Center Design (CCC) was a rotatable design but that the Face Centered Design (CCF) is not as it does not depends only on R.

Which gives us with Maple™ 4.00b by proceeding exactly with the same above given code:

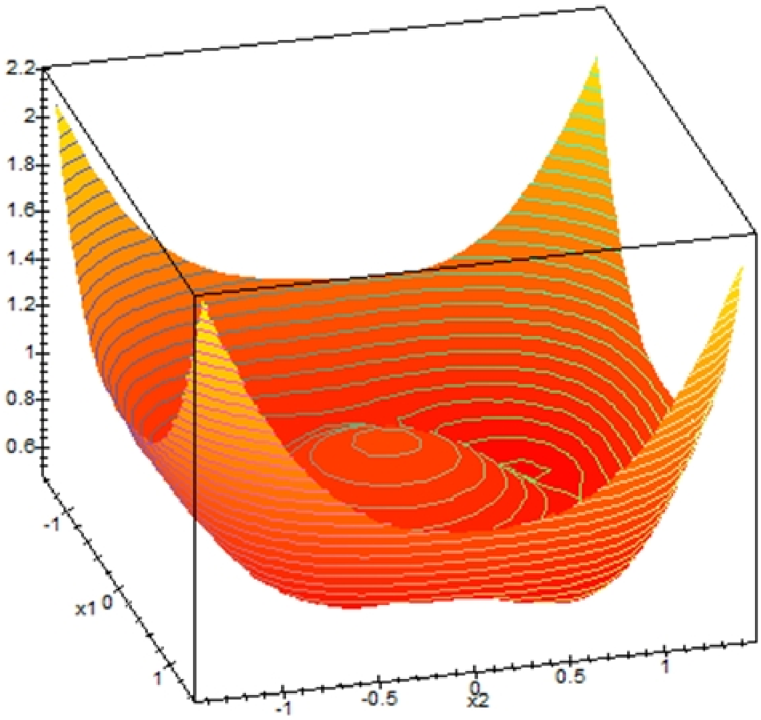

Figure 16.253: **2D Faced-centered Design variance perspective plot in Maple™ 4.00b**

Either seen from above we get the corresponding famous chart available in many textbooks:

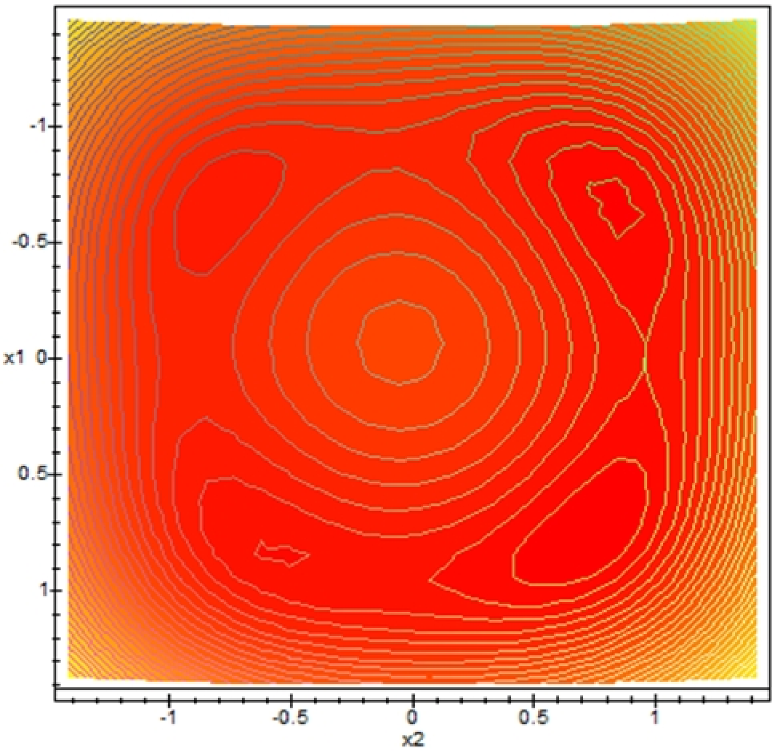

Figure 16.254: **2D Faced-centered Design variance top plot in Maple™ 4.00b**

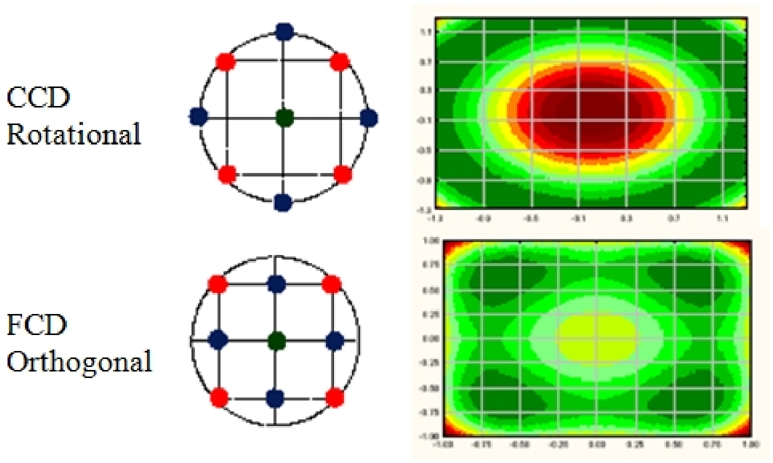
The two previous designs are frequently summarized with the following figure:



In fact there are three Composite Central Design:

1. Circumscribed (CCD)
2. Inscribed (ICD)
3. Face centered (FCD)

Response surface methodology is obviously often applied to pilot plant operations by research and development personnel but when it is applied to a full-scale production process, it is usually only done once (or very infrequently) because the experimental procedure is relatively elaborate. However, conditions that were optimum for the pilot plant may not be optimum for the full-scale process. Indeed, the operation "scale-up" of the pilot plant to the full-scale production process usually results in distortion of the optimum conditions. Even if the full-scale plant begins operation at the optimum, it will eventually’ ’drift" away from that point because of variations in raw materials, environmental changes, and operating personnel.

A method is needed for the continuous monitoring and improvement of a full-scale process with the goal of moving the operating conditions toward the optimum or following a "drift." The method should not require large or sudden changes in operating conditions that might disrupt production. "Evolutionary operation (EVOP)" was proposed by Box (11957 according to holocene calendar) as such an operating procedure. It is designed as a method of routine plant operation that is carried out by manufacturing personnel with minimum assistance from the research and development staff.

EVOP consists of systematically introducing small changes in the levels of the operating variables under consideration. Usually, a 2^k design is employed to do this. The changes in the variables are assumed to be small enough that serious disturbances in yield, quality, or quantity will not occur, yet large enough that potential improvements in process performance will eventually be discovered. Data are collected on the response variables of interest at each point of the 2^k design. When one observation has been taken at each design point, a cycle is said to have been completed. The effects and interactions of the process variables may then be computed. Eventually, after several cycles, the effect of one or more process variables or their interactions may appear to have a significant effect on the response. At this point, a decision may be made to change the basic operating conditions to improve the response. When improved conditions have been detected, a phase is said to have been completed.

In testing the significance of process variables and interactions, an estimate of experimental error is required. This is calculated from the cycle data. Also, the 2^k design is usually centered about the current best operating conditions. By comparing the response at this point with the 2^k points in the factorial portion, we may check on curvature or change in mean (CIM); that is, if the process is really centered at the maximum, say, then the response at the center should be significantly greater than the responses at the 2^k-peripheral points.

In theory, EVOP can be applied to k process variables. In practice, only two or three variables are usually considered. We will give an example of the procedure for two variables. Box and Draper (11969 according to holocene calendar) give a detailed discussion of the three-variable case, including necessary forms and worksheets. Myers and Montgomery (11995 according to holocene calendar) discuss the computer implementation of EVOP.

16.7.4.5 Optimal Designs

In the design of experiments, "optimal designs" are a class of experimental designs that are optimal with respect to some statistical criterion. The creation of this field of statistics has been credited to Danish statistician Kirstine Smith.

In the design of experiments for estimating statistical models, optimal designs allow parameters to be estimated without bias and with minimum variance. A non-optimal design requires a greater number of experimental runs to estimate the parameters with the same precision as an optimal design. In practical terms, optimal experiments can reduce the costs of experimentation.

The optimality of a design depends on the statistical model and is assessed with respect to a statistical criterion, which is related to the variance-matrix of the estimator. Specifying an appropriate model and specifying a suitable criterion function both require understanding of statistical theory and practical knowledge with designing experiments.

We will begin here with the study of "D-optimal design" which is a form of experimental design provided by a computer algorithm for which we will give the mathematical background a little further below. These types of computer-aided designs are particularly useful when conventional plans do not apply.

Unlike standard classical models such as factorial design and fractional factorial designs or Taguchi designs, D-optimal designs are generally not orthogonal but are very flexible, hence their great practical importance.

D-optimal plans are always an option whatever the degree of the model the experimenter wishes to use (eg first order, second order with or without interactions, complete quadratic, cubic, etc.).

The D-optimal designs are associated with a regression model based on the fact that since in the case of the multiple linear regression we have (see section Numerical Methods page 6379):

$$\mathrm{V}\left(\hat{\vec{\beta}}\right)=\sigma_{\varepsilon}^{2}(X^{T}X)^{-1} \qquad (16.7.559)$$

then we must be able to find the component values of the matrix X which minimize the variances (the elements of the diagonal of this matrix as we have proved in the section of Theoretical Computing!). As this optimization operation is tricky, it is necessary to optimize a scalar value relative to the dispersion matrix $(X^{T}X)^{-1}$.

If we write:

$$(X^{T}X)^{-1}=A^{-1} \qquad (16.7.560)$$

Then let us recall that we have proved in the section of Linear Algebra (see page 1980) that the components of the inverse of the matrix A are given by:

$$b_{ij}=\frac{1}{\det(A)}(-1)^{i+j}\det(A_{ji}) \qquad (16.7.561)$$

Therefore minimize all the components is equivalent as to maximize the determinant of A and hence to maximize the determinant of $(X^{T}X)^{-1}$. It is for this reason that we speak of D-optimal designs for "Determinant-optimal designs" because trying to minimize the diagonal components (and in general all components) of the variance-covariance matrix is equivalent to seeking to maximize the determinant of $(X^T X)$:

$$\boxed{\max\ \det(X^T X)} \tag{16.7.562}$$

Another approach of minimizing the diagonal components of the variance-covariance matrix can be in choosing the scalar value to minimize, and therefore to minimize the trace (or the Average of the trace) of the information matrix:

$$\boxed{\min\ \text{tr}\left((X^T X)^{-1}\right)} \tag{16.7.563}$$

and we then speak of an "A-optimal design" which is numerically more expensive in algorithmic terms than the search for the D-optimal plan because it is necessary to reverse the information matrix but it is a criterion that is often considered more natural.

However, the majority of software specialized in experimental designs propose to determine the D-optimal or A-optimal designs but there are many other possible criteria that we will not present here such as E-optimality, G-optimality, etc.

Obviously before that the D or A-optimal design or other can be generated, the experimenter must know the theoretical model he wants! Thus, knowing the model, the number of factors and levels of each factor we known then the complete factorial design and from the number of real tests (runs) that can be made by the experimenter (economically speaking!), we must find the most effective sub-set that will be a D-optimal, A-optimal design or other...

It seems that to date the software uses evolutionary algorithms (see section Numerical Methods page 7022) to determine the optimal design so in extenso there is no guarantee that the given optimal design is really the optimal one (except if one restarts the calculation a great number of times always falling on the same result).

The advantage of D-optimal or A-optimal designs or other designs of the same family is that they are very flexible and often more suited to the real needs of the experimenters.

OK... it may seems quite abstract for some readers so let us see a companion example.

Suppose that an experimenter has 3 controlled variables and that seeks to determine a model of the type:

$$y = a_0 + a_1 x_1 + a_2 x_2 + a_3 x_3 + a_{11} x_1^2 \tag{16.7.564}$$

and we will consider that it has the following parameters:

$$\begin{aligned} &x_1 : 5 \text{ levels: } (-1, -0.5, 0, +0.5, +1)\\ &x_2 : 2 \text{ levels: } (-1, +1)\\ &x_3 : 2 \text{ levels: } (-1, +1) \end{aligned} \tag{16.7.565}$$

and that he can only do 12 trials (for economic reasons or times reasons or else...!). In this case, given that one of the factors have 5 levels, it is out of question for this to use fractional factorial designs or the Plackett-Burman designs. Even if Taguchi's designs manage certain factors at more than 2 levels there is no Taguchi plan for this special scenario (at least as far as we know...) so we must also forget them. The same applies to composite surface designs or Box-Behnken designs.

The only thing that can be done is either to use a complete factorial design (but again it would require 20 tests which is not conceivable!) or a D or A-optimal design.

Obviously the complete factorial plan would require $5 \cdot 2 \cdot 2 = 20$ tests (runs) which would be:

Run	x_1	x_2	x_3
1	-1	-1	-1
2	-1	-1	$+1$
3	-1	$+1$	-1
4	-1	$+1$	$+1$
5	-0.5	-1	-1
6	-0.5	-1	$+1$
7	-0.5	$+1$	-1
8	-0.5	$+1$	$+1$
9	0	-1	-1
10	0	-1	$+1$
11	0	$+1$	-1
12	0	$+1$	$+1$
13	$+0.5$	-1	-1
14	$+0.5$	-1	$+1$
15	$+0.5$	$+1$	-1
16	$+0.5$	$+1$	$+1$
17	$+1$	-1	-1
18	$+1$	-1	$+1$
19	$+1$	$+1$	-1
20	$+1$	$+1$	$+1$

Table 16.54: **Starting full design for D-optimal design seeking**

So that everyone can use an accessible tool, we will show how to extract a D or A-optimal design of 12 tests using a simple spreadsheet software like Microsoft® Excel® 14.0.7015 by first constructing the following table corresponding to the matrix in its totality:

	A	B	C	D	E	F
1	**Run**	**Ordinate at origin**	x_1	x_2	x_3	x_1^2
2	1	1	-1	-1	-1	1
3	2	1	-1	-1	1	1
4	3	1	-1	1	-1	1
5	4	1	-1	1	1	1
6	5	1	-0.5	-1	-1	0.25
7	6	1	-0.5	-1	1	0.25
8	7	1	-0.5	1	-1	0.25
9	8	1	-0.5	1	1	0.25
10	9	1	0	-1	-1	0
11	10	1	0	-1	1	0
12	11	1	0	1	-1	0
13	12	1	0	1	1	0
14	13	1	0.5	-1	-1	0.25
15	14	1	0.5	-1	1	0.25
16	15	1	0.5	1	-1	0.25
17	16	1	0.5	1	1	0.25
18	17	1	1	-1	-1	1
19	18	1	1	-1	1	1
20	19	1	1	1	-1	1
21	20	1	1	1	1	1

Figure 16.255: Starting full design for D-optimal design seeking in Microsoft® Excel® 14.0.7015

Then we construct the following structure a little further on the same sheet:

	H	I	J	K	L	M	N
1	**Solution**	**Run**	**Ordinate at origin**	x_1	x_2	x_3	x_1^2
2	1		1	=INDEX($C$2:$E$21,$I2,1)	=INDEX($C$2:$E$21,$I2,2)	=INDEX($C$2:$E$21,$I2,3)	=K2^2
3	2		1	=INDEX($C$2:$E$21,$I3,1)	=INDEX($C$2:$E$21,$I3,2)	=INDEX($C$2:$E$21,$I3,3)	=K3^2
4	3		1	=INDEX($C$2:$E$21,$I4,1)	=INDEX($C$2:$E$21,$I4,2)	=INDEX($C$2:$E$21,$I4,3)	=K4^2
5	4		1	=INDEX($C$2:$E$21,$I5,1)	=INDEX($C$2:$E$21,$I5,2)	=INDEX($C$2:$E$21,$I5,3)	=K5^2
6	5		1	=INDEX($C$2:$E$21,$I6,1)	=INDEX($C$2:$E$21,$I6,2)	=INDEX($C$2:$E$21,$I6,3)	=K6^2
7	6		1	=INDEX($C$2:$E$21,$I7,1)	=INDEX($C$2:$E$21,$I7,2)	=INDEX($C$2:$E$21,$I7,3)	=K7^2
8	7		1	=INDEX($C$2:$E$21,$I8,1)	=INDEX($C$2:$E$21,$I8,2)	=INDEX($C$2:$E$21,$I8,3)	=K8^2
9	8		1	=INDEX($C$2:$E$21,$I9,1)	=INDEX($C$2:$E$21,$I9,2)	=INDEX($C$2:$E$21,$I9,3)	=K9^2
10	9		1	=INDEX($C$2:$E$21,$I10,1)	=INDEX($C$2:$E$21,$I10,2)	=INDEX($C$2:$E$21,$I10,3)	=K10^2
11	10		1	=INDEX($C$2:$E$21,$I11,1)	=INDEX($C$2:$E$21,$I11,2)	=INDEX($C$2:$E$21,$I11,3)	=K11^2
12	11		1	=INDEX($C$2:$E$21,$I12,1)	=INDEX($C$2:$E$21,$I12,2)	=INDEX($C$2:$E$21,$I12,3)	=K12^2
13	12		1	=INDEX($C$2:$E$21,$I13,1)	=INDEX($C$2:$E$21,$I13,2)	=INDEX($C$2:$E$21,$I13,3)	=K13^2

18							
19							
20							
21							

Figure 16.256: Preparation of D-optimal design with formulas in Microsoft® Excel® 14.0.7015

Now let's us recall that finding a D-optimal design is equivalent to find the components of X

such as:

$$\max\left\{\det(X^TX)\right\} \tag{16.7.566}$$

so in one of the cells we should write (be careful this is a matrix function so we must validate by Ctrl + Shift + Enter):

	P
1	**Determinant:**
2	=MDETERM(MMULT(TRANSPOSE(J2:N13),J2:N13))

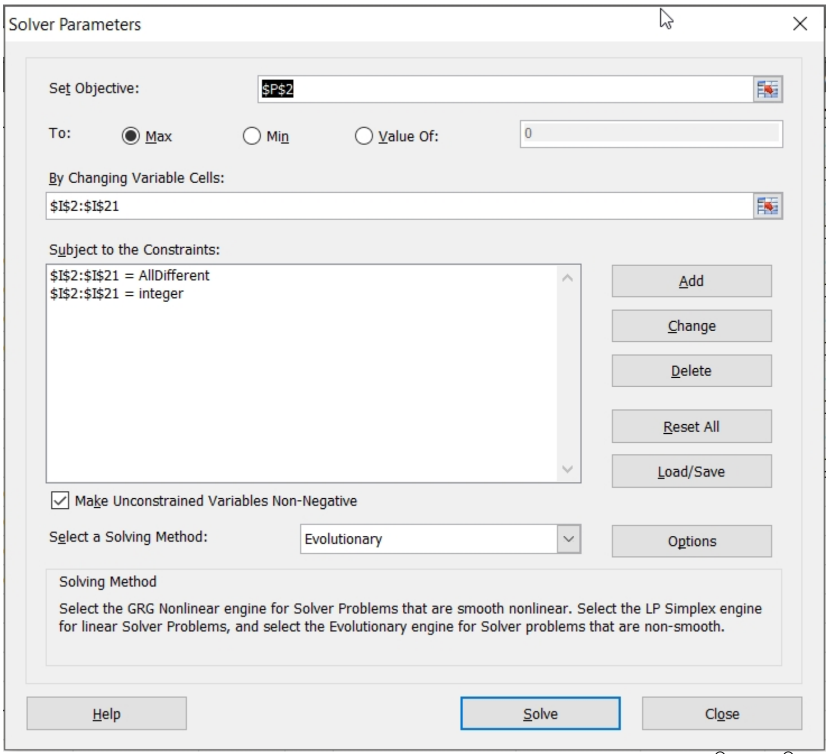
But if we follow the method advocated by the NIST on their page here:

http://www.itl.nist.gov/div898/handbook/pri/section5/pri521.htm

We would have to maximize the determinant of the submatrix (which in all rigour is false but anyway let us do as they say...) and then we write rather:

	P
1	**Déterminant:**
2	=MDETERM(MMULT(TRANSPOSE(K2:M13),K2:M13))

Then we launch the solver of this version of Microsoft® Excel® in evolutionary mode:



Set Objective: $P$2

To: ● Max ○ Min ○ Value Of: 0

By Changing Variable Cells: $I$2:$I$21

Subject to the Constraints:

$I$2:$I$21 = AllDifferent
$I$2:$I$21 = integer

☑ Make Unconstrained Variables Non-Negative

Select a Solving Method: Evolutionary

Solving Method

Select the GRG Nonlinear engine for Solver Problems that are smooth nonlinear. Select the LP Simplex engine for linear Solver Problems, and select the Evolutionary engine for Solver problems that are non-smooth.

Figure 16.257: **Evolutionary solver settings for seeking D-optimal design in Microsoft® Excel® 14.0.7015**

You may perhaps be wondering why more variable cells should be selected than necessary. This is because of the intrinsic operation of the Microsoft® Excel® solver. If we take the cells `I2` to `I13` it will not find any solution that you put additional constraints or not to the solver!

If we run the solver, we get:

	H	I	J	K	L	M	N	O	P
1	**Solution**	**Run**	**Ordinate at origin**	x_1	x_2	x_3	x_1^2		**Déterminant:**
2	1	3	1	-1	1	-1	1		1296
3	2	8	1	-0.5	1	1	0.25		
4	3	16	1	0.5	1	1	0.25		
5	4	1	1	-1	-1	-1	1		
6	5	18	1	1	-1	1	1		
7	6	4	1	-1	1	1	1		
8	7	19	1	1	1	-1	1		
9	8	17	1	1	-1	-1	1		
10	9	15	1	0.5	1	-1	0.25		
11	10	20	1	1	1	1	1		
12	11	14	1	0.5	-1	1	0.25		
13	12	2	1	-1	-1	1	1		
14		7							
15		10							
16		13							
17		12							
18		11							
19		6							
20		5							
21		9							

Figure 16.258: **Final D-optimum design following NIST recommendation in Microsoft® Excel® 14.0.7015**

that gives us a determinant of 1296. The result provided by the NIST has in comparison a determinant of 1156. The D-optimal experimental design given by the NIST is indeed:

Run	x_1	x_2	x_3
1	$+1$	-1	-1
2	-1	-1	$+1$
3	-1	$+1$	-1
4	-1	$+1$	$+1$
5	0	-1	-1
6	0	-1	$+1$
7	0	$+1$	-1
8	0	$+1$	$+1$
9	$+1$	-1	-1
10	$+1$	-1	$+1$
11	$+1$	$+1$	-1
12	$+1$	$+1$	$+1$

Table 16.55: **Final D-optimal design**

Where does this difference comes from???!!!!! This is quite easy to understand: It is impossible to find all coefficients with the system we get with Microsoft® Excel® as we still have 4 levels, 2 levels and 2 levels so this system cannot be solved as we would need 16 runs to solve it without alias!!!! So the real algorithm to reach 12 runs has to eliminate one of the level of the first factor and the main purpose of D-optimum design is to find which level should be eliminate to keep the maximum information!

Remark

Caution! Depending on the softwares packages used for the analysis of DoE, you might come across a different result because they basically use almost all different algorithms (Federov's Method, Modified Federov's Method or K-Exchange Method for most known one):

Then, it is customary in practice and if we conform ourselves to the NIST results... to make the calculations of the following efficiency indices relative to the matrix obtained (the choice is completely empirical but well... it seems that most statistical software has its own indicators...):

$$\begin{aligned}\text{D-efficiency} &= \min\left\{\dfrac{1}{N_D\left(\det(X^TX)\right)^{-1/p}}\right\}\\ \text{A-efficiency} &= \min\left\{\text{tr}\left((X^TX)^{-1}\right)\right\}\\ \text{G-efficiency} &= \max\left\{\dfrac{\sqrt{N/p}}{\sigma_G}\right\}\end{aligned}\tag{16.7.567}$$

where in the G-efficiency, the term σ_G is the smallest variance in the diagonal of the projection matrix $X(X^TX)^{-1}X^T$.

What gives in Microsoft® Excel®:

	R	S	T	U	V	W	X	Y
1	D-efficiency:	=MDETERM(MINVERSE(MMULT(TRANSPOSE(J2:N13),J2:N13)))^(-1/5)/12						
2	A-efficiency:	=SUM(R6,S7,T8,U9,V10)*(12/5)						
3	G-efficiency:	=SQRT(5/12)/MAX(R13,S14,T15,U16,V17)						
4								
5	**Matrix for A-efficiency:**							
6	0.250	0.000	0.000	0.000	-0.250			
7	0.000	0.125	0.000	0.000	0.000			
8	0.000	0.000	0.083	0.000	0.000			
9	0.000	0.000	0.000	0.083	0.000			
10	-0.250	0.000	0.000	0.000	0.375			
11								
12	**Matrix for G-efficiency:**							
13	0.645	0.500	0.500	0.289	0.408			
14	0.500	0.645	0.289	0.500	0.000			
15	0.500	0.289	0.645	0.500	0.000			
16	0.289	0.500	0.500	0.645	#NUM!			
17	0.408	0.000	0.000	#NUM!	0.645			

Figure 16.260: **Explicit formulas for index efficiency compliant to NIST in Microsoft® Excel® 14.0.7015**

where in the relations of the cells `S1` to `S3`, the 5 is the number of columns of the experiment matrix and the 12 is the number of rows. To do the calculations of the A-efficiency and G-efficiency we need in Microsoft® Excel® both matrices explicitly (since this spreadsheet does not have functions for the trace of a matrix nor for the maximum of the trace) as that we have in `R6` (and the whole range of the relative matrix) the following matrix relation (to be validated with Ctrl+Shit+Enter):

```
=MINVERSE(MMULT(TRANSPOSE(J2:N13),J2:N13))
```

and in `R13` (and in all the corresponding range) the following matrix relation (to be validated with Ctrl+Shit+Enter):

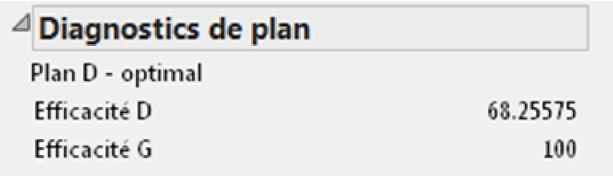
```
=SQRT(MMULT(J2:N13,MMULT(MINVERSE(MMULT(TRANSPOSE(J2:N13),J2:N13))
,TRANSPOSE(J2:N13))))
```

What gives:

	R	S	T	U	V
1	D-efficiency:	0.6826			
2	A-efficiency:	2.2000			
3	G-efficiency:	1.0000			
4					
5	**Matrix for A-efficiency:**				
6	0.250	0.000	0.000	0.000	-0.250
7	0.000	0.125	0.000	0.000	0.000
8	0.000	0.000	0.083	0.000	0.000
9	0.000	0.000	0.000	0.083	0.000
10	-0.250	0.000	0.000	0.000	0.375
11					
12	**Matrix for G-efficiency:**				
13	0.645	0.500	0.500	0.289	0.408
14	0.500	0.645	0.289	0.500	0.000
15	0.500	0.289	0.645	0.500	0.000
16	0.289	0.500	0.500	0.645	#NUM!
17	0.408	0.000	0.000	#NUM!	0.645

Figure 16.261: **Index efficiency conforming to NIST in Microsoft® Excel® 14.0.7015**

and perfectly matches (obviously...) the values given by the NIST! We also see that JMP (SAS) also gives (with the difference that it multiplies D-efficiency and G-efficiency by a factor 100) as shown in the printscreen of the french version below:



Diagnostics de plan

Plan D - optimal

Efficacité D 68.25575

Efficacité G 100

Figure 16.262: **JMP (SAS) efficiency index of optimal designs**

while the Minitab software (version 16.1.1 and earlier) gives the D and G optimality but calculates it in a bizarre and obscure way in my point of view.

In order to fit an optimality criterion the companion example above show us that we have to define the number of experiments we want to have in the design. The selection of this factor is very important because changing the number of the design runs alters the model matrix and another optimal design is chosen. There are no rules to define this number, but the minimum is model-dependent. A model with p coefficients can only be investigated with a D-optimal design which has at least p runs. In most cases, it is useful to create different designs that differ in the number of runs and compare the efficiency of the designs. A design with a few more or less design runs than the desired one can have a higher determinant and hence is the best design to perform. A software like Minitab for reasons that are unknown to us don't give however the possibility to have a number of runs equal to the number of factors.

16.7.4.6 Mixture Design

When a product is formed by mixing together two or more ingredients, the product is named a "mixture", and the ingredients are named "mixture components". In a general mixture problem, the measured response is assumed to depend only on the proportions of the ingredients in the mixture, not the amount of the mixture. For example, the taste of a fruit punch recipe (i.e., the response) might depend on the proportions of watermelon, pineapple and orange juice in the mixture. The taste of a small cup of fruit punch will obviously be the same as a big cup.

Sometimes the responses of a mixture experiment depend not only on the proportions of ingredients, but also on the settings of variables in the process of making the mixture. For example, the tensile strength of stainless steel is not only affected by the proportions of iron, copper, nickel and chromium in the alloy; it is also affected by process variables such as temperature, pressure and curing time used in the experiment.

One of the purposes of conducting a mixture experiment is to find the best proportion of each component and the best value of each process variable, in order to optimize a single response or multiple responses simultaneously. In this chapter, we will discuss how to design effective mixture designs and how to analyse data from mixture experiments with and without process variables.

There are several different types of mixture designs. The most common ones are "simplex lattice", "simplex centroid", "simplex axial" and "extreme vertex designs", each of which is used for a different purpose.

- If there are many components in a mixture, the first choice is to screen out the most important ones. Simplex axial and Simplex centroid designs are used for this purpose.
- If the number of components is not large, but a high order polynomial equation is needed in order to accurately describe the response surface, then a Simplex lattice design can be used.
- Extreme vertex designs are used for the cases when there are constraints on one or more components (e.g., if the proportion of watermelon juice in a fruit punch recipe is required to be less than 30%, and the combined proportion of watermelon and orange juice should always be between 40% and 70%).

So often in practice we are interested in studying mixtures. In other words, we want to know the proportion of ingredients needed to achieve a certain result. The cases of application are so numerous that it would be futile to enumerate them all here.

The fact that the proportions must be added is the key element of the simple mixture design since if we denote by x_i the proportion of the ingredient i then under unconstrained mixture we have:

$$\begin{gathered}1 \geq x_i \geq 0\\ \sum_{i=1}^{k} x_i = 1\end{gathered} \tag{16.7.568}$$

or written slightly differently:

$$\begin{gathered}100\% \geq x_i \geq 0\% \\ \sum_{i=1}^{k} x_i = 100\%\end{gathered} \tag{16.7.569}$$

where the last relation is named logically "fundamental constraint of unconstrainted mixtures".

So we already notice that it is not possible to vary one parameter (ingredient) without the other being modified. So the control variables are not independent! We can not then use the techniques seen so far!

As we will see just below, the response surface of a mixture design is a simplex (connected surface as introduced in the section of Geometric Shapes) of dimension k with $k-1$ edges (and generally plunged into a space of dimension k).

For example, with two factors (binary mixture) the simplex is simply a line segment ranging from $(0,1)$ to $(1,0)$ in terms of coordinates. With three factors, the simplex is a triangle with three edges with three vertices of coordinates $(1,0,0)$, $(0,1,0)$ and $(0,0,1)$:

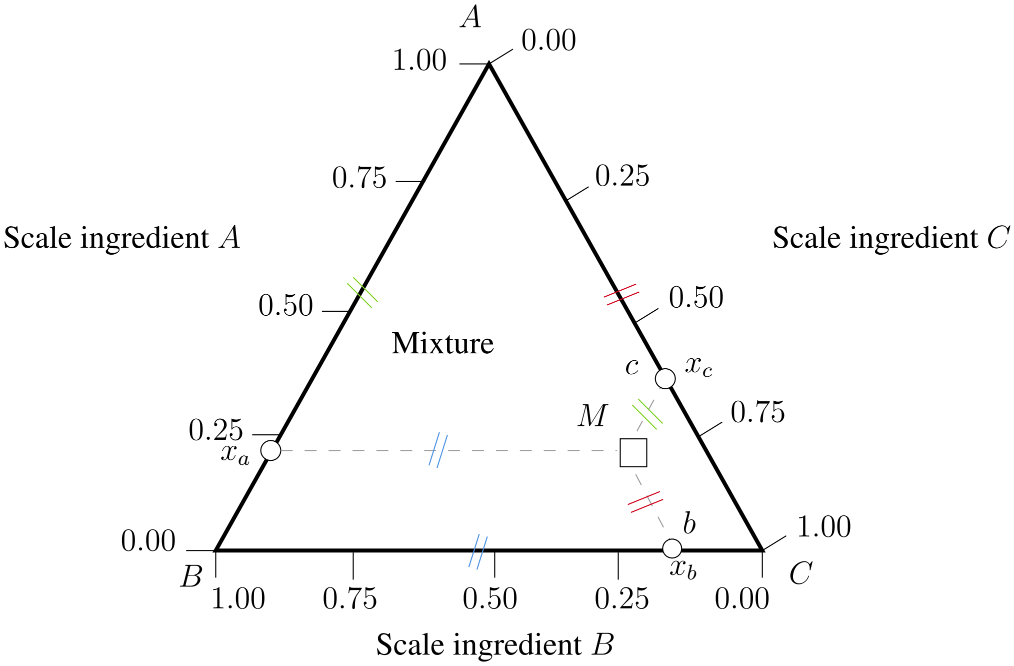


Figure 16.263: **Three factors mixtures design simplex**

where the segments of the point M at the concentration points are logically the translations of the edges of the triangle with for condition that the sum of the segments being equal to a unit length.

There are several ways of arranging the experimental points whose in our field of study are (from top to bottom in the figure below):

- Simplex lattice designs

- Simplex centroid designs
- Augmented simplex centroid designs
- and some other exotics one...

(0, 1/2, 1/2, 0)
$x_3 = 1$
(0, 1/3, 1/3, 1/3)
(0, 1/2, 0, 1/2)

Figure 16.265: 4 **factors simplex centroid example**

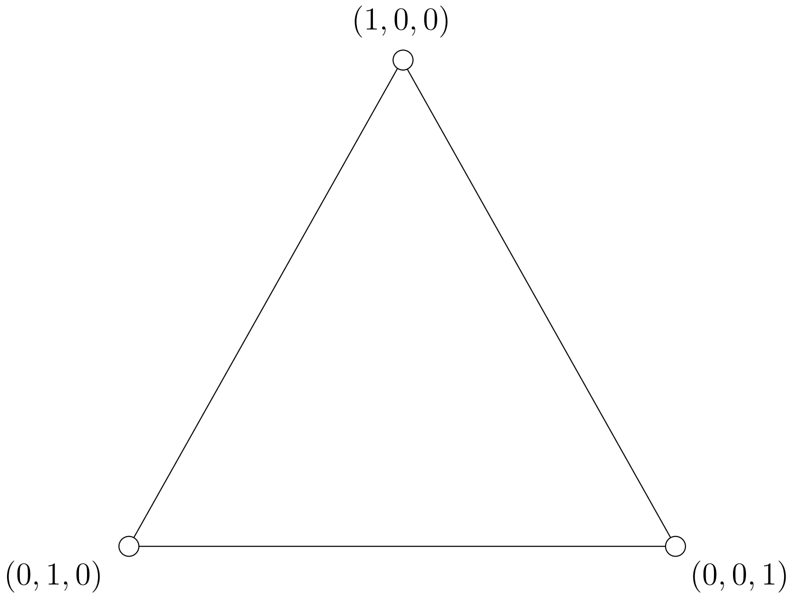
16.7.4.6.1 Network mixture designs (simplex lattice designs)

The "network mixture designs" more commonly named "Simplex lattice designs" and sometimes just "L-simplex design" or "Scheffé's designs" are those most often studied in schools because they are the least abstract and algebraically the most accessible. Thus, in a network mixture design of p variables and where the intervals of values are cut in m pieces, the reader will notice by trying manually on a sheet of paper that we get the following table of number of runs (that is to say: the cost of the corresponding design):

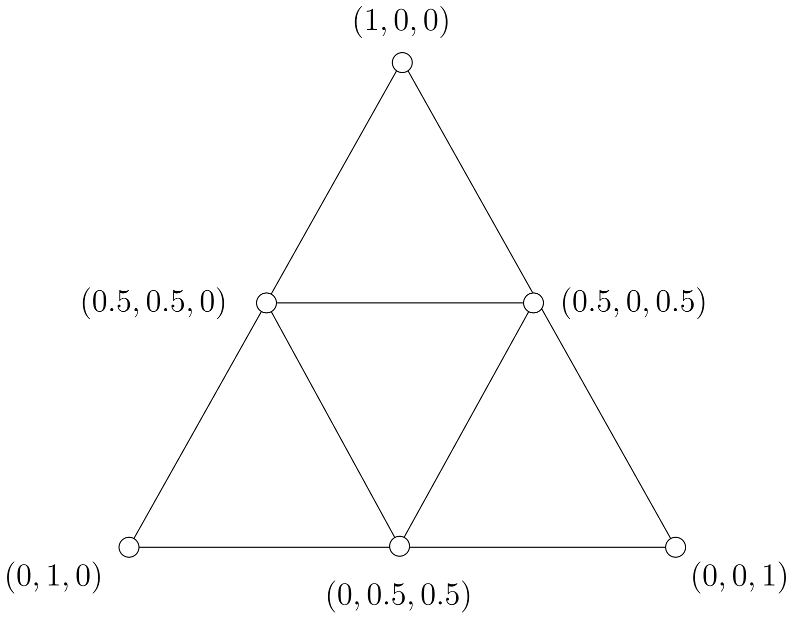
	m		
p	1 (pure simplex)	2	3
3	3	6	10
4	4	10	20
5	5	15	35
6	6	21	56
7	7	28	84

Table 16.56: **Number of points in a mixture lattice design (non-centered)**

OK this table may be a quite abstract for some people. So let us consider an illustration of the case $p=3$ and $m=1$ (we see clearly the $N=3$ runs):

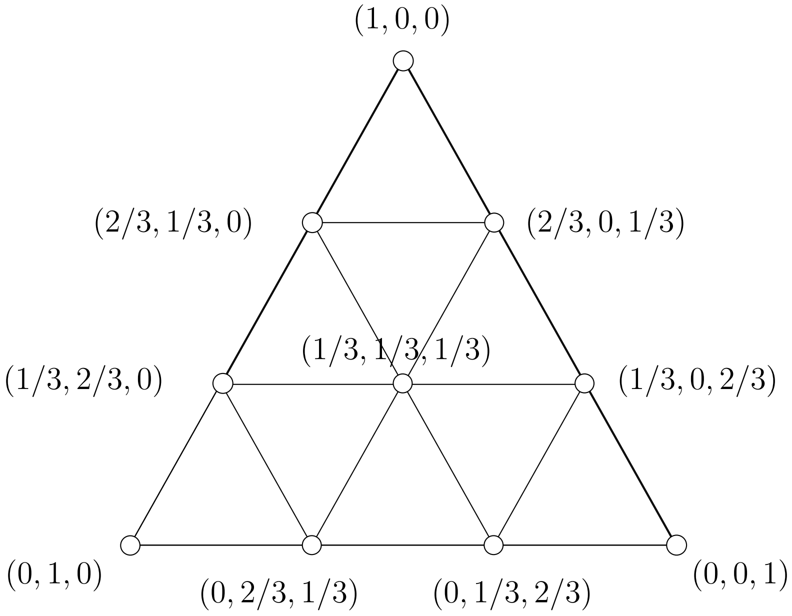


and for the case $p=3$ and $m=2$ (we see clearly the $N=6$ runs):



(1, 0, 0)
(0.5, 0.5, 0)
(0.5, 0, 0.5)
(0, 1, 0)
(0, 0.5, 0.5)
(0, 0, 1)

and finally for the case $p=3$ and $m=3$ (we see clearly the $N=10$ runs):



(1, 0, 0)
(2/3, 1/3, 0)
(2/3, 0, 1/3)
(1/3, 1/3, 1/3)
(1/3, 2/3, 0)
(1/3, 0, 2/3)
(0, 1, 0)
(0, 2/3, 1/3)
(0, 1/3, 2/3)
(0, 0, 1)

A very common mixture design is the $\{p,m\}=3,2$ with 6 experimental points as seen above but with an addition point. This is why in many textbooks we can find: $\{p,m\}=3,2=7$ as there is an addition center point!

In the general case of non-centered lattice mixture designs we find by a little bit trial and error that the cost (runs) of such a simplex is given by:

$$\boxed{N_{\text{SLD}}=C_{m}^{q+m-}=\frac{(q+m-1)!}{m!(q-1)!}} \tag{16.7.570}$$

and for a centered lattice design of q factors by:

$$\boxed{N_{\text{CLD}}=2^q-1} \tag{16.7.571}$$

Let us also indicate that logically nothing prevents the support (domain of definition) of the mixtures from being constrained, we then speak of "extreme vertices designs" that cover only a subportion or smaller space within the simplex. Thus, in the case of a ternary mixture design, nothing prevents us from having a case where each of the components has only upper limit values but the lower value can be zero! Here is for example a special case of constraint mixture design:

or that the ratio of two ingredients is constant, or that the sum of two ingredients gives a constant proportion. In short there may be many scenarios, but in the case of limited boundary, it is customary to write:

$$1 \geq U_i \geq x_i \geq L_i \geq 0$$
$$\sum_{i=1}^{k} x_i = 1 \tag{16.7.572}$$

and this is what we name "linear constraints" (as it is obvious if each ingredient is bounded that the sum is also bounded!).

Remark

It is quite possible to treat both the mixing variables (the proportions of the constituents) and the design factors of the experiments. To illustrate this situation, we can take the example of a chocolate manufacturer. The study of the composition of the chocolate gives rise to a mixtures design and the conditions of preparation give rise to a factorial design (or other ...). At each point of experiments of the factorial design, it is necessary to realize mixture design!!!! There is thus rapidly a large number of tests to be carried out since it is necessary to carry out np experiments if the mixture design has n runs and the factorial design has p runs.

We then consider the particular simple linear model (thus still an approximation ... and there are many other theoretical models that are not linear):

$$y = \beta_0 + \sum_i \beta_i x_i \tag{16.7.573}$$

or seen with the statistician point of view:

$$y = \mathrm{E}(\hat{y}) = \mathrm{E}\left(\hat{\beta}_0 + \sum_i \hat{\beta}_i x_i\right) \tag{16.7.574}$$

But since we have the constraint that $\sum_{i=1}^{k} x_i = 1$ the $\hat{\beta}_i$ can not be determined uniquely if we go through the usual linear system. One of the x_i must be used to determine the coefficients uniquely and must therefore be eliminated (concept of degree of freedom)! It is obviously very annoying in practice.

So mathematically, nothing prevents us from writing:

$$\hat{y} = \hat{\beta}_0 + \sum_i \hat{\beta}_i x_i = \hat{\beta}_0 \cdot 1 + \sum_i \hat{\beta}_i x_i = \hat{\beta}_0 \sum_{i=1}^{k} x_i + \sum_{i=1}^{k} \hat{\beta}_i x_i = \sum_{i=1}^{k} (\hat{\beta}_0 + \hat{\beta}_i) x_i \tag{16.7.575}$$

and if we change the notations:

$$(\hat{\beta}_0 + \hat{\beta}_i) = \hat{b}_i \tag{16.7.576}$$

the previous relation can then be written:

$$\hat{y} = \sum_{i=1}^{k} \hat{b}_i x_i \tag{16.7.577}$$

The mathematical model may of course also contain interactions. For example in the case of two factors, we could write with interactions and at the second degree:

$$\hat{y}=\hat{\beta}_0+\sum_i \hat{\beta}_i x_i+\sum_i \hat{\beta}_{ii}x_i^2+\sum_{i<j}\hat{\beta}_{ij}x_i x_j \tag{16.7.578}$$

and by applying the identity:

$$x_1+x_2+\ldots=\sum_i x_i=1 \tag{16.7.579}$$

then:

$$x_i^2=x_i\left(1-\sum_{j\neq i}x_j\right) \tag{16.7.580}$$

Therefore:

$$\begin{aligned}\hat{y}&=\hat{\beta}_0\left(\sum_i x_i\right)+\sum_i \hat{\beta}_i x_i+\sum_i\left[\hat{\beta}_{ii}x_i\left(1-\sum_{j\neq i}x_j\right)\right]+\sum_{i<j}\hat{\beta}_{ij}x_i x_j\\&=\sum_i\left(\hat{\beta}_0+\hat{\beta}_i+\hat{\beta}_{ii}\right)x_i-\sum_i\left[\hat{\beta}_{ii}x_i\sum_{j\neq i}x_j\right]+\sum_{i<j}\hat{\beta}_{ij}x_i x_j\\&=\sum_i\left(\hat{\beta}_0+\hat{\beta}_i+\hat{\beta}_{ii}\right)x_i+\sum_{i<j}\hat{\beta}_{ij}x_i x_j-\sum_i\left[\hat{\beta}_{ii}x_i\sum_{j\neq i}x_j\right]\\&=\sum_i\left(\hat{\beta}_0+\hat{\beta}_i+\hat{\beta}_{ii}\right)x_i+\sum_{i<j}\hat{\beta}_{ij}x_i x_j-\sum_{i<j}(\hat{\beta}_{ii}-\hat{\beta}_{jj})x_i x_j\\&=\sum_i \hat{b}x_i+\sum_{i<j}(\hat{\beta}_{ij}-\hat{\beta}_{ii}-\hat{\beta}_{jj})x_i x_j\\&=\sum_i \hat{b}_i x_i+\sum_{i<}\hat{b}_{ij}x_i x_j\end{aligned} \tag{16.7.581}$$

with:

$$\begin{aligned}\hat{b}_i&=\hat{\beta}_0+\hat{\beta}_i+\hat{\beta}_{ii}\\\hat{b}_{ij}&=\hat{\beta}_{ij}-\hat{\beta}_{ii}-\hat{\beta}_{jj}\end{aligned} \tag{16.7.582}$$

Either with three ingredients this gives for example:

$$\hat{y}=\sum_i \hat{b}_i x_i+\sum_{i<j}\hat{b}_{ij}x_i x_j=\hat{b}_1x_1+\hat{b}_2x_2+\hat{b}_3x_3+\hat{b}_{12}x_1x_2+\hat{b}_{13}x_1x_3+\hat{b}_{23}x_2x_3 \tag{16.7.583}$$

and so on for n components and the idea is the same for the third degree and beyond. It is Henry Scheffé that suggested to describe mixture properties by reduced polynomials subject to the normalization condition.

The number of terms will then obviously be for this model of the second degree:

$$n+\frac{n(n-1)}{2}=\frac{n(n+1)}{2} \tag{16.7.584}$$

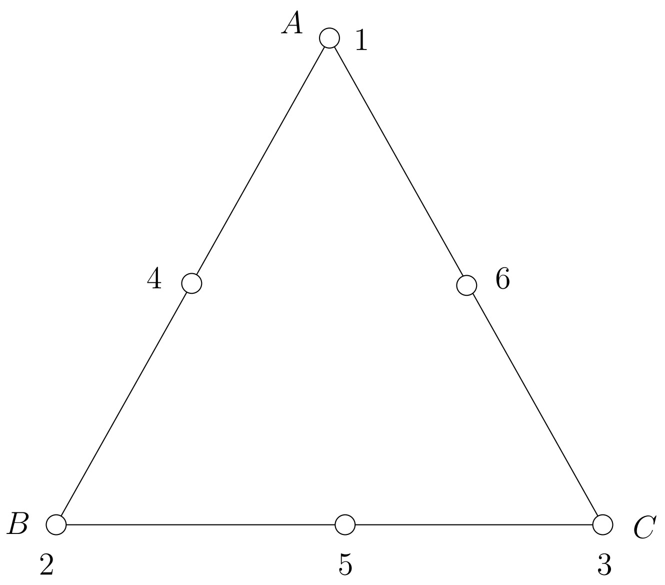
We can then use the following table of control (for those who like to do the calculations by hand) by stopping at the power of three (yes we have to stop one day or another...):

# of factors	**# terms with linear model**	**# terms with quadratic model**	**# terms with cubic model**
2	2	3	$-$
3	3	7	7
4	4	10	14
5	5	15	24
...	...	...	...
n	n	$\dfrac{n(n+1)}{2}$	$\dfrac{n(n^2+5)}{6}$

Table 16.57: **L-mixture designs terms for linear, quadratic and upper models**

Now let us come back to our initial example:

$$\hat{y}=\hat{b}_1x_1+\hat{b}_2x_2+\hat{b}_3x_3+\hat{b}_{12}x_1x_2+\hat{b}_{13}x_1x_3+\hat{b}_{23}x_2x_3 \tag{16.7.585}$$



for the following both reasons:

1. There are 6 measurement points and this is good because we have 6 coefficients to determine and we will need 6 equations at least.
2. The choice of the arrangement of the 6 points is quite intuitive. Indeed, if you imagine first taking 3 points, which ones are furthest from each other? They will be those of the summits of course! Once these three points are taken, what are the three other potential points that are the furthest away from it, but at the same time the furthest away from each other? They will be those in the middle of the edges!

We will then write algebraically the following that resume the above figure:

- For 3 of the 6 points on the vertices: y_i for $x_i = 1$, $x_j = 0$ with $i, j = 1, 2, 3$ under the constraint that $j \neq 1$
- For 3 of the 6 points on the middle of the edges: y_{ij} for $x_i = \dfrac{1}{2}$, $x_j = \dfrac{1}{2}$, $x_k = 0$ under the constraint that $i < j, k \neq i, j$

What injected into:

$$\hat{y} = \hat{b}_1 x_1 + \hat{b}_2 x_2 + \hat{b}_3 x_3 + \hat{b}_{12} x_1 x_2 + \hat{b}_{13} x_1 x_3 + \hat{b}_{23} x_2 x_3 \tag{16.7.586}$$

gives 6 equations with 6 unknowns:

$$\begin{aligned} \hat{y}_1 &= \hat{b}_1 \\ \hat{y}_2 &= \hat{b}_2 \\ \hat{y}_3 &= \hat{b}_3 \\ \hat{y}_{12} &= \hat{b}_1 \left(\frac{1}{2}\right) + \hat{b}_2 \left(\frac{1}{2}\right) + \hat{b}_{12} \left(\frac{1}{4}\right) \\ \hat{y}_{13} &= \hat{b}_1 \left(\frac{1}{2}\right) + \hat{b}_3 \left(\frac{1}{2}\right) + \hat{b}_{13} \left(\frac{1}{4}\right) \\ \hat{y}_{23} &= \hat{b}_2 \left(\frac{1}{2}\right) + \hat{b}_3 \left(\frac{1}{2}\right) + \hat{b}_{23} \left(\frac{1}{4}\right) \end{aligned} \tag{16.7.587}$$

The search for the coefficients for these 6 equations is immediate:

$$\begin{aligned} \hat{b}_1 &= \hat{y}_1 \\ \hat{b}_2 &= \hat{y}_2 \\ \hat{b}_3 &= \hat{y}_3 \\ \hat{b}_{12} &= 4\hat{y}_{12} - 2\hat{y}_1 - 2\hat{y}_2 = 4\hat{y}_{12} - 2(\hat{y}_1 + \hat{y}_2) \\ \hat{b}_{13} &= 4\hat{y}_{13} - 2\hat{y}_1 - 2\hat{y}_3 = 4\hat{y}_{13} - 2(\hat{y}_1 + \hat{y}_3) \\ \hat{b}_{23} &= 4\hat{y}_{13} - 2\hat{y}_2 - 2\hat{y}_3 = 4\hat{y}_{23} - 2(\hat{y}_2 + {}''\hat{y}_3) \end{aligned} \tag{16.7.588}$$

Either in a generic way:

$$\hat{b}_i = \hat{y}_i \qquad \hat{b}_{ij} = 4\hat{y}_{ij} - 2(\hat{y}_i + 2\hat{y}_j) \tag{16.7.589}$$

If we make repeated measurements in quantities r_{ij}, r_i, r_j, then we have:

$$\hat{b}_i = \bar{y}_i \qquad \hat{b}_{ij} = 4\bar{y}_{ij} - 2(\bar{y}_i + 2\bar{y}_j) \tag{16.7.590}$$

Either by extension:

$$\begin{aligned} b_i &= \mathrm{E}(\hat{b}_i) = \mathrm{E}(\bar{y}_i) \\ b_j &= \mathrm{E}(\hat{b}_j) = \mathrm{E}(\bar{y}_j) \\ b_{ij} &= \mathrm{E}(\hat{b}_{ij}) = \mathrm{E}(4\bar{y}_{ij} - 2(\bar{y}_i + \bar{y}_j)) = 4\mathrm{E}(\bar{y}_{ij}) - 2\mathrm{E}(\bar{y}_i) - 2\mathrm{E}(\bar{y}_j) \end{aligned} \tag{16.7.591}$$

and for the variance (which will be useful for making inference on the values of the coefficients):

$$\begin{aligned}\mathrm{V}(b_i)&=\mathrm{V}(\bar{y}_i)=\frac{\hat{\sigma}_{y_i}^2}{r}\\ \mathrm{V}(b_j)&=\mathrm{V}(\bar{y}_j)=\frac{\hat{\sigma}_{y_j}^2}{r}\\ \mathrm{V}(b_{ij})&=\mathrm{V}(\hat{b}_{ij})=16\frac{\hat{\sigma}_{y_{ij}}^2}{r}+4\frac{\hat{\sigma}_{y_i}^2}{r}+4\frac{\hat{\sigma}_{y_j}^2}{r}\end{aligned}\tag{16.7.592}$$

Some statistical software and authors even consider that (we must then verify that this hypothesis is well satisfied with typically a Fisher test):

$$\hat{\sigma}_{y_i}^2=\hat{\sigma}_{y_j}^2=\hat{\sigma}_{y_{ij}}^2=\hat{\sigma}^2\tag{16.7.593}$$

Then it remains:

$$\begin{aligned}\mathrm{V}(b_i)&=\mathrm{V}(\bar{y}_i)=\frac{\hat{\sigma}^2}{r}\\ \mathrm{V}(b_j)&=\mathrm{V}(\bar{y}_j)=\frac{\hat{\sigma}^2}{r}\\ \mathrm{V}(b_{ij})&=\mathrm{V}(\hat{b}_{ij})=16\frac{\hat{\sigma}^2}{r}+4\frac{\hat{\sigma}^2}{r}+4\frac{\hat{\sigma}^2}{r}=24\frac{\hat{\sigma}^2}{r}\end{aligned}\tag{16.7.594}$$

Some statistical softwares assume that (so take care that this assumption is not rejected in the practice!):

$$\hat{b}_i=\mathcal{N}\left(b_i,\frac{\hat{\sigma}^2}{r}\right)\qquad\hat{b}_{ij}=\mathcal{N}\left(b_{ij},\frac{24\hat{\sigma}^2}{r}\right)\tag{16.7.595}$$

It is also interesting to measure the experimental variance of the model. Therefore in the general second degree case that is for recall written:

$$\hat{y}=\sum_i\hat{b}_ix_i+\sum_{i<j}\hat{b}_{ij}x_ix_j\tag{16.7.596}$$

Then we have:

$$\begin{aligned}\mathrm{V}(\bar{y})&=\mathrm{V}\left(\sum_i\hat{b}_ix_i+\sum_{i<j}\hat{b}_{ij}x_ix_j\right)=\mathrm{V}\left(\sum_i\bar{y}_ix_i+\sum_{i<j}(4\bar{y}_{ij}-2(\bar{y}+\bar{y}_j))x_ix_j\right)\\ &=\mathrm{V}\left(\sum_i\bar{y}_ix_i\right)+\mathrm{V}\left(\sum_{i<j}(4\bar{y}_{ij}-2(\bar{y}+\bar{y}_j))x_ix_j\right)\\ &=\sum_i\frac{\hat{\sigma}}{r}x_i^2+\sum_{i<j}24\frac{\hat{\sigma}}{r}(x_ix_j)^2=\frac{\hat{\sigma}}{r}\left(\sum_i x_i^2+24\sum_{i<j}(x_ix_j)^2\right)\end{aligned}\tag{16.7.597}$$

or if the measurement are not in equal quantities:

$$\mathrm{V}(\bar{y})=\bar{\sigma}^2\left(\sum_i\frac{x_i^2}{r_i}+24\sum_{i<j}\frac{(x_ix_j)^2}{r_{ij}}\right)\tag{16.7.598}$$

which can sometimes be found in the following way in the literature:

$$\begin{aligned}
\mathrm{V}(\bar{y}) &= \mathrm{V}\left(\sum_i \hat{b}_i x_i + \sum_{i<j} \hat{b}_{ij} x_i x_j\right) = \mathrm{V}\left(\sum_i \bar{y}_i x_i + \sum_{i<j} \left(4\bar{y}_{ij} - 2(\bar{y}_i + \bar{y}_j)\right) x_i x_j\right) \\
&= \left(\sum_i \bar{y}_i x_i - 2\sum_{i<j} (\bar{y}_i + \bar{y}_j) x_i x_j + \sum_{i<j} 4\bar{y}_{ij} x_i x_j\right) \\
&= \mathrm{V}\left(\sum_i \bar{y}_i \left[x_i - 2x_i \left(\sum_{j\neq i} x_j\right)\right] + \sum_{i<j} 4\bar{y}_{ij} x_i x_j\right)
\end{aligned} \tag{16.7.599}$$

and as:

$$\sum_j x_j = 1 \Leftrightarrow 1 - x_i = \sum_{j \neq i} x_j \tag{16.7.600}$$

Therefore it comes:

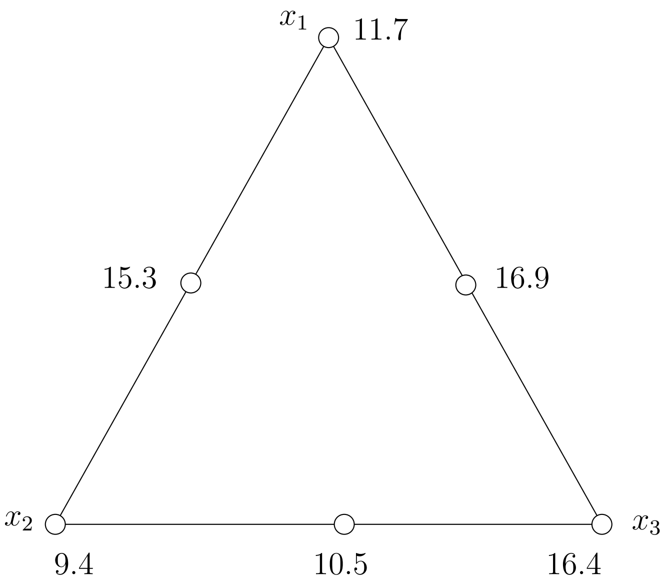
$$\begin{aligned}
\mathrm{V}(\bar{y}) &= \mathrm{V}\left(\sum_i \bar{y}_i \left[x_i - 2x_i \left(\sum_{j\neq i} x_j\right)\right] + \sum_{i<j} 4\bar{y}_{ij} x_i x_j\right) \\
&= \mathrm{V}\left(\sum_i \bar{y}_i \left[x_i - 2x_i(1 - x_i)\right] + \sum_{i<j} 4\bar{y}_{ij} x_i x_j\right) \\
&= \mathrm{V}\left(\sum_i \bar{y}_i \left[x_i(2x_i - 1)\right] + \sum_{i<j} 4\bar{y}_{ij} x_i x_j\right) = \mathrm{V}\left(a_i \bar{y}_i + \sum_{i<j} a_{ij} \bar{y}_{ij}\right) \\
&= \hat{\sigma}^2 \left(\sum_i \frac{a_i^2}{r_i} + \sum_{i<j} \frac{a_{ij}^2}{r_{ij}}\right)
\end{aligned} \tag{16.7.601}$$

with:

$$\begin{aligned}
a_i &= x_i(2x_i - 1) \\
a_{ij} &= 4x_i x_j
\end{aligned} \tag{16.7.602}$$

✍**Example:**

Let us consider that three constituents that are polyethylene x_1, polystyrene x_2 and polypropylene x_3, are mixed in order to obtain a fiber whose measure of interest is the elongation at a constant force with the following values of the mean elongations obtained for each of the points of the mixture design network:



with the measurements detailed in the corresponding table below:

Experiment point	**Polyethylene x_1**	**Polystyrene x_2**	**Polypropylene x_3**	**Observed elongation y_i**	**Average elongation $\bar{y}_i$**
1	1	0	0	11.0, 12.4	11.7
2	0.5	0.5	0	15.0,14.8,16.1	15.3
3	0	1	0	8.8,10.00	9.4
4	0	0.5	0.5	10.0,9.7,11.8	10.5
5	0	0	1	16.8,16.0	16.4
6	0.5	0	0.5	17.7,16.4,16.6	16.9
			Number of measurements:	15	
			Average:	13.54	

and we will use the model:

$$\hat{y} = \hat{b}_1 x_1 + \hat{b}_2 x_2 + \hat{b}_3 x_3 + \hat{b}_{12} x_1 x_2 + \hat{b}_{13} x_1 x_3 + \hat{b}_{23} x_2 x_3 \qquad (16.7.603)$$

with:

$$\hat{b}_i = \bar{y}_i \qquad \hat{b}_{ij} = 4\bar{y}_{ij} - 2(\bar{y}_i + \bar{y}_j) \qquad (16.7.604)$$

Which gives us:

$$\begin{aligned}
\hat{b}_1&=\bar{y}_1=\frac{(11.0+12.4)}{2}=11.7\\
\hat{b}_2&=\bar{y}_2=\frac{(8.8+10.0)}{2}=9.2\\
\hat{b}_3&=\bar{y}_3=\frac{(16.8+16.0)}{2}=16.4\\
\hat{b}_{12}&=4\bar{y}_{12}-2(\bar{y}_1+\bar{y}_2)=4\frac{(15.0+14.8+16.1)}{3}-2(11.7+9.4)=19.0\\
\hat{b}_{13}&=4\bar{y}_{13}-2(\bar{y}_1+\bar{y}_3)=4\frac{(17.7+16.4+16.6)}{3}-2(11.7+16.4)=11.4\\
\hat{b}_{23}&=4\bar{y}_{23}-2(\bar{y}_2+\bar{y}_3)=4\frac{(10.0+9.7+11.8)}{3}-2(9.4+16.4)=-9.6
\end{aligned}\tag{16.7.605}$$

So at the level of the influences, we already see that (without even needing to make a statistical test of significant difference):

$$\hat{b}_3>\hat{b}_1>\hat{b}_2\tag{16.7.606}$$

with the obvious that follows. We also observe already that:

$$\hat{b}_{12}>0\qquad\hat{b}_{13}>0\qquad\hat{b}_{23}<0\tag{16.7.607}$$

which means that the components 1 and 2, 1 and 3 contributes positively to the effect were are looking for when the interaction 2 and 3 decrease that later.

Now, let us calculate and check if we have well:

$$\hat{\sigma}_{y_i}^2=\hat{\sigma}_{y_j}^2=\hat{\sigma}_{ij}^2=\hat{\sigma}\tag{16.7.608}$$

Therefore:

$$\begin{aligned}
\hat{\sigma}_{y_1}^2&=0.98 &\quad \hat{\sigma}_{y_{12}}^2&=0.49\\
\hat{\sigma}_{y_2}^2&=0.72 &\quad \hat{\sigma}_{y_{13}}^2&=0.49\\
\hat{\sigma}_{y_3}^2&=0.32 &\quad \hat{\sigma}_{y_{23}}^2&=1.29\\
\hat{\sigma}^2&=9.6326
\end{aligned}\tag{16.7.609}$$

With for recall (requested by reader) for example:

$$\bar{y}_{12}=\frac{15.0+14.8+16.1}{3}=15.3\tag{16.7.610}$$

and then:

$$\hat{\sigma}_{y_{12}}^2=\frac{1}{3-1}\left((15.0-\bar{y}_{12})^2+(14.8-\bar{y}_{12})^2+(\bar{y}_{12}-16.1)^2\right)=0.49\tag{16.7.611}$$

and also:

$$\begin{aligned}\hat{\sigma} &= \frac{1}{15-1}\left[\begin{array}{c}(11-13.54)^2+(12.4-13.54)^2+(15-13.54)^2+(14.8-13.54)^2\\+(16.1-13.54)^2+(8.8-13.54)^2+(10-13.54)^2+(10-13.54)^2\\+(9.7-13.54)^2+(11.8-13.54)^2+(16.8-13.54)^2+(16-13.54)^2\\+(17.7-13.54)^2+(16.4-13.54)^2+(16.6-13.54)^2\end{array}\right]\\&=\frac{1}{14}134.856\cong 9.6326\end{aligned} \tag{16.7.612}$$

We see then obviously that we quite far from the assumption of equality of variance...

Therefore what can we do???

In fact apart to do the calculations of $\hat{\sigma}$ using the global average $\bar{y}$ as detailed just above, we notice that was is not realistic in the choice of the calculation of $\hat{\sigma}$ as done is that we consider that the average $\bar{y}$ should be the same for all the levels of the components which is obviously not true! Therefore as during our study of the ANOVA, we will use the residual variance V_R (that is we know is also named "grouped variance" or "pooled variance") and that is given therefore by:

$$\begin{aligned}\hat{\sigma}^2=\hat{\sigma}_R^2 &= \frac{1}{\sum_i r_i-1}\left[\begin{array}{c}(11-\bar{y}_1)^2+(12.4-\bar{y}_1)^2+(15-\bar{y}_{12})^2+(14.8-\bar{y}_{12})^2\\(16.1-\bar{y}_{12})^2+(8.8-\bar{y}_2)^2+(10-\bar{y}_2)^2+(10-\bar{y}_{23})^2\\(9.7-\bar{y}_{23})^2+(11.8-\bar{y}_{23})^2+(16.8-\bar{y}_3)^2+(16-\bar{y}_3)^2\\(17.7-\bar{y}_{13})^2+(16.4-\bar{y}_{13})^2+(16.6-\bar{y}_{13})^2\end{array}\right]\\&=\frac{6.56}{(2-1)+(3-1)+(2-1)+(3-1)+(2-1)+(3-1)}=\frac{6.56}{15-6}=\frac{6.56}{9}\\&\cong 0.73\end{aligned} \tag{16.7.613}$$

We see then that the compromise is much better ... (without however of course to be exact!). We then have using the results prove earlier above:

$$\begin{aligned}\hat{\sigma}_{b_i}&=\sqrt{\text{V}(b_i)}=\sqrt{\frac{\hat{\sigma}_R^2}{r}}=\sqrt{\frac{0.73}{2}}\cong 0.60\\\hat{\sigma}_{b_{ij}}&=\sqrt{\text{V}(b_{ij})}=\sqrt{\hat{\sigma}^2\left(\frac{16}{r_{ij}}+\frac{4}{r_i}+\frac{4}{r_j}\right)}=\hat{\sigma}\sqrt{\frac{16}{r_{ij}}+\frac{8}{r_i}}=\sqrt{0.73}\sqrt{\frac{16}{3}+\frac{8}{2}}\cong 2.61\end{aligned} \tag{16.7.614}$$

Our model is then traditionally written:

$$\hat{y}=\underbrace{11.7x_1}_{(0.60)}+\underbrace{9.4x_2}_{(0.60)}+\underbrace{16.4x_3}_{(0.60)}+\underbrace{19.0x_1x_2}_{(2.61)}+\underbrace{11.4x_1x_3}_{(2.61)}-\underbrace{9.6x_2x_3}_{(2.61)} \tag{16.7.615}$$

which corresponds exactly to the second decimal point to what a software like Minitab gives us. Then, to find the triplet that maximizes the function it is enough to use a solver like the one integrated into Microsoft® Excel®.

Let us now recall that:

$$\begin{aligned}\hat{b}_i&=\hat{\beta}_0+\hat{\beta}_i+\hat{\beta}_{ii}\\ \hat{b}_{ij}&=\hat{\beta}_{ij}-\hat{\beta}_{ii}-\hat{\beta}_{jj}\end{aligned}\tag{16.7.616}$$

And as in our example the model has no pure quadratic term, it reduces to:

$$\begin{aligned}\hat{b}_i&=\hat{\beta}_0+\hat{\beta}_i\\ \hat{b}_{ij}&=\hat{\beta}_{ij}\end{aligned}\tag{16.7.617}$$

We have then:

$$\begin{aligned}\hat{b}_1&=\hat{\beta}_0+\hat{\beta}_1=11.7\\ \hat{b}_2&=\hat{\beta}_0+\hat{\beta}_2=9.4\\ \hat{b}_3&=\hat{\beta}_0+\hat{\beta}_3=16.4\end{aligned}\tag{16.7.618}$$

We see then that to determine $\hat{\beta}_0$ we have to make a choice on one of the $\hat{\beta}_i$ (as we are not able to refer to the experimental value in the present case since the absence of any ingredient in the mixture will only give a empty entity and then it is quite difficult to test an elongation on nothing... but this, however, raises the principle of the approach). We will choose empirically $\hat{\beta}=0$, then it comes:

$$\begin{aligned}\hat{\beta}_3&=0\\ \hat{\beta}_0&=16.4\\ \hat{\beta}_1&=11.7-16.4=-47\\ \hat{\beta}_2&=9.4-16.4=-7.0\\ \hat{\beta}_{12}&=19.0\\ \hat{\beta}_{13}&=11.4\\ \hat{\beta}_{23}&=-9.6\end{aligned}\tag{16.7.619}$$

The model with the ordinate at the origin (at least if it had a physical sense) would then be written:

$$\hat{y}=\underbrace{16.4}_{0.60}-\underbrace{4.7x_1}_{(?)}-\underbrace{7.0x_2}_{(?)}+\underbrace{19.0x_1x_2}_{(2.61)}+\underbrace{11.4x_1x_3}_{(2.61)}-\underbrace{9.6x_2x_3}_{(2.61)}\tag{16.7.620}$$

with in brackets the variances that do not change for the relative coefficients. There are two coefficients whose variances will change!

We have indeed:

$$\text{V}(\hat{\beta}_i)=\text{V}(b_i-\hat{\beta}_0)=\text{V}(b_i)+\text{V}(\hat{b}_3)=1.2\tag{16.7.621}$$

Therefore:

$$\hat{\sigma}_{\beta_i}=\sqrt{\text{V}(\beta_i)}\cong 1.09\tag{16.7.622}$$

Hence:

$$\hat{y}=\underbrace{16.4}_{0.60}-\underbrace{4.7x_1}_{(1.09)}-\underbrace{7.0x_2}_{(1.09)}+\underbrace{19.0x_1x_2}_{(2.61)}+\underbrace{11.4x_1x_3}_{(2.61)}-\underbrace{9.6x_2x_3}_{(2.61)} \tag{16.7.623}$$

We can even make an ANOVA of the regression (see section Numerical Methods page 6335) as for the more" traditional" experimental design and as we have studied (proved!) in the section of Theoretical Computing, we will need the following values:

$$\begin{array}{ccccc} Q_T & = & Q_A & + & Q_R \\ \sum_i (y_i-\bar{y})^2 & = & \sum_i (\hat{y}_i-\bar{y})^2 & + & \sum_i (y_i-\hat{y}_i)^2 \\ N-1 & = & k-1 & + & N-k \end{array}$$

Then let us use the following table:

Observed value y_i	Predicted value $\hat{y}_i$	Residuals $(y_i-\hat{y}_i)$	Deviation $(y_i-\bar{y}_i)$	Deviation of regression $(\hat{y}_i-\bar{y})$
11	11.7	-0.7	-2.5	-1.8
12.4	11.7	0.7	-1.1	-1.8
15.0	15.3	-0.3	1.5	1.8
14.8	15.3	-0.5	1.3	1.8
16.1	15.3	0.8	2.6	1.8
10.0	9.4	0.6	-3.5	-4.1
8.8	9.4	-0.6	-4.7	-4.1
10.0	10.5	-0.5	-3.5	-3.0
9.7	10.5	-0.8	-3.8	-3.0
11.8	10.5	1.3	-1.7	-3.0
16.8	16.4	0.4	3.3	2.9
16.0	16.4	-0.4	2.5	2.9
17.7	16.9	0.8	4.2	3.4
16.4	16.9	-0.5	2.9	3.4
16.6	16.9	-0.3	3.1	3.4

Then we have:

$$\begin{array}{ccccc} Q_T & = & Q_A & + & Q_R \\ \sum_i (y_i-\bar{y})^2 & = & \sum_i (\hat{y}_i-\bar{y})^2 & + & \sum_i (y_i-\hat{y}_i)^2 \\ 138.88 & = & 128.32 & + & 6.56 \\ N-1 & = & k-1 & + & N-k \\ 14 & = & 5 & + & 9 \end{array}$$

We then have the following one-way fixed factor ANOVA table (see section Statistics page 1004):

Source	Sum of squares	χ^2 df	Average of squares	F	Critical F
Inter-Class	$Q_A = 128.32$	5	$\text{MSk} = \dfrac{128.32}{5}$	$\dfrac{\text{MSk}}{\text{MSE}} = 31.5$	$F_{5,9}^{\text{crit.}} = 3.481$
Intra-Class	$Q_R = 6.56$	9	$\text{MSE} = \dfrac{6.56}{5}$		
Total	$Q_T = 134.88$	14			

Table 16.58: **One way fixed factor ANOVA table for mixture design**

where the limit has been calculated with the following function of the spreadsheet software Microsoft® Excel® 14.0.7106:

`=F.INV(95%,5,9)=3.481`

Hence as 31.5 (corresponding p-value of 0.002%) is far above 3.481 we reject the null hypothesis H_0 that the model coefficients are non-significant (i.e. they are therefore significantly different from zero). In extenso this also leads us to reject the fact that the response surface is plane (since the coefficients of the interactions are also significant).

The reader interested can see the study of this mixture in the `R` or Minitab companion books.

16.7.4.6.2 Full Factorial Combined with Mixture Design-Crossed Design

In 11981 (holocene calendar), Cornell [113] published in its book the results of experimental studies where the quality of a fish patty was defined by both its composition and production process. The experiment included seven different mixtures prepared by mixing different species of fish and then subjecting the resulting patty to various cooking conditions and defined in accord with simplex centroid design (see figure below).

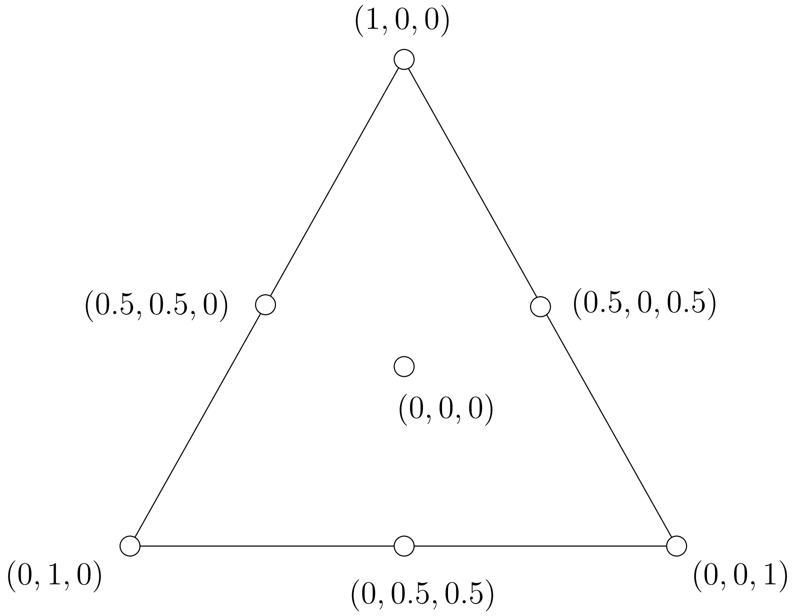


Figure 16.267: **Simplex Centroid Design**

The preparation procedure of the defined mixtures or a formulation included three control process factors with associated variation levels: baking temperature from 190 $[°\text{C}]$ to 218 $[°\text{C}]$; time in the oven from 25 [min] to 40 [min]; deep fat frying time from 25 [s] to 40 [s]. Process factor levels have been varied in accordance with the 2^3 full factorial experiment. Design of experiment 7×2^3 with 56 trials of a simplex centroid design $\times 2^3$ full factorial design has been sufficient for mathematical modelling of the observed phenomenon (see figure below):

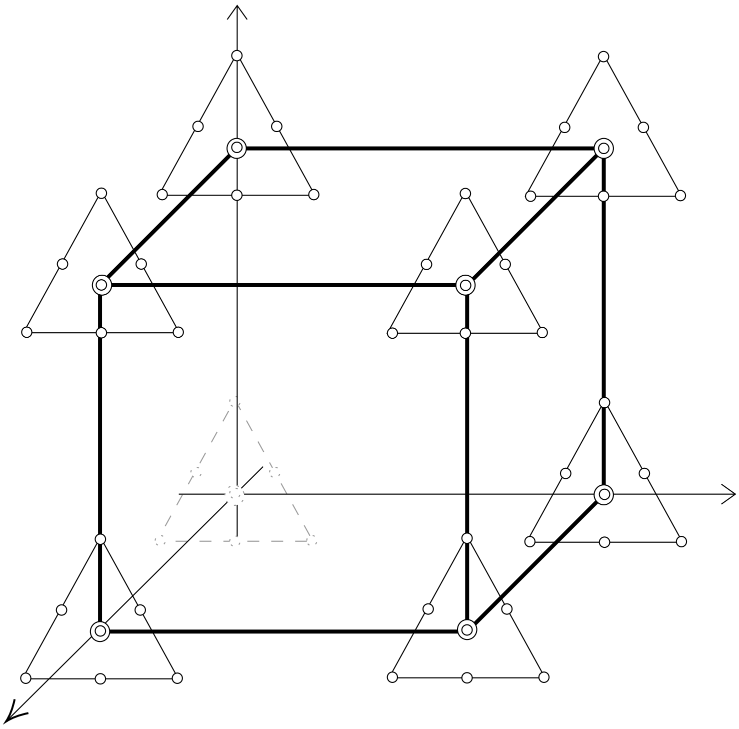

Figure 16.268: **Simplex centroid design in each point of a 2^3 full factorial experiment**

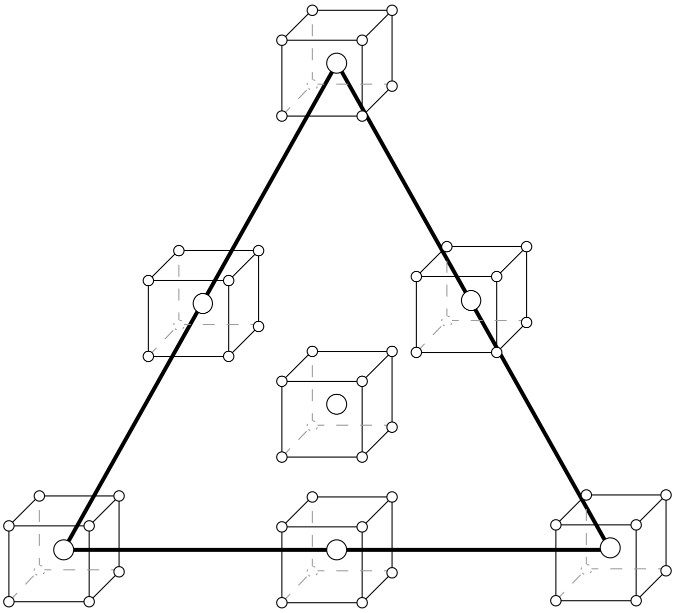

Figure 16.269: **2^3 factorial design in each point of a simplex centroid design**

A regression model with 56 regression coefficients or reduced regression model with 18 coefficients has been sufficient for an adequate description of the problem.

This was the first example of application of a mixture design × process factor design in experimental studies. Since such designs contain a relatively large number of factors, it is of interest to replace full factorial designs of process factors with fractional factor designs. Today all modern statistical softwares include the analysis of "design-crossed design".

✍**Example:**

Assume a design has 3 mixture components and 2 process variables, as illustrated in the above figure.

For the 3 mixture components, the following special cubic Scheffé model is used:

$$y=\beta_1x_1+\beta_2x_2+\beta_3x_3+\beta_{12}x_1x_2+\beta_{13}x_1x_3+\beta_{32}x_2x_3+\beta_{123}x_1x_2x_3 \tag{16.7.624}$$

For the 2 process variables the following model is used:

$$y=\alpha_0+\alpha_1z_1+\alpha_2z_2+\alpha_{12}z_1z_2 \tag{16.7.625}$$

The combined model with both mixture components and process variables is assumed, for being able to make an ANOVA, as following (quite strong assumption in the point of view of the physicist...):

$$\begin{aligned}y=&\sum_{i=1}^{3}\gamma_i^0x_i+\sum\sum_{i<j}^{3}\gamma_{ij}^0x_ix_j+\gamma_{123}^0x_1x_2x_3\\&+\left(\sum_{i=1}^{3}\gamma_i^1x_i+\sum\sum_{i<j}^{3}\gamma_{ij}^1x_ix_j+\gamma_{123}^1x_1x_2x_3\right)z_1\\&+\left(\sum_{i=1}^{3}\gamma_i^2x_i+\sum\sum_{i<j}^{3}\gamma_{ij}^2x_ix_j+\gamma_{123}^2x_1x_2x_3\right)z_2\\&+\left(\sum_{i=1}^{3}\gamma_i^{12}x_i+\sum\sum_{i<j}^{3}\gamma_{ij}^{12}x_ix_j+\gamma_{123}^{12}x_1x_2x_3\right)z_2\end{aligned} \tag{16.7.626}$$

The above combined model has total of $7\times4=28$ terms. By expanding it, we get the following model:

$$\begin{aligned}y=&\gamma_1^0x_1+\gamma_2^0x_2+\gamma_3^0x_3+\gamma_{12}^0x_1x_2+\gamma_{13}^0x_1x_3+\gamma_{23}^0x_2x_3+\gamma_{123}^0x_1x_2x_3\\&+\gamma_1^1x_1z_1+\gamma_2^1x_2z_1+\gamma_3^1x_3z_1+\gamma_{12}^1x_1x_2z_1+\gamma_{13}^1x_1x_3z_1+\gamma_{23}^1x_2x_3z_1+\gamma_{123}^1x_1x_2x_3z_1\\&+\gamma_1^2x_1z_2+\gamma_2^2x_2z_2+\gamma_3^2x_3z_2+\gamma_{12}^2x_1x_2z_2+\gamma_{13}^2x_1x_3z_2+\gamma_{23}^2x_2x_3z_2+\gamma_{123}^2x_1x_2x_3z_2\\&+\gamma_1^{12}x_1z_1z_2+\gamma_2^{12}x_2z_1z_2+\gamma_3^{12}x_3z_1z_2+\gamma_{12}^{12}x_1x_2z_1z_2+\gamma_{13}^{12}x_1x_3z_1z_2+\gamma_{23}^{12}x_2x_3z_1z_2\\&+\gamma_{123}^{12}x_1x_2x_3z_1z_2\end{aligned} \tag{16.7.627}$$

The combined model basically crosses every term in the mixture components model with every term in the process variables model. From a mathematical point of view, this model is just a regular regression model. Therefore, the traditional regression analysis method can still be used for obtaining the model coefficients and calculating the ANOVA table.

The reader can see a real application example of crossed designs in the Minitab companion book if necessary.

16.7.4.7 General DoE diagnostic tools

We have seen so far the almost all DOE use statistical analysis based on ANOVA, ANCOVA and obviously linear regression null hypothesis tests. But most DoE softwares propose a bunch of other more or less empirical diagnostics for the analysis of the designs and this is what we will focus below in details.

16.7.4.7.1 Lenth's PSE Pareto Margin Error for unreplicated factorial designs

G.E.P. Box and R.D. Meyer introduced in 11986 (holocene calendar) a method for assessing the sizes of contrasts in unreplicated factorial and fractional factorial designs. This was useful a technique and an associated graphical display popularly known as a "Bayes plot" made it even more effective but very hard to interpret. Therefore Russell V. Lenth proposed a new method 11989 (holocene calendar) that is still currently used in many statistical softwares.

The "Lenth's Pseudo Standard Error" (abbreviated "Lenth's PSE") is a common indicator in DoE softwares Pareto outputs (even if it is not real Pareto charts...) that provides an analytical basis for testing the effects in an unreplicated (single replicate) two-level factorial design[29]. Lenth's method estimates the variance of an effect from the smallest (presumably insignificant) effect estimates.

So... Lenth proposed a method for estimating the standard deviation of the effects on the basis that if the coded factors x_i (for simplification reasons but it also applies to non-coded and non-normalized effects) have their effects that follow a Normal distribution $E_i = \mathcal{N}(0,\sigma)$ then the median of the absolute value of the coded effects $|E_i|$ is in theory equal to the half-Normal distribution (see section Statistics page 796):

$$1.5M_e \cong \sigma \qquad (16.7.628)$$

and again (!) this last relation can be easily generalized to non-coded effects (just return back to that proof and add a non-zero mean in the development of the proof)!

What Lenth has proposed is first to eliminate all effects that satisfies:

$$|E_i| > 2.5 \cdot (1.5M_e) \qquad (16.7.629)$$

that is to say:

$$|E_i| > 2.5\sigma \qquad (16.7.630)$$

denoted s_0.

The `R` software gives with the **fdrtool** package:

```
>1-phalfnorm(2.5,theta=sqrt(pi/2),lower.tail=T,log.p=F)=0.012
```

---

[29] It should not then be necessary to precise that it therefore not applies to General factorial Designs

The reason why Lenth's made this choice are explained in a quite obscure way in its original article... in our point of view. His argument is that simulations shows that the $1.5M_e$ is overestimate in practice therefore eliminate factors with high amplitude effect seems to give a more accurate result.

After the elimination the proposition is to calculate a pseudo standard error with the remaining effects (that therefore should converge to the σ of all effects):

$$\boxed{\text{PSE} = \underset{|E_i|<2.5s_0}{1.5M_e(|E_i|)} \cong \sigma_{\text{effect}}} \tag{16.7.631}$$

where Lenth's assume that σ_{effect} is the standard error of the mean and that therefore we can do inference using the Student T distribution such at an α bilateral threshold we have the following margin error:

$$\text{ME} = T_{\alpha/2,m/3}\text{PSE} \tag{16.7.632}$$

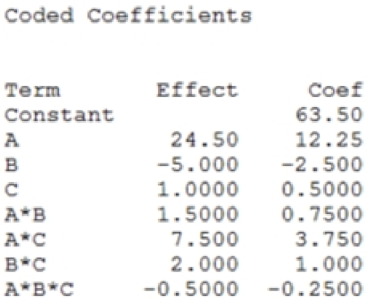
where m is the total number of effects and the division by 3 comes from a Monte Carlo study that was conducted by Lenth.

✍**Example:**

To make an example let us consider the following experiment that we already know (but we have removed the replication):

Trial N°	x_1	x_2	x_3	y_i
1	-1	-1	-1	59
2	$+1$	-1	-1	74
3	-1	$+1$	-1	50
4	$+1$	$+1$	-1	69
5	-1	-1	$+1$	50
6	$+1$	-1	$+1$	81
7	-1	$+1$	$+1$	46
8	$+1$	$+1$	$+1$	79

We now already how to perform the calculations manually of the effect so we will not come back on this topic. We will just communicate the output given by Minitab 17.1.3:



```
Coded Coefficients

Term        Effect      Coef
Constant               63.50
A            24.50     12.25
B           -5.000    -2.500
C           1.0000    0.5000
A*B         1.5000    0.7500
A*C          7.500     3.750
B*C          2.000     1.000
A*B*C      -0.5000   -0.2500
```

Therefore in absolute value, we have:

$$24.5, 5, 1, 1.5, 7.5, 2, 0.5$$

Ordered:

$$0.5, 1, 1.5, 2, 5, 7.5, 24.5$$

So it is immediate that the median is equal to:

$$M_e = 2 \tag{16.7.633}$$

So all the effects that are smaller or equal to $2.5(1.5M_e) = 7.5$ are (Lenth takes strictly smaller but Minitab doesn't follow this rule):

$$0.5, 1, 1.5, 2, 5, 7.5$$

Therefore:

$$\text{PSE} = 1.5\underset{|E_i|<2.5s_0}{M_e(|E_i|)} \cong \sigma_{\text{effect}} = 1.5 \cdot 1.75 = 2.625 \tag{16.7.634}$$

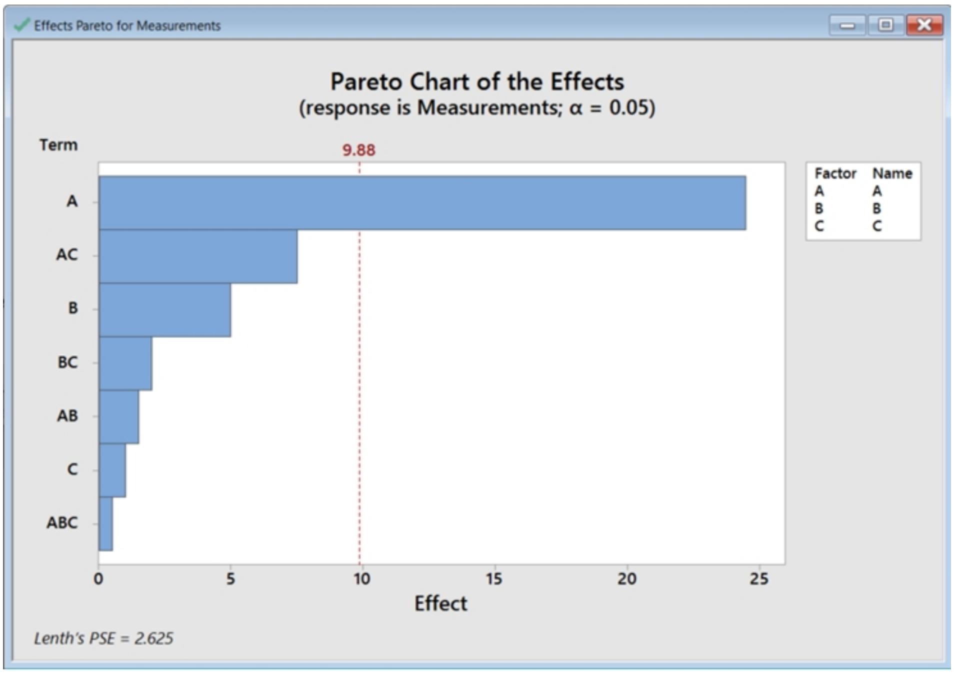
So finally:

$$\text{ME} = T_{\alpha/2,m/3} \cdot 2.625 = T_{5\%/2,7/3} 3.76 \cdot 2.625 \cong 9.8808 \tag{16.7.635}$$

Where the T value was obtained with `R` since Microsoft® Excel® doesn't accept fractional degrees of freedom:

```
>qt(.975,df=7/3)=3.764123
```

Minitab 17.1.3 makes a summary of all calculations done above as following:



Effects Pareto for Measurements
Pareto Chart of the Effects
(response is Measurements; α = 0.05)
Term

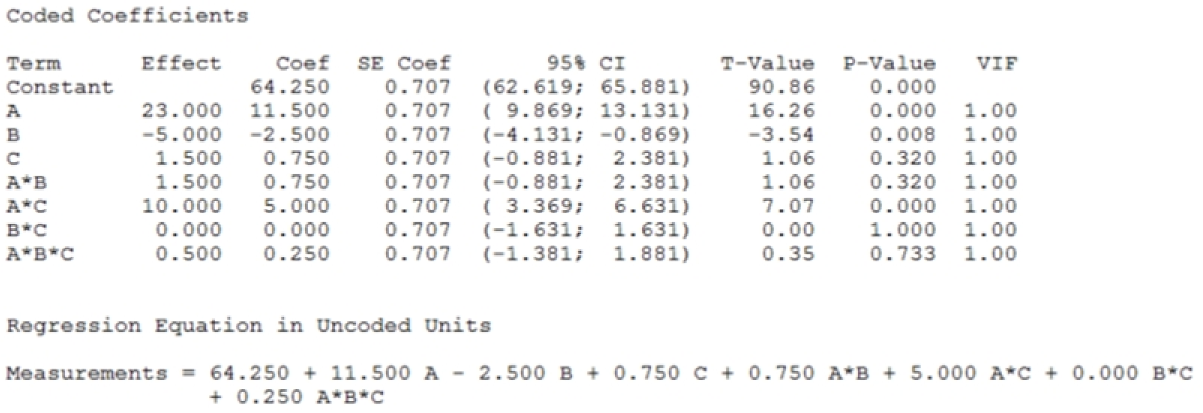
Factor Name
A A
B B
C C
Lenth's PSE = 2.625

16.7.4.7.2 Pareto Margin Error for replicated factorial designs

Let us recall that we have studied the following replicated experiment earlier above:

Trial N°	x_1	x_2	x_3	y_{i1}	y_{i2}	$\bar{y}_i$
1	-1	-1	-1	59	61	60
2	$+1$	-1	-1	74	70	72
3	-1	$+1$	-1	50	58	54
4	$+1$	$+1$	-1	69	67	68
5	-1	-1	$+1$	50	54	52
6	$+1$	-1	$+1$	81	85	83
7	-1	$+1$	$+1$	46	44	45
8	$+1$	$+1$	$+1$	79	81	80

and that we get by hand exactly the same results as given by Minitab 17.1.3:



```
Coded Coefficients

Term       Effect     Coef  SE Coef         95% CI         T-Value  P-Value   VIF
Constant            64.250    0.707  (62.619; 65.881)       90.86    0.000
A          23.000   11.500    0.707  ( 9.869; 13.131)       16.26    0.000   1.00
B          -5.000   -2.500    0.707  (-4.131; -0.869)       -3.54    0.008   1.00
C           1.500    0.750    0.707  (-0.881;  2.381)        1.06    0.320   1.00
A*B         1.500    0.750    0.707  (-0.881;  2.381)        1.06    0.320   1.00
A*C        10.000    5.000    0.707  ( 3.369;  6.631)        7.07    0.000   1.00
B*C         0.000    0.000    0.707  (-1.631;  1.631)        0.00    1.000   1.00
A*B*C       0.500    0.250    0.707  (-1.381;  1.881)        0.35    0.733   1.00

Regression Equation in Uncoded Units

Measurements = 64.250 + 11.500 A - 2.500 B + 0.750 C + 0.750 A*B + 5.000 A*C + 0.000 B*C
               + 0.250 A*B*C
```

Figure 16.270: **Replicated factorial design effects C.I. with Minitab 17.1.3**

It must be remembered that for the constant and all coefficients the T-value above was respectively of the form (and it must also be remembered that $\hat{\sigma}_{\text{eff}}$ can be calculated only if there are replications!):

$$\begin{gathered}\text{Average} \pm T_{\alpha/2,2^k}\frac{\hat{\sigma}_y}{\sqrt{N}}\\ E_{Gx_i} \pm T_{\alpha/2,N/r}\hat{\sigma}_{\text{eff}}\end{gathered} \tag{16.7.636}$$

Therefore we see that all Student's T distribution have always the same degrees of freedom!!! That will be written:

$$T_{\alpha/2,2^k} \tag{16.7.637}$$

So we could use the limit T-value (we have seen earlier above how to calculate it) in absolute value to compare the amplitude of every factor. And this is what Minitab give as output when the design is replicated:

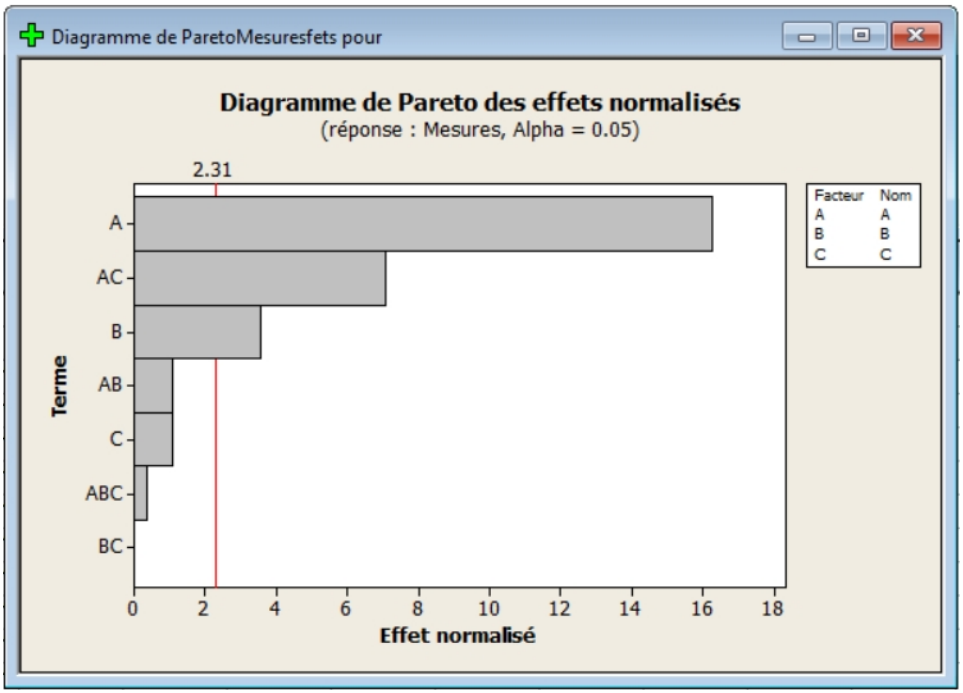


Figure 16.271: **Replicated factorial design T-value with Minitab 15.1.1**

Now the question that arise is: What is this red line and how it is calculated?

The choice (not rigorously justified as far as I know) used by most softwares is to compare all these values with the quantile $T_{\alpha/2,2^k}$ that gives in our case with Microsoft® Excel® 14.0.7177:

```
=TINV(97.5%,8)=2.30600414
```

and this is the value of the red line we can see on the plot above.

16.7.4.7.3 Desirability

The "desirability function" approach to simultaneously optimizing multiple equations was originally proposed by Edwin C. Jr Harrington (11980 according to holocene calendar). Essentially, the approach is to translate the functions to a common scale ($[0, 1]$), combine them using the geometric mean and optimize the overall metric. The equations may represent model predictions or other equations.

For example, desirability functions are popular in response surface methodology as a method to simultaneously optimize a series of quadratic models. A response surface experiment may use measurements on a set of outcomes. Instead of optimizing each outcome separately, settings for the predictor variables sought to satisfy all of the outcomes at once.

Also, in drug discovery, predictive models can be constructed to relate the molecular structures of compounds to characteristics of interest (such as absorption properties, potency and selectivity for the intended target). Given a set of predictive models built using existing compounds, predictions can be made on a large set of virtual compounds that have been designed but not necessarily synthesized. Using the model predictions, a virtual compound can be scored on how well the model results agree with required properties. In this case, ranking compounds on multiple endpoints may be sufficient to meet the scientist's needs.

Originally, Harrington used exponential functions to quantify desirability. In this text we will introduce simple discontinuous functions of G. Derringer and R. Suich.

Suppose that there are N equations or function to simultaneously optimize, denoted $f_i(\vec{x})$ with $i=1\ldots N$. For each of the i functions, an individual "desirability" function is constructed that is high when $f_i(\vec{x})$ is at the desirable level (such as a maximum, minimum, or target) and low when $f_n(\vec{x})$ is at an undesirable value. Derringer and Suich proposed three forms of these functions, corresponding to the type of optimization goal. For maximization of $f_i(\vec{x})$, the function:

$$d_i^{\text{max}} = \begin{cases} 0 & \text{if } f_i(\vec{x}) < L \\ \left(\dfrac{f_i(\vec{x})-L}{H-L}\right)^w & \text{if } L \leq f_i(\vec{x}) \leq H \\ 1 & \text{if } f_i(\vec{x}) > H \end{cases} \qquad (16.7.638)$$

can be used, where L is the lower limit that we allow to our variable of interest, H its high (maximal) value that we allow, and w is the weight that are all three chosen by the investigator. When the equation is to be minimized, they proposed the function:

$$d_i^{\text{min}} = \begin{cases} 0 & \text{if } f_i(\vec{x}) > H \\ \left(\dfrac{f_i(\vec{x})-H}{L-H}\right)^w & \text{if } L \leq f_i(\vec{x}) \leq H \\ 1 & \text{if } f_i(\vec{x}) < L \end{cases} \qquad (16.7.639)$$

and for target T situations:

$$d_i^{\text{target}} = \begin{cases} \left(\dfrac{f_i(\vec{x})-L}{T-L}\right)^{w_1} & \text{if } L \leq f_i(\vec{x}) \leq T \\ \left(\dfrac{f_i(\vec{x})-H}{T-H}\right)^{w_2} & \text{if } T \leq f_i(\vec{x}) \leq H \\ 0 & \text{otherwise} \end{cases} \qquad (16.7.640)$$

These functions are on the same scale (output in range $[0,1]$) and are discontinuous at the points L, H, and T. The values of w, w_1 or w_2 can be chosen so that the desirability criterion is easier or more difficult to satisfy. The scaling factors w are useful when one equation is of great importance than the other. Examples of the functions are given in the figure below:

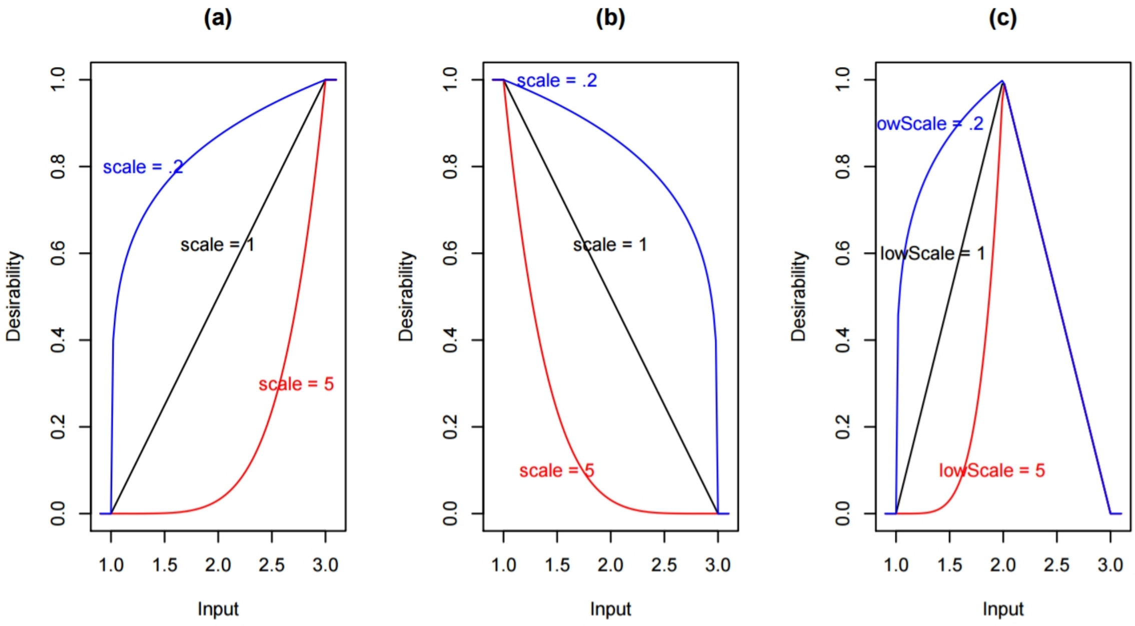

Figure 16.272: **Derringer and Suich desirability functions plot (source: Max Kuhn R Software)**

It should be noted that any function can be used to mirror the desirability of a model. For example, Del Castillo, Montgomery, and McCarville (11996 according to holocene calendar) develop alternative desirability functions that can be used in conjunction with gradient based optimization routines.

Given that the N desirability functions $d_1, \ldots, d_r$ are on the $[0, 1]$ scale, they can be combined to achieve an overall desirability function, D. One method of doing this is by the geometric mean and then we speak of "composite desirability":

$$\boxed{D = \left(\prod_{i=1}^{N} d_i \right)^{1/N}} \tag{16.7.641}$$

The geometric mean has the property that if any one model is undesirable ($d_i = 0$), the overall desirability is also unacceptable ($D = 0$). Once D has been defined and the prediction equations for each of the N equations have been computed, it can be use to optimize or rank the predictors.

In Minitab (see our companion book on that software) the composite desirability is the geometric mean of the individual desirabilities if and only if the "importance" parameter (whose value must be between 0.1 and 10) are all equals to 1.

16.7.5 Quality Control on Reception (Lot Acceptance Sampling Plans)

The "quality control on reception" or simply "acceptance test" or "statistical batch control" or following NIST[30] "Lot Acceptance Sampling Plans (LASPs)" is an extremely important field, wide and mathematically technical of statistical quality control in the industry (food, pharma, consumer goods) and services companies (repetitive action, process controls, surveys, assessments). Its purpose, according to the norm NF X06-021, is to allow the application on a controlled batch (products or services) of one or the other following decisions: Acceptance or Rejection at different stages of a production / development to see if a batch is admissible for the following steps or to check the deliverable before sending it to the customer.

QUALITY CONTROL
APPROVED

Remark

We will introduce here only the basics of this subject because the special cases require considerable mathematical background! It is also for this reason why many companies (SMEs and multinationals) that use interns or students that don't have a mathematical background to define quality controls in order to save money are found later with considerable problems in compliance with laws and quality standards! However, what we introduce here should be the minimum-minimorum knowledge of any active quality responsible or quality engineer or responsible for reception control of suppliers in any organization (industrial or administrative) otherwise they should have absolutely no credibility from people hiring such "specialists" or from external consultants! Also beware of companies - especially multinationals - who are looking for quality specialists mastering Microsoft® Excel® or Microsoft Access. Because it will mean that they use non-professional tools to do a job that should to be done with the professional statistical tools (what Microsoft® Excel® and Microsoft Access are not) !!! So in terms of internal organization, you can ensure that such companies organize and analyse anything, anyhow, with unsuitable tools and therefore that there is a general mess internally.

The purpose of quality control on reception (acceptance sampling) is not to estimate the quality of a lot, but only to accept or reject it. The acceptance is not a substitute for process control methods such as control charts or capability analysis. A dynamic use of these tools during manufacturing will result in reducing and, in some cases, eliminate the need to perform incoming or outcoming inspection/controls.

There are three main approaches to evaluate a batch:

- Either accept the batch without inspection (useful in situations where absolute trust relations exists between the customer and supplier or we now that defects are impossible).

---

[30] National Institute of Standards and Technology

- Either take a sample (sampling) and draw conclusions about the whole batch from the sample (useful in most cases because inexpensive and highly motivates the supplier to improve quality but there is a risk of rejecting good batches or accept bad one). For example Mulhouse PSA controls 5% of vehicles coming out of their factories every day.

- Either inspect all units in the batch (especially useful when the supplier can not prove that its process control is capable of producing in the specifications or when the monitored characteristic is very critical).

For the result of a batch control by sampling to be scientifically reliable, it is trivially important that, when collecting a sample of individuals, no preference is given to individuals from the whole population. Ideally, each individual batch must have the same probability of being draw from the sample.

The characteristics controlled can be:

- **Qualitative (attributes):** the appearance of a product, the presence or absence of a non-compliant element, failure to comply with a calibre of control, an achieved result or not. Individuals are then directly classified as compliant or non-compliant identified by the statistical number of defects they have.

  Remark

  In my job of consultant I saw once a customer that had for process to reject definitively any supplier that do one and only one first failure. This is a zero tolerance approach and is quite not scientific as I warn this customer... But when people don't have any statistical culture it's a waste of time trying to explain them why it's very likely not the best kind of strategy...

- **Quantitative (variables or measurement):** characteristic measured on a continuous scale: volume, length, weight, ...

Let us notice finally that there are two ways to classify acceptance plans. The first family is to define the following two categories:

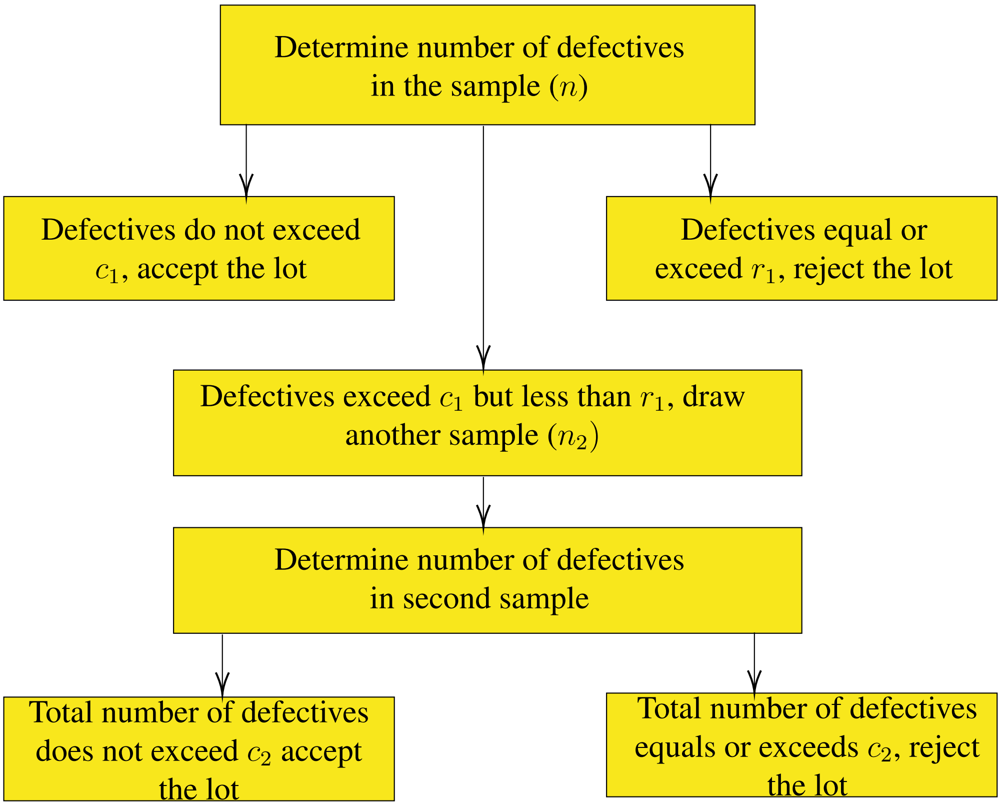
1. The "control of the proportion of non-compliant items by counting" or also simply named "attribute control": One or more characteristics of qualitative or quantitative type are controlled for each item in order to classify it as compliant or non-compliant according certain criteria. The decision is based on the number of non-compliant individuals found in the samples.

2. The "control of the proportion of non-compliant individuals by measuring" or also simply named "variable control". A characteristic is measured for each item and a decision is made based on the average and dispersion of the characteristic calculated on all the items collected.

We can also classify the acceptance plans depending on the number of samples taken.

- A "simple sampling plan" involves taking n items in a batch of size N and make a decision based on them.

- A "double sampling plan" involves taking a sample from the first batch and draw one of these three conclusions: (1) accept the batch, (2) reject the batch or (3) resample. If a second sample is taken, the information of the two samples are gathered to decide whether to accept or reject the batch (if we repeat this strategy, then we speak of "multiple sampling plan"). The idea is illustrated in the following figure:



Determine number of defectives in the sample (n)
Defectives do not exceed c_1, accept the lot
Defectives equal or exceed r_1, reject the lot
Defectives exceed c_1 but less than r_1, draw another sample (n_2)
Determine number of defectives in second sample
Total number of defectives does not exceed c_2 accept the lot
Total number of defectives equals or exceeds c_2, reject the lot

- A "progressive or sequential sampling plan" is the extreme case of multiple sampling plan. The items are removed one by one and after each sampling a decision is made: (1) accept, (2) reject or finally (3) take a new item.

When the defective units found in an inspected sample are removed and replaced with compliant products, we speak of "rectifying inspection". Obviously if the lot (batch) is rejected, 100% inspection may be performed and all defective units could be replace or a new lot send by the supplier (this is the subject of a cost analysis or legal contract terms between the supplier and the customer).

✍**Example:**

A soft drink producer wants to control a property of the bottles that are supplied to him. For this, it uses a simple reception plan by monitoring the proportion of nonconforming items by a measuring when a batch of bottles are delivered to him:

1. Collect a number n of units (bottles) of the batch (single sampling)
2. Measure pressure at which each of the n bottles broke (destructive testing)
3. Calculate the statistical indicators of the observed values.
4. Follow the acceptance decision rule or rejection that will be determined.

Remark

As for the control charts we will see further below, applying a sampling plan is a hypothesis test. It can lead to right or wrong decisions. The risks are those of accepting a non-compliant batch (Type II Error) or to reject a batch that is compliant (Type I Error).

Obviously sampling has advantages and disadvantages (pros & cons if you prefer). Here is the list of the most common advantages:

1. It's cheaper because you do not control everything ...
2. There is less manipulation of the products thus less waste
3. There needs to mobilize less people or control machines
4. This dramatically reduces inspection errors
5. The return of a whole batch just because of a non-compliant sample tends to motivate more the supplier to the quality ...

But it also has disadvantages such as:

1. The risk of accepting non-compliant batches (type II error) and reject good one (Type I error)...
2. Requires more intellectual skills of employees working in quality department (mathematical capacities...) and well-written contracts ...

16.7.5.1 Simple acceptance sampling plan by measurement for a unique tolerance with known standard deviation

For this type of sampling plan, we will assume that the sample n is much smaller than the total batch of size N (a factor of 10 at least) such that $n \ll N$ and the standard deviation σ is known!

The characteristic X measured for each item of the sample is assumed to follow a Normal distribution with identical mean μ and standard deviation σ (or variance) and the calculation of these last two parameters is based on the use of the sample mean (estimator of maximum likelihood of the mean as seen in the section Statistics at page 818) and of the unbiased estimator of the standard deviation (maximum likelihood estimator of the standard deviation as seen in the section Statistics at the same page as the previously mentioned one). This hypothesis implies that the product of the supplier is manufactured under statistical control!

✍**Example:**

In our example, the producer of soft drinks, he gets lots of $10,000$ bottles (so we will consider that the sample satisfy the above condition of $n \ll N$).

We write (see section Statistics page 692):

$$\bar{X} = \frac{1}{n}\sum_{i=1}^{n} X_i \qquad \text{and} \qquad X = \mathcal{N}\left(\mu, \frac{\sigma}{\sqrt{n}}\right) \tag{16.7.642}$$

Remark

The proper way to compute probabilities of acceptance should be to use the hypergeometric distribution as we have seen in the section Statistics (see page 672). But if the lot size is large relative to the sample size, the binomial distribution may be used. If the probabilities are quite small the binomial distribution can be approximated by a Normal distribution. This approximation is quite satisfactory if the lot size is more than ten times the sample size and non-compliant items are rare. In other words, if the lot size N is large enough to be declared as infinite, the distribution of the number of non-compliants in a random sample of n units will be binomial with parameters $\mu = np$ and $\sigma = np(1-p)$ as proved in the section Statistics (see page 692).

We will assume that the customer and the supplier have agreed on specification limits (tolerances). We denote will denote as usual these limits USL (Upper Specification Limit(and LSL (Lower Specification Limit(.

Given D the proportion (unknown!) of non-compliant products (defective), it is naturally given in the field statistical processes control by:

$$D = P(X < \text{LSL}) + P(X > \text{USL}) = P\left(Z < \frac{\text{LSL}-\mu}{\sigma}\right) + P\left(Z > \frac{\text{USL}-\mu}{\sigma}\right) \tag{16.7.643}$$

In practice, in order to save money in the context of quality tests, we try to reduce (reformulate) any control problem to a single calibre. In fact the problem can always with or without reformulation be reduced to have a proportion of non-compliant below the LSL or above USL to reject the batch if the supplier's production is in statistical control. Hence the fact that in practice the mathematical developments are made only in relation to a single bound which we will denote by BSL for "batch specification limit".

Thus, we reduce the problems of single sampling (or we manage the problems such that it can be reduced to such a formulation):

$$D=P(X<\text{BSL}) \qquad \text{or} \qquad D=P(X>\text{BSL}) \tag{16.7.644}$$

✍**Example:**

In the context of our companion example, the producer of soft drinks, it is the pressure resistance of a batch of $10,000$ bottles that we would like to control. The producer has agreed with its supplier to a lower specification limit for this property, chosen at 22.5 limits a majority of the bottles must exceed without blow up. So:

$$D=P(X<\text{LSL})=P(22.5<\text{LSL})$$

We will assume that past data were used to estimate precisely the standard deviation of the blow up pressure limit and which can therefore be considered as known and equal to 1.5 and is under statistical control.

Because obviously if the proportion of non-compliant items is more (or less) that defines the quality contract, it will be also the same the opposite bound in the same proportions as the supplier is supposed to have its manufacturing process under statistical control!!!

Before going further into the mathematical developments, there is an important thing to remember:

If we imagine ourselves to be a supplier, it is obvious that we would like to have a level of quality such that the cumulative probability that the customer mistakenly reject a batch is small (because as a supplier we are contractually obliged to take the back the batch even if a full second sampling control later shows that he seems to be wrong!). For this purpose, the supplier defines a value D_s of the percentage of non-compliant products, named "Acceptable Quality Level" (AQL), below which he assumes that the batch may be rejected only very rarely. In addition, the supplier also defines α as the maximum cumulative probability of seeing a batch being rejected that has a percentage of non-conformity less than or equal to D_f (so it is the cumulative probability that a customer would reject by error a batch). This is written as:

$$P(\text{Reject a batch}|D\leq D_s)\leq\alpha \tag{16.7.645}$$

more of often written:

$$\boxed{P(\text{Reject a batch}|D\leq \text{AQL})\leq\alpha} \tag{16.7.646}$$

where α is named course ... "supplier's risk[31]" and is generally in the range of 0.1 to 10%.

---

[31] α is the supplier's risk as it represents the likelihood that given a lot whose defect/defective rate is equal to the AQL, it will be improperly rejected. The higher the α, the more likely "acceptable" lots will be rejected causing harm to the supplier.

In other words, the Acceptable Quality Level is the defect/defective rate that we wish to accept a high proportion of the time $(1-\alpha)$. That is, given for example an AQL of 1.5% and an α of 5%, we would expect to accept lots that had 1.5% defective units 95% of the time.

Finally, if we imagine that we are the customer, it is obvious that we would like the cumulative probability of wrongly accepting a batch that does not meet the contract quality to be quite small for obvious cost reasons. For this, the customer must on his side defines a value D_c of the proportion of non-compliant items, know under the name "Quality Level Limit" (QLL) or following NIST "Lot Tolerance Percent Defective" (LTPD) or following Minitab Software "Rejectable Quality Level" (RQL), beyond which the customer considers that the batch can be accepted wrongly only rarely. He also defines β as the maximum cumulative probability of having to accept a batch that has a proportion of non-compliant item greater than or equal to D_c (so it is the cumulative probability that wrongly accept a batch of the supplier). This is written as:

$$P(\text{Accept a batch}|D \geq D_c) \leq \beta \qquad (16.7.647)$$

more often written:

$$\boxed{P(\text{Accept a batch}|D \geq \text{QLL}) \leq \beta} \qquad (16.7.648)$$

where β is named obviously ... "customer risk[32]" and is also generally in the range of 5 to 10%.

In other words, the Rejectable Quality Level (RQL) is the defect/defective rate that we wish to reject a high proportion of the time $(1-\beta)$. That is, given for example a RQL of 7.5% and a β of 10%, we would expect to reject lots that had 7.5% defective units 90% of the time (accept only 10% of the time).

Where the ANSI (MIL-STD-105) is an AQL system that protects manufacturer/supplier (if the quality is at the AQL let us make sure we can ship), RQL systems protect the consumer/customer (if the quality is at the RQL let us make sure we reject).

To summarize the situation may be illustrated by the following table (which is similar in all points to the table of Type I and II errors already seen in the section Statistics):

	State of Nature	
Decision resulting from sampling	The batch is not good (QLL) (H_0 **false**)	The batch is good (AQL) (H_0 **true**)
Reject (batch) H_0	Correctly reject null decision ($1-\beta$: Power of the test)	Type I Error (Risk α)
Fail to reject (batch) H_0	Type II Error (Risk β)	Correct decision

---

[32] β is the customers' risk (or "consumer's risk") as it represents the likelihood that given a lot whose defect/defective rate is equal to the RQL, it will be found acceptable. The higher the β, the more likely "rejectable" lots will be accepted causing harm to the customer (consumer).

Note that the US Government is moving to eliminate the use of AQLs in all contracts[33] «...to support the movement away from an AQL-based inspection (detection) strategy to implementation of an effective prevention-based strategy including a comprehensive quality system, continuous improvement...» (MIL-STD 1916, 1-APR 1996, p1).

✍**Example:**

In the context of our companion example - the producer of soft drinks - which receives batches of $10,000$ bottles whose pressure resistance (BSL) must be greater than 22.5 with a standard deviation σ under statistical control equal to 1.5, the supplier and the customer each have fixed the risks they agree to take:

- The supplier would like that a batch with less than 1% of non-compliant to be rejected by error by the customer to be at maximum of 5% of cases (cumulative probability of type I error). Thus:

$$P(\text{Reject a batch}|D\leq \text{AQL})\leq\alpha\Rightarrow P(\text{Reject a batch}|D\leq 1\%)\leq 5\%$$

- The customer would like that a batch withmore than 5% of non-compliant bottles to be wrongly accepted in less than 10% of cases (cumulative probability of type II error). Thus:

$$P(\text{Accept a batch}|D\leq \text{QLL})\geq\alpha\Rightarrow P(\text{Accept a batch}|D\geq 5\%)\leq 10\%$$

Remark

The decision rule to accept or reject a batch for a control by measurement is generally based on the estimated arithmetic mean of the characteristic of the sample rather than based on a estimate of non-compliant proportion.

For what follows, when we write:

$$D=P(X<\text{LSL}) \tag{16.7.649}$$

the specificity is that in practice D is requested and σ is given. The remainder is either to calculate or to eliminate (indeed the quality practitioner should normally only talk in terms of cumulative probability and proportions or factors to define its quality policy and LSL is not a cumulative probability neither a percentage or a factor independent of the thing that we analyse!). Thus we write:

$$D=P(X<\text{LSL})=P\left(Z<\frac{\text{LSL}-\mu}{\sigma}\right) \tag{16.7.650}$$

So with the usual score (centered reduce variable as seen in the section Statistics page 696):

$$Z=\frac{\text{LSL}-\mu}{\sigma} \tag{16.7.651}$$

---

[33] This is typically the case of "Accept on none (defects)" plans. Fore more information see the Minitab companion book or [509]

Obviously we draw from this that limit average value of the sample is:

$$\mu_D = \text{LSL} - Z_D\sigma \qquad (16.7.652)$$

where Z_D is the level D of percentile of the standard centered Normal distribution (as usual). Unfortunately, we still have LSL that is there. Can we eliminate it? For this we have in the context that if the measurement (or manufacturing) is under statistical control:

$$\bar{X} = \mathcal{N}\left(\mu, \frac{\sigma}{\sqrt{n}}\right) \qquad (16.7.653)$$

The cumulative probability to accept (we could have done it for the rejection but we had to choose one of the both for the example...) the batch when the non-compliant rate is D is deducted in the context of using the average of the measurements becomes:

$$P_D = P(\bar{X} \geq \text{LSL} + k\sigma) \qquad (16.7.654)$$

in the special case where the measurement should not be less than some given value BSL (as is the case of the above example with the soft drink bottles!). Obviously k could be a real positive or negative number as we know but not equal to Z_D and we will how to find a way to determine it from the supplier and customer risk level!!!

Hence:

$$P_D = P(\bar{X} \geq \text{LSL} + k\sigma) = P\left(\frac{\bar{X} - \mu_D}{\frac{\sigma}{\sqrt{n}}} \geq \frac{\text{LSL} + k\sigma - \mu_D}{\frac{\sigma}{\sqrt{n}}}\right) = P\left(Z \geq \frac{LSL + k\sigma - \mu_D}{\frac{\sigma}{\sqrt{n}}}\right)$$
$$= P\left(Z \geq \frac{\text{LSL} + k\sigma - (\text{LSL} - Z_D\sigma)}{\frac{\sigma}{\sqrt{n}}}\right) = P\left(Z \geq \frac{k\sigma + Z_D\sigma}{\frac{\sigma}{\sqrt{n}}}\right) = P\left(Z \geq \sqrt{n}(k + Z_D)\right) \qquad (16.7.655)$$

Then we have a very interesting result! The cumulative probability to accept the batch when the non-compliant rate is D is then given in the special case there where the measurement should not be below a specific limit by:

$$P_D = P(Z \geq \sqrt{n}(k + Z_D)) \qquad (16.7.656)$$

and the probability to reject it in the case of a measure beyond which we should not go:

$$P_D = P(Z \leq \sqrt{n}(k + Z_D)) \qquad (16.7.657)$$

and what is good in this result is that the problem is then reduced to a percentile Z_D that is easy to choose (norm or policy choices), of the sample size n and a factor k so only independent elements of the type of measurement itself and that can then be used in any job for any type of object and facilitates the writing of contract (plus we have eliminated the explicit use of the standard deviation) !!

Obviously, as we know, the supplier and the customer must agree to a sampling plan corresponding to build quality tests meeting expectations of the one and the other. What we know so far is that they respectively require an α (supplier risk) and a β (customer risk) that allows them to immediately calculate the $Z_{D,\alpha}, Z_{D,\beta}$ respectively. However it is necessary to calculate the number of individuals n sampled and the factor k that satisfy the respective requirements.

To do this, remember that if α is the supplier risk (cumulative probability that the customer mistakenly rejects the batch) and the β the customer risk (cumulative that he wrongly accepts supplier batch) and that:

$$P_D = P(Z \geq \sqrt{n}(k+Z_D)) \tag{16.7.658}$$

the cumulative probability of accepting a batch with a lower limit, then we must (!) have:

$$\begin{aligned} 1-\alpha &= P(Z \geq \sqrt{n}(k+Z_{D,\alpha})) \\ \beta &= P(Z \geq \sqrt{n}(k+Z_{D,\beta}) \end{aligned} \tag{16.7.659}$$

or after rearrangement:

$$\begin{aligned} \alpha &= P(Z \leq \sqrt{n}(k+Z_{D,\alpha})) \\ 1-\beta &= P(Z \leq \sqrt{n}(k+Z_{D,\beta}) \end{aligned} \tag{16.7.660}$$

To understand why we write these both relations the reader can take the two extreme situation where $\alpha=\beta=0$ and $\alpha=\beta=1$ (with their respective $Z_{D,\alpha}, Z_{D,\beta}$) to better understand (we can detail on request with an explicit example).

If we solve this system we can get the n and k we are looking for so that the customer and supplier get the sampling plan their both expecting!

So we can rewrite the previous system as:

$$\begin{aligned} Z_\alpha &= \sqrt{n}(k+Z_{D,\alpha}) \\ Z_{1-\beta} &= \sqrt{n}(k+Z_{D,\beta}) \end{aligned} \tag{16.7.661}$$

Therefore:

$$\frac{Z_\alpha}{\sqrt{n}} - Z_{D,\alpha} = \frac{Z_{1-\beta}}{\sqrt{n}} - Z_{D,\beta} = k \tag{16.7.662}$$

from which we can take out n:

$$\begin{aligned} &\frac{Z_\alpha}{\sqrt{n}} - \frac{Z-1-\beta}{\sqrt{n}} = Z_{D,\alpha} - Z_{D,\beta} \Leftrightarrow \frac{1}{\sqrt{n}} = \frac{Z_{D,\alpha}-Z_{D,\beta}}{Z_\alpha - Z_{1-\beta}} \\ &\Leftrightarrow \sqrt{n} = \frac{Z_\alpha - Z_{1-\beta}}{Z_{D,\alpha}-Z_{D,\beta}} \end{aligned} \tag{16.7.663}$$

Finally:

$$\boxed{n = \left(\frac{Z_\alpha - Z_{1-\beta}}{Z_{D,\alpha}-Z_{D,\beta}}\right)^2} \tag{16.7.664}$$

and for k:

$$\begin{aligned} k &= \frac{Z_\alpha}{\sqrt{n}} - Z_{D,\alpha} = \frac{Z_\alpha}{\dfrac{Z_\alpha - Z_{1-\beta}}{Z_{D,\alpha}-Z_{D,\beta}}} - Z_{D,\alpha} = \frac{Z_\alpha(Z_{D,\alpha}-Z_{D,\beta})}{Z_\alpha - Z_{1-\beta}} - Z_{D,\alpha} \\ &= \frac{Z_\alpha(Z_{D,\beta}-Z_{D,\alpha})}{Z_{1-\beta}-Z_\alpha} - Z_{D,\alpha} = \frac{Z_\alpha(Z_{D,\beta}-Z_{D,\alpha}) - Z_{D,\alpha}(Z_{1-\beta}-Z_\alpha)}{Z_{1-\beta}-Z_\alpha} \\ &= \frac{Z_\alpha Z_{D,\beta} - Z_\alpha Z_{D,\alpha} - Z_{D,\alpha}Z_{1-\beta} - Z_{D,\alpha}Z_\alpha}{Z_{1-\beta}-Z_\alpha} \end{aligned} \tag{16.7.665}$$

So that finally:

$$\boxed{k=\frac{Z_\alpha Z_{D,\beta}-Z_{D,\alpha}Z_{1-\beta}}{Z_{1-\beta}-Z_\alpha}} \tag{16.7.666}$$

✍**Examples:**

E1. In the context of our companion example - the producer of soft drinks - which receives batches of $10,000$ bottles whose pressure resistance (LSL) must be at least of 22.5 with a standard deviation under statistical control equal to 1.5, remember that the supplier and the customer each have fixed the risks they are ok to assume such that:

$$\begin{aligned}P(\text{Reject a batch}|D\leq\text{AQL})\leq\alpha\Rightarrow P(\text{Reject a batch}|D\leq 1\%)\leq 5\%\\ P(\text{Accept a batch}|D\leq\text{QLL})\geq\alpha\Rightarrow P(\text{Accept a batch}|D\geq 5\%)\leq 10\%\end{aligned}$$

We then have using Microsoft® Excel® 11.8346:

$$n=\left(\frac{Z_\alpha-Z_{1-\beta}}{Z_{D,\alpha}-Z_{D,\beta}}\right)^2=\left(\frac{\texttt{NORMSINV(5\%)}-\texttt{NORMSINV(1-10\%)}}{\texttt{NORMSINV(1\%)}-\texttt{NORMSINV(5\%)}}\right)^2 \tag{16.7.667}$$

and (calculated with the same Microsoft® Excel® functions so we omit to explicit them again):

$$k=\frac{Z_\alpha Z_{D,\beta}-Z_{D,\alpha}Z_{1-\beta}}{Z_{1-\beta}-Z_\alpha}\cong 1.943 \tag{16.7.668}$$

The sampling plan is then to collect and analyse a sample of size $n=18$, calculate the arithmetic average $\bar{X}$ and apply the following decision rule:

$$\begin{aligned}\text{Accept the batch if:}\bar{X}\geq\text{LSL}+k\sigma=22.5+1.943\cdot 1.5\cong 25.4\\ \text{Reject the batch if:}\bar{X}<\text{LSL}+k\sigma\cong 25.4\end{aligned} \tag{16.7.669}$$

Let us suppose now that a sample size of 18 is taken and gives the following results:

$$\begin{gathered}25.6,26.0,23.0,27.0,27.5,29.0,28.5,26.0,25.6\\ 25.8,26.5,28.8,27.3,25.2,27.1,29.8,26.5,27.8\end{gathered}$$

Then we have:

$$\bar{X}=26.8\geq 25.4$$

and therefore the batch is accepted. You should know that many practitioners prefer the following calculation using a "quality index", denoted Q, simply using the following equation:

$$Q=\frac{\bar{X}-LSL}{\sigma}=\frac{26.8-22.5}{1.5}\cong 2.86>k$$

therefore the batch is accepted.

Remark

In the latter case it is still recommended in practice to calculate the unbiased estimator of the standard deviation of the sample to ensure it is not too far from the standard deviation of the contract (even if it may not be the same for small samples)!

E2. A second typical calculation made by practitioners (often just for curiosity or sometimes to make a quality report to the board committee) resulting from the first example is: What is the cumulative probability that we reject with n and k given, a batch of which the proportion of non-compliant D would be 5%? Then, we use the following proved relation:

$$P_D = P(Z \leq \sqrt{n}(k + Z_D))$$

Thus with the previous values:

$$P_D = P(Z \leq \sqrt{18}(1.943 + \texttt{NORMSINV(5\%)})) \cong 89.70\%$$

and the cumulative probability that we accept the batch is then of $1 - 89.70\%$ or 10.29%.

16.7.5.1.1 Calculation of the parameters using the norm AF-X06-023

The norm AFNOR X06-023 offers a slightly different method to determine k and n, not directly based on the customer's risk and the supplier's risk, but only base on the "Acceptable Quality Level" (AQL.). In addition, this norm also takes into account the size N of the tested batch (considered previously as infinite) and of the desired level of control.

Remark

The equivalent international norm to the AFNOR X06-023 seems to be the ISO 3951:1981 that to my knowledge gives very different values from that of the AFNOR for reasons that I don't understand quite well (I hope it's just because I did not understand something...).

The method proposed by AFNOR X06-023 is of the type "recipe" but is requested by certain European standards so the industry have no choice but to apply it. But at the end, the numerical values are relatively close to those obtained with the previously proved relations. In fact their real usefulness is that they are simple to implement in much more complex situations than those we have just studied.

Depending on the context, the norm proposes to apply different levels of control:

- **Normal control**: that has to be chosen when we are in close trusted relation with the supplier and we have a look in real time on the quality of its production using computer remote monitoring tools .
- **Reinforced control**: which is stricter than the normal control (n is greater) and is intended

to better protect customers against the risk of having to accept bad batches (Type I Error). This type of control should be performed temporarily when there are serious reasons for considering that the production quality is not (or is no more) what is should be until we return back to the normal (deliveries are suspended between this time).

- **Reduced control**: that is the most economical one and can be applied when based on previously tested and accepted batches, we can believe that the supplier master well the quality its processes

✍**Examples:**

E1. In the context of our companion example - the producer of soft drinks - which receives batches of $10,000$ bottles whose pressure resistance (LSL) must be at least of 22.5 with a standard deviation under statistical control equal to 1.5, remember that the supplier and the customer each have fixed the risks they are ok to assume such that:

$$\begin{gathered}P(\text{Reject a batch}|D\leq\text{AQL})\leq\alpha\Rightarrow P(\text{Reject a batch}|D\leq 1\%)\leq 5\%\\ P(\text{Accept a batch}|D\leq\text{QLL})\geq\alpha\Rightarrow P(\text{Accept a batch}|D\geq 5\%)\leq 10\%\end{gathered}$$

We must then use the norm AFNOR X06-023 with a NQA of 1%.

The norm requires the choice of a control level. We will take that of type II. A table in this norm tells us that we must use the code **L** for the next step. The final table thus gives us for a NQA of 1% and a L coll the following cell:

1.06%	
$n=25$	$k=1.97$
4.28%	

corresponding to:

D_s	
n	k
D_c	

or more traditionally:

AQL	
n	k
LTPD (QLL)	

Therefore, the norm indicates that a sample size n of 25 should be used and a k of 1.97! The plan insures risks slightly smaller than the plan calculated above but is more expensive because requires bigger samples.

E2. Practitioners when they use norms often want to calculate the customer and supplier risk associated to the selected AQL and the corresponding parameters given by the norm. Then using:

$$k=\frac{Z_\alpha}{\sqrt{n}}-Z_{D,\alpha} \tag{16.7.670}$$

It comes:

$$Z_\alpha=\sqrt{n}(k+Z_{D,\alpha}) \tag{16.7.671}$$

Either as part of our example and always using Microsoft® Excel® 11.8346:

$$Z_\alpha=\texttt{SQRT(25)(1.97+NORMSINV(1.06))}\cong -1.67 \tag{16.7.672}$$

Therefore:

$$\alpha=\texttt{NORMSINV(-1.67)}=4.73\% \tag{16.7.673}$$

to be compared to the 5%. As well as:

$$Z_{1-\beta}=\sqrt{n}(k+Z_{D,\beta}) \tag{16.7.674}$$

Either as part of our example and always using Microsoft® Excel® 11.8346:

$$Z_{1-\beta}=\texttt{SQRT(25)(1.97+NORMSINV(4.28\%))}\cong 1.25 \tag{16.7.675}$$

it comes:

$$1-\beta=\texttt{NORMSINV(1.25)}=89.52\% \tag{16.7.676}$$

and finally:

$$\beta=1-89.52\%=10.48\% \tag{16.7.677}$$

to be compared to the 10%.

16.7.5.2 Simple acceptance sampling plan by attribute

The attributes acceptance plans are simpler than the sampling plans by measurement, but they are often more expensive (in number of samples) than acceptance plans by measurement and are therefore advise only when we can not summarize information on the quality of a unit by measurement or that the cost of analyses my measurement are too high compared to a simple classification of compliant or non-compliant units.

The "simple acceptance plan by attributes", as already mentioned, is an acceptance test procedure the consist to draw a random sample of a given size n in a batch. The sampled units (in a homogeneous way!) are then inspected and classified as compliant or non-compliant (avoid using the term "defective" as it is not same!).

Given X be the number of non-compliant components found in the sample. If $X \leq A$, the quality of the batch is considered good and the batch is accepted. If $X \geq R$ with in the case of simple acceptance plan by attribute: $R = A + 1$ the batch quality is considered as poor and the batch is not accepted.

✍**Example:**

Bottles by batch size of $N = 10,000$ are received by a customer. The control procedure used empirically a simple acceptance plan by attribute: it collects a sample of size $n = 200$. The acceptance criterion A is $X \leq 1$ and the rejection criterion R is $X \geq 2$.

Let us recall before going further into the mathematical details of the calculations of the strategy of a single sampling plan by attributes the principles of double and multiple sampling plans by attributes for the general culture:

- The "double acceptance plan by attributes" is an acceptance test procedure having two stages of decision. It involves first taking a first sample size of a size smaller than the one we would collect for a single acceptance plan. The first stage of decision is based on information provided by the first sample. If the quality of the first sample is considered good enough, the batch is accepted. If judged bad enough, the batch is not accepted. However if the quality of the first sample is judged as intermediate, a second sample is taken and inspected in order to accept or reject the batch. the second stage of the decision criteria are based on information collected on the two samples.

  ✍**Example:**

  Bottles by batch size of $N = 10,000$ are received by a customer. The control procedure used empirically the following acceptance plan by attributes: it takes a first sample size $n_1 = 125$. The acceptance criterion A in the first stage is the $X_1 = 0$ and the rejection criterion R is $X_1 \geq 2$. If the quality is not satisfactory, we take a second sample of size $n_2 = 125$ with an acceptance criterion A in the second stage of $X_2 \leq 1$ and the rejection criterion R is $X_2 \geq 2$.

  We will come back on a much more detailed and formal example of double acceptance plan by attribute further below!!

- The "multiple acceptance sampling plan by attribute" is simply a generalization of the double acceptance sampling plan by attributes having D decision steps instead of 1 for the simple acceptance plan or 2 for the double acceptance plan...

Let us come back to our mathematical developments of a single sampling acceptance plan by attributes. If we denote now n the batch size, p the sample size and m the total number of defective in the batch, then the probability of having k non-compliant items among p is (always using as from the beginning of this textbook a notation for the binomial coefficient that is not-compliant with the norm ISO 31-11):

$$P(n,p,m,k)=\frac{C_k^m C_{p-k}^{n-m}}{C_p^n} \tag{16.7.678}$$

To be consistent with the tradition of the field of acceptance plan, let's first change these notations. Let us denote by n the sample size and N the batch size. It comes then:

$$P(N,n,m,k)=\frac{C_k^m C_{n-k}^{N-m}}{C_n^N} \tag{16.7.679}$$

Let's do a second change of notation. Let us denote by p the proportion of non-compliant items in the batch. It then comes the traditional customary notation:

$$P(N,n,p,k)=\frac{C_k^{Np} C_{n-k}^{N-Np}}{C_n^N} \tag{16.7.680}$$

Thus, the cumulative probability of accepting a batch of quality p is given by:

$$P_a=P(X\leq A)=\sum_{k=0}^{A}P(N,n,p,X=k)=\sum_{k=0}^{A}\frac{C_k^{Np} C_{n-k}^{N-Np}}{C_n^N} \tag{16.7.681}$$

✍**Example:**

What is the cumulative probability of drawing 5 non-compliant items (acceptance criterion) of a batch of $10,000$ bottles (N) from which we took a sample of 200 individuals (n), the proportion of non-compliant is known to be of 5% (p). So with Microsoft® Excel® 14.0.6123 we get as cumulative probability of acceptance:

$$\begin{aligned}P_a=P(X\leq A)&=\sum_{k=0}^{A}\frac{C_k^{Np} C_{n-k}^{N-Np}}{C_n^N}=\sum_{k=0}^{5}\frac{C_k^{10000\cdot 5\%} C_{200-k}^{10000-10000\cdot 5\%}}{C_{200}^{10000}}\\&=\texttt{HYPGEOM.DIST(5,200,10000*5\%,10000,1)}=6.05\%\end{aligned} \tag{16.7.682}$$

Remark

A classic common mistake business that I see from Quality Manager of some of the best luxury international brands based in Switzerland is to believe that the acceptance criteria is proportional to the batch size! In other words that if for $10,000$ bottles, the fact to a test sample of 200 items (2%) gives a cumulative probability of acceptance of $\cong 6\%$, then on $1,000$ bottles, a sample of 20 items (still 2%) gives the same cumulative probability of acceptance. In fact, with Microsoft® Excel® 14.0.6123, we then not have 6.05% anymore but 99.7% (!!!)... the difference is then considerable !!

If we recall (see above the simple acceptance plans by measurement) that if α is the supplier risk (cumulative probability that the customer rejects by error the batch whose proportion of non-compliant items is equal to p_α: type I Error) and β the customer risk (cumulative probability of accepting by error a batch of a supplier whose proportion of non-compliant items is p_β: type II Error), then so that the supplier and the customer have the sampling plan corresponding to each of their quality requirements we have to solve following system:

$$\begin{aligned}1-\alpha &= \sum_{k=0}^{A}\frac{C_k^{Np_\alpha}C_{n-k}^{N-Np_\alpha}}{C_n^N}\\ \beta &= \sum_{k=0}^{A}\frac{C_k^{Np_\beta}C_{n-k}^{N-Np_\beta}}{C_n^N}\end{aligned} \tag{16.7.683}$$

As far as we know it is not possible to solve this system analytically. The techniques of operational research techniques (see section Numerical Methods page 6645) using the simplex method, the gradient method or Newton method fail miserably in finding a solution to this system (which is quite normal in fact...). By cons, with evolutionary algorithms (tool available in Microsoft® Excel® 14.0.6123 or also in MATLAB®) we can find acceptable solutions, but the settings are not easy.

Therefore, assuming that the size of batches submitted for inspection is large relative to the sample size $N \gg n$, and using the binomial approximation of the hypergeometric distribution (approximation proved in the section Statistics at page 672), we have:

$$P_a = P(X\leq A) = \sum_{k=0}^{A}P(n,p,X=k) = \sum_{k=0}^{A}C_k^n p^k(1-p)^{n-k} = \sum_{k=0}^{A}C_k^n p^k q^{n-k} \tag{16.7.684}$$

The advantage of this approximation is huge! The total size N of the batch is no longer involved in the problem!

✍**Examples:**

E1. What is the cumulative probability of drawing 5 non-compliant items (acceptance criterion) of a batch of $10,000$ bottles (N) from which we took a sample of 200 individuals (n), whose proportion of non-compliant is known to be as equal to 5% (p). While Microsoft® Excel® 14.0.6123 we get:

$$\begin{aligned}P_a = P(X\leq A) &= \sum_{k=0}^{A}C_k^n p^k q^{n-k} q^{n-k} = \sum_{k=0}^{5}C_k^{200}0.05^k 0.95^{200-k}\\ &= \texttt{BINOMDIST(5,200,5\%,1)} = 6.23\%\end{aligned} \tag{16.7.685}$$

E2. The latter relation is also used in reliability engineering (see earlier above)!!! Indeed, suppose we wish to know the number of elements n we need to take to make a reliability demonstration plan showing with 90% of cumulative probability that the number A of failures (non-compliance) is equal to zero knowing that their reliability is 80%. Then this is equivalent to search n such that we are the closest to:

$$\begin{aligned}P_a=P(X\leq 0)=\sum_{k=0}^{A}C_k^n p^k q^{n-k}=\sum_{k=0}^{A}C_k^n(1-R)^k R^{n-k}=\sum_{k=0}^{0}C_k^n 0.2^k 0.8^{n-k}\\=R^n=0.8^n=1-90\%=10\%\end{aligned} \tag{16.7.686}$$

Therefore:

$$n=\frac{\log(0.1)}{\log(0.8)}=10.31885\cong 11 \tag{16.7.687}$$

So the nearest value n for this is to take 11 items (this is the value that also returns the worldwide reference reliability software Weibull++). We can then use the same previous calculation:

$$\texttt{BINOMDIST(0,11,20\%,1)}=8.59\%$$

Within the area of reliability, it is customary to name this approach "nonparametric binomial demonstration test plan of the reliability"... (we will come back on this subject further below).

E3. Let us see now a last example relatively to reliability. Remember that we have proved earlier above that for the Weibull distribution with one parameter, we had:

$$R(t)=e^{-\left(\frac{t}{\eta}\right)^{\beta}} \tag{16.7.688}$$

And let suppose that we previous tests have shown that at a time t equal to $2,000$ days, we had a reliability of 80% and we know that the shape parameter β is equal to 2. We would like to know what sample size we need to take for a reliability test of $1,500$ days shows with maximum 90% cumulative probability 1 non-compliance (that is: 1 failure). For this, we first determine the scale parameter:

$$\begin{aligned}R(t)=e^{-\left(\frac{t}{\eta}\right)^{\beta}}\Rightarrow\eta=\frac{t}{(-\ln(R(t)))^{1/\beta}}=\frac{2000}{(-\ln(R(2000)))^{1/2}}\\=\frac{2000}{(-\ln(0.8))^{1/2}}\cong 4233.87\end{aligned} \tag{16.7.689}$$

Then it comes for this same test at $1,500$ day a reliability of:

$$R(1500)=e^{-\left(\frac{1500}{4233.87}\right)^{2}}\cong 0.882=88.2\% \tag{16.7.690}$$

By injecting into the binomial law, we then have:

$$P_a=P(X\leq 1)=\sum_{k=0}^{A}C_k^n p^k q^{n-k}=\sum_{k=0}^{1}C_k^n(1-0.882)^k 0.882^{n-k}=1-90\%=10\% \tag{16.7.691}$$

Solving for n, we get the integer value n of 32 items (the same value as that returned then by the worldwide reference reliability software Weibull++). We are then left with:

= `BINOMDIST(1,32,1-88.2%,1)` = 10.50%

Remark

Again... a common (beginner) mistake that is classic in corporation is to think that the acceptance criterion is proportional to the batch size. In other words that if for $10,000$ bottles, the fact to test a sample of 200 items (2%) gives a cumulative probability of acceptance of $\cong 6\%$, the a on a batch of $1,000$ bottles, a sample of 20 items (2%) gives the same cumulative probability of acceptance... In fact, with Microsoft® Excel® 14.0.6123, we have don't have 6.23% anymore but 99.7%... the difference is huge!!

Returning to the theory .... the system we had then with the Hypergeometric law can be written when $N \gg n$ as:

$$\boxed{\begin{aligned} 1-\alpha &\cong \sum_{k=0}^{A} C_k^n p_\alpha^k (1-p_\alpha)^{n-k} = \sum_{k=0}^{A} C_k^n p_\alpha^k q_\alpha^{n-k} \\ \beta &\cong \sum_{k=0}^{A} C_k^n p_\beta^k (1-p_\beta)^{n-k} = \sum_{k=0}^{A} C_k^n p_\beta^k q_\beta^{n-k} \end{aligned}} \qquad (16.7.692)$$

But once again, it is not possible (as far as we know) to solve the previous system analytically. In 11967 (holocene calendar), Harry R. Larson then created a chart of the cumulative binomial frequently referred to as the "Larson's binomial nomograph" (I never found or seen an equivalent for a hypergeometric law unfortunately...) which allows approximately to solve the problem of determining the value of A and n for the acceptance plan:

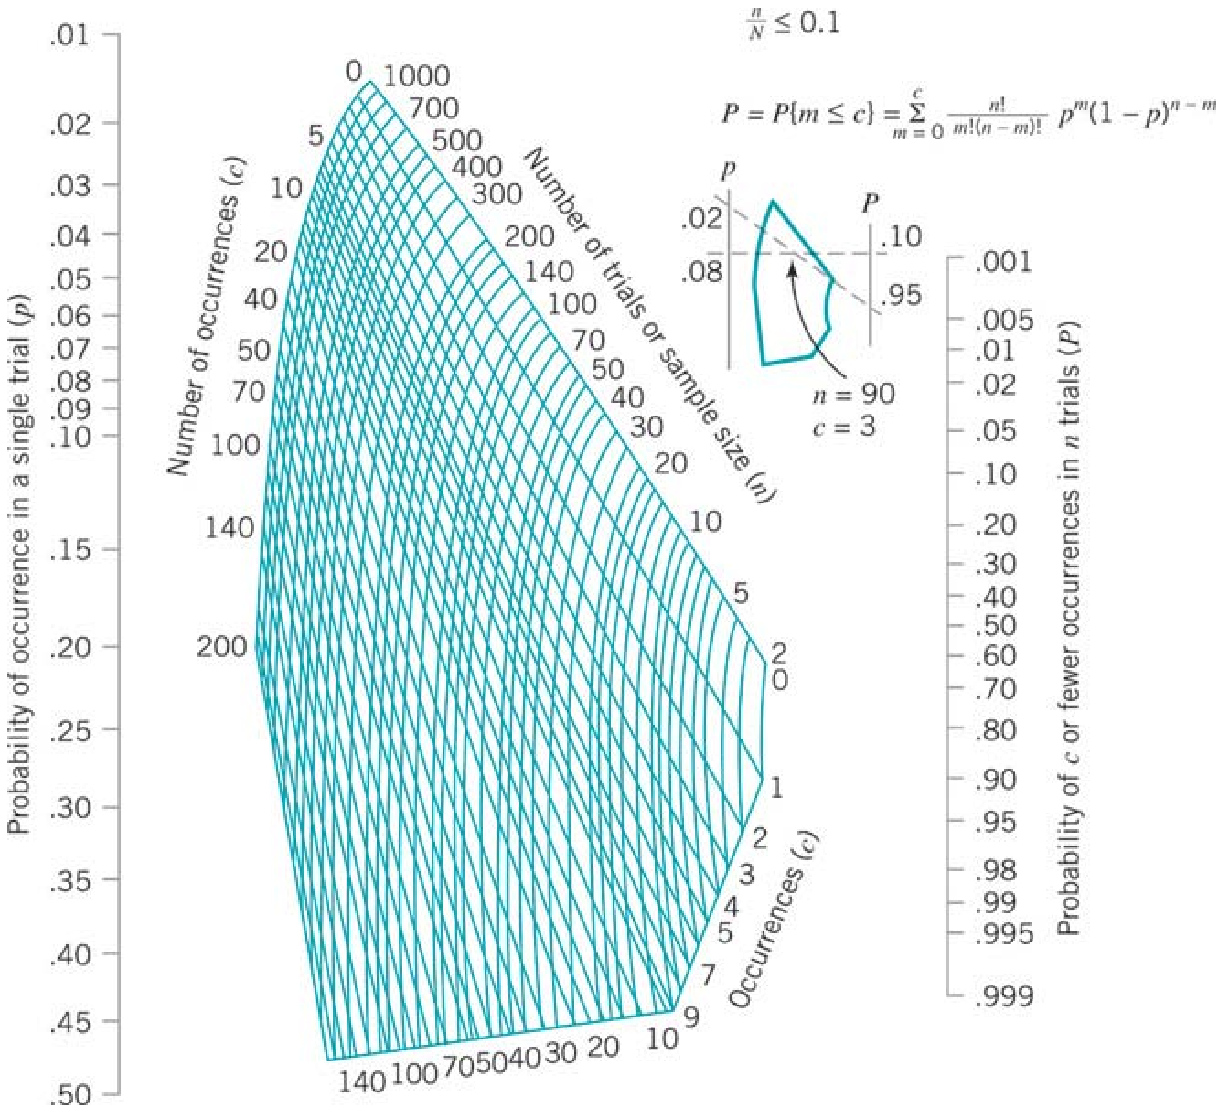


Figure 16.274: **Larson's binomial nomograph (source: Montgomery)**

✍**Example:**

A batch of bottles is delivered under the form of $10,000$ units corresponding to N. We seek to establish an approval control acceptance plan by attributes with the cumulative probability (supplier risk) α of 1% that the customer rejects the batch by error with less than 2.5% (p_α) of non-compliant. At his side the customer wishes a cumulative probability (customer risk) β of 10% of accepting by error a batch with more than 5% (p_β) of non-compliant (in fact the requirements are independent of the size N of the batch).

The goal is therefore to determine the value of A and n using the nomograph. For this, as shown in the nomograph, we must draw two lines:

- Starting points of the two lines: 0.99 (100% -1%) and 0.1 (10%) of the right axis.
- Finishing point of the two lines: 0.025 (2.5%) and 0.05 (5%) of the left axis.

and the intersection of the two lines will give the desired parameters. Thus in this case:

$$A \cong 30 \quad (16.7.693)$$

$$n \cong 700 \quad (16.7.694)$$

We also see that if we put these two values inside:

$$\begin{aligned} 1-\alpha &\cong \sum_{k=0}^{A} C_k^n p_\alpha^k (1-p_\alpha)^{n-k} = \sum_{k=0}^{A} C_k^n p_\alpha^k q_\alpha^{n-k} \\ \beta &\cong \sum_{k=0}^{A} C_k^n p_\beta^k (1-p_\beta)^{n-k} = \sum_{k=0}^{A} C_k^n p_\beta^k q_\beta^{n-k} \end{aligned} \quad (16.7.695)$$

with Microsoft® Excel®, we're actually far from the expected result! So the error of the nomograph can lead to the impression of rough approximations! But change in Microsoft® Excel® the value 30 by 27 and the value 700 by 695 and you'll see what you can conclude...

We also see through this example that an attribute acceptance plan is actually also much more expensive than a acceptance plan by measurement (since we took the same values of α and β as for the example with the same parameters as during our study of the acceptance plans with measurement but we have $n=700$ instead of $n \cong 18$).

The reader may have perhaps noticed that N does not affect the value of A and n when we use the Larson's nomograph. So if we use computer tools to find the solution, we can therefore put that n is between 0 and $1,000$ and A between 0 and 150 as we can see it on the nomograph.

Remark

Finally, let us indicate that some use the Poissonian approximation of the binomial distribution (when the probability (proportion) of non-compliants is very small and that the batch size is very big and sometimes even when these criteria are far from being respected ...) following:

$$P(k)=\frac{\lambda^k e^{-\lambda}}{k!} \Rightarrow P(k \leq c)=\sum_{k=0}^{c} \frac{(np)^k e^{-np}}{k!} \quad (16.7.696)$$

16.7.5.2.1 Calculation of the parameters using the norm ISO 2859-1

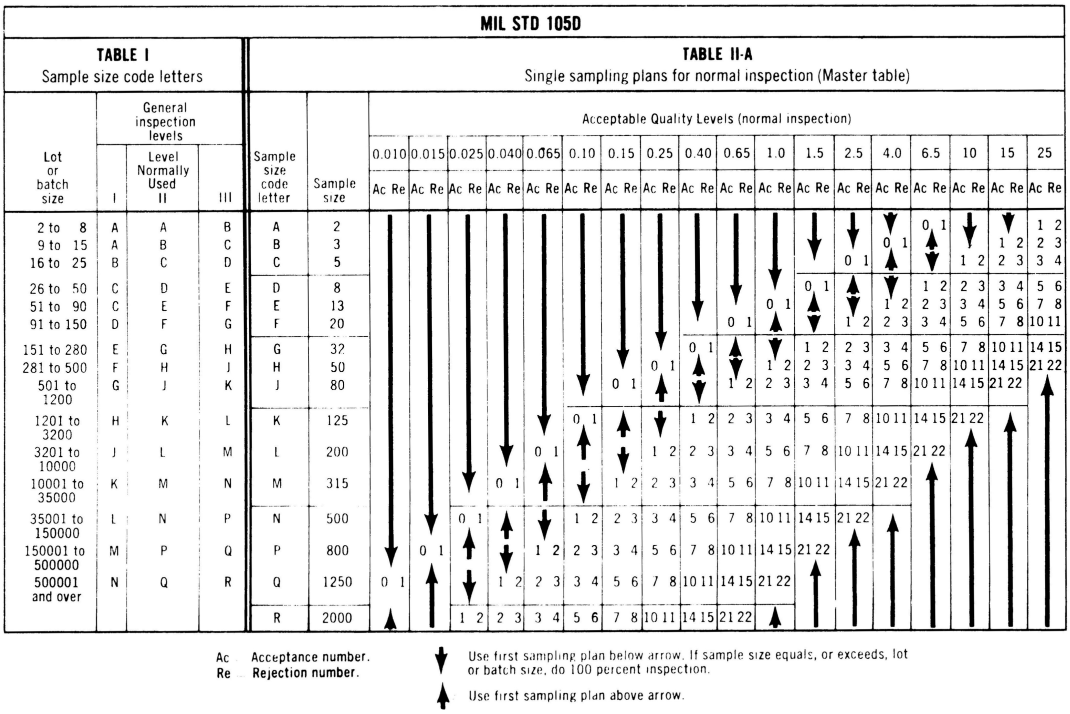
The norm ISO 2859 (which derives from the norm MIL 105E) is dedicated to sampling procedures for inspection by attributes. Along with the norm AFNOR X06-023 it is based on the concept of AQL (percentage of non-compliant items that should not be exceeded for a production, controlled on a series of batches, so that it can be considered as satisfactory).

Following this norm, the NQA must be one of the 26 values recommended by the norm. We will choose for example here the inspection level number II of this norm (they are described in the norm documentation). With respect to the chosen effective, as the AFNOR norm, ISO 2589 provides a symbol (letter) which will then be used in a table. Finally, depending on the type of acceptance plan (simple, double or triple) we find the parameters A and n.

✍**Examples:**

E1. In the context of our companion example - the producer of soft drinks - which receives batches of $10,000$ bottles, the AQL quality level is 1%. As for example with the AFNOR norm, we will take a type II control based on a simple acceptance plan.

A table in the norm (see below) tells us that we must use the code L for the next step. Then for simple control, the standard says to use to use the table IIA.



MIL STD 105D

TABLE I
Sample size code letters

Lot or batch size	General inspection levels I	General inspection levels Level Normally Used II	General inspection levels III
2 to 8	A	A	B
9 to 15	A	B	C
16 to 25	B	C	D
26 to 50	C	D	E

Ac = Acceptance number.
Re = Rejection number.
↓ Use first sampling plan below arrow. If sample size equals, or exceeds, lot or batch size, do 100 percent inspection.
↑ Use first sampling plan above arrow.

Figure 16.275: **MIL 105E acceptance sampling table**

We can then read that n must be equal to 200 and A is equal to 5. We therefore find that the value obtained is very different from that the one calculated theoretically. Honestly the reason for this difference is unknown to me...

E2. Practitioners in the use of this norm often want to calculate the supplier and customer risk factors associated to the values of n and A provided by the norm in relation to the NQA. selected for a batch of a given quality. So as in this case, $200/10,000$ is smaller than 10%, we can use the binomial approximation of the hypergeometric law. Suppose we therefore wish to calculate the risk for the supplier of the previous example (the one with the use of the nomograph):

$$\begin{aligned}1-\alpha &\cong \sum_{k=0}\sum_{k=0}^{A} C_k^n p_\alpha^k (1-p_\alpha)^{n-k} = \sum_{k=0}^{5} C_k^{200} 0.025_\alpha^k (1-0.025)^{200-k} \\ &= \texttt{BINOMDIST(5,200,2.5\%,1)} = 61.59\%\end{aligned} \tag{16.7.697}$$

hence a supplier risk of $100\%-61.59\%$ that is 38.40% which is considerable! Thus, this sampling plan obtained via the norm is suitable for proportions of non-compliants much lower that 2.5% (in fact less than $\cong 1.25\%$).

For the customer risk, we proceed in the same way:

$$\begin{aligned}\beta &\cong \sum_{k=0}^{A} C_k^n p_\beta^k (1-p_\beta)^{n-k} = \sum_{k=0}^{5} C_k^{200} 0.05_\beta^k (1-0.05)^{200-k} \\ &= \texttt{BINOMDIST(5,200,5\%,1)} = 6.23\%\end{aligned} \tag{16.7.698}$$

which is here a more acceptable result. In fact we find that the norm is more appropriated to the criteria of the customer rather than that of the supplier.

Remark

The software Quick Control Pro (used sometimes by the Swiss Watch industry) of the company Logystem SA manages the acceptance sampling according to the norms ISO 2859 and ISO 3951.

16.7.5.3 Double acceptance sampling plan by attribute

Now let us come back on the double acceptance sampling using the binomial approximation that is for recall:

$$P_a = P(X \leq A) = \sum_{k=0}^{A} P(n,p,X=k) = \sum_{k=0}^{A} C_k^n p^k (1-p)^{n-k} = \sum_{k=0}^{A} C_k^n p^k q^{n-k} \tag{16.7.699}$$

and let us consider a double sampling plan with:

$$\begin{aligned} n_1 &= 50 \\ n_2 &= 100 \end{aligned}$$

and where the proportion of non-compliant is known as being equal to 5%. So, in this case the cumulative probability of having, for example, at least 1 non-compliant item at the first sampling and corresponding to the probability of accepting the batch is equal to:

$$P_a^1 = P(X_1 \leq 1) = \sum_{k_1=0}^{1} \frac{50!}{k_1!(50-k_1)!} 0.05^{k_1} (1-0.05)^{50-k_1} \cong 0.279 \tag{16.7.700}$$

So far nothing special! Now to get the probability of acceptance of the batch on the second sampling, we list all the ways we can get the second sampling.

For this, suppose for example that the batch is accepted if and only if the cumulative number of non-compliant items overall the both sampling is between 2 and 3 units (arbitrary simplified choice for the example).

We then have the following possible ordered combinations of drawing between the two samplings (notice that the sum is always between 0 and 3):

$$\{0,2\},\{0,3\},\{1,1\},\{1.2\},\{3.0\},\{2.1\},\{2.0\}$$

But as already mentioned we accept the batch if and only the first sampling gives a number of non-compliant equal or less than 1, it then remains only the following combinations:

$$\{3,0\},\{2,1\},\{2,0\}$$

to consider in this double acceptance sampling. So we need to calculate the following probabilities:

$$\begin{aligned}P_a&=P_a^1+P_a^2=0.279+[P(X_1=2,X_2\leq 1)+P(X_1=3,X_2=0)]\\&\cong 0.279+[P(X_1=2)P(X_2\leq 1)+P(X_1=3)P(X_2=0)]\\&=0.279+\left[\begin{array}{c}\dfrac{50!}{2!48!}0.05^2 0.95^{48}\sum_{k_2=0}^{1}\dfrac{100!}{k_2!(100-k_2)!}0.05^{k_2}0.95^{100-k_2}+\\\dfrac{50!}{3!47!}0.05^3 0.95^{47}\dfrac{100!}{0!100!}0.05^0 0.95^{100}\end{array}\right]\\&\cong 0.279+[0.261\cdot 0.037+0.220\cdot 0.0059]=0.279+[0.0097+0.001]\\&=0.279+0.0107=0.2897\end{aligned}\tag{16.7.701}$$

16.7.5.4 Operating characteristic curve (OC)

The "operating characteristic curve" (OC) depicts the discriminatory power of an acceptance sampling plan (by measurement or by attribute!). The OC curve plots the probabilities of accepting a lot versus the fraction defective.

If we assume that the lot size N is very large, as compared to the sample size n, so that removing the sample doesn't significantly change the remainder of the lot, no matter how many defects are in the sample. Then the distribution of the number of defectives, d, in a random sample of n items is approximately binomial as we know.

When the OC curve is plotted, the sampling risks are obvious. You should always examine the OC curve before using a sampling plan.

The idea in practice is to compare OC curves to help choose the appropriate sampling plan for various n (sampling size) and A ("acceptance number[34]" often denoted c in the US literature of "criterion").

This curve that is obtained by plotting on a graph the cumulative probability of acceptance of a batch in function of the proportion of non-compliant items (named sometimes "effective quality" axes).

We can build this curve for the Normal approximation, Binomial approximation or also with the exact case of the Hypergeometric law!

✍**Example:**

For a quality control by attribute acceptance plan, we apply the control plan on a sample of $n=700$ items, the batch will be accepted if the number of non-compliant items is less than or equal to 30 ($A \leq 30$) or in percentages ($A \leq 4.28\%$) as determined in our previous example!

---

[34] The maximum number of defects that can find and still allow the lot to be accepted.

We want to plot the cumulative probability to accept the batch for a range of non-compliant proportion between $0-7\%$ by step of 0.1%.

Thus the purpose is explicitly to plot:

$$P_a(p)=P(X\leq A)=\sum_{k=0}^{A} C_k^n p^k qn-k=\sum_{k=0}^{A} C_k^n p^k(1-p)^{n-k} \tag{16.7.702}$$

That is often written in the US literature as:

$$P_a(d)=P(X\leq c)=\sum_{k=0}^{c} C_k^n d^k(1-d)^{n-k} \tag{16.7.703}$$

Therefore in our example:

$$P_a(p)=P(X\leq 5)=\sum_{k=0}^{5} C_k^{200} p^k(1-p)^{200-k} \tag{16.7.704}$$

In a spreadsheet software like Microsoft® Excel® 14.0.7166 this gives (first rows only):

	A	B
1	Effective	Cumulated Probability
2	0.00%	100.00%

24	4.40%	48.92%
25	4.60%	38.91%

	A	B
1	Effective Quality	Cumulated Probability
2	0	=BINOM.DIST(30,700,A2,TRUE)
3	0.002	=BINOM.DIST(30,700,A3,TRUE)
4	0.004	=BINOM.DIST(30,700,A4,TRUE)
5	0.006	=BINOM.DIST(30,700,A5,TRUE)
6	0.008	=BINOM.DIST(30,700,A6,TRUE)
7	0.01	=BINOM.DIST(30,700,A7,TRUE)
8	0.012	=BINOM.DIST(30,700,A8,TRUE)
9	0.014	=BINOM.DIST(30,700,A9,TRUE)
10	0.016	=BINOM.DIST(30,700,A10,TRUE)
11	0.018	=BINOM.DIST(30,700,A11,TRUE)
12	0.02	=BINOM.DIST(30,700,A12,TRUE)
13	0.022	=BINOM.DIST(30,700,A13,TRUE)
14	0.024	=BINOM.DIST(30,700,A14,TRUE)
15	0.026	=BINOM.DIST(30,700,A15,TRUE)
16	0.028	=BINOM.DIST(30,700,A16,TRUE)
17	0.03	=BINOM.DIST(30,700,A17,TRUE)
18	0.032	=BINOM.DIST(30,700,A18,TRUE)
19	0.034	=BINOM.DIST(30,700,A19,TRUE)
20	0.036	=BINOM.DIST(30,700,A20,TRUE)
21	0.038	=BINOM.DIST(30,700,A21,TRUE)
22	0.04	=BINOM.DIST(30,700,A22,TRUE)
23	0.042	=BINOM.DIST(30,700,A23,TRUE)
24	0.044	=BINOM.DIST(30,700,A24,TRUE)
25	0.046	=BINOM.DIST(30,700,A25,TRUE)

And if we do a plot adding at the same time the OC curve using the hypergeometric law and the ideal OC curve (sampling plan that discriminates perfectly between good and bad batches) we get:

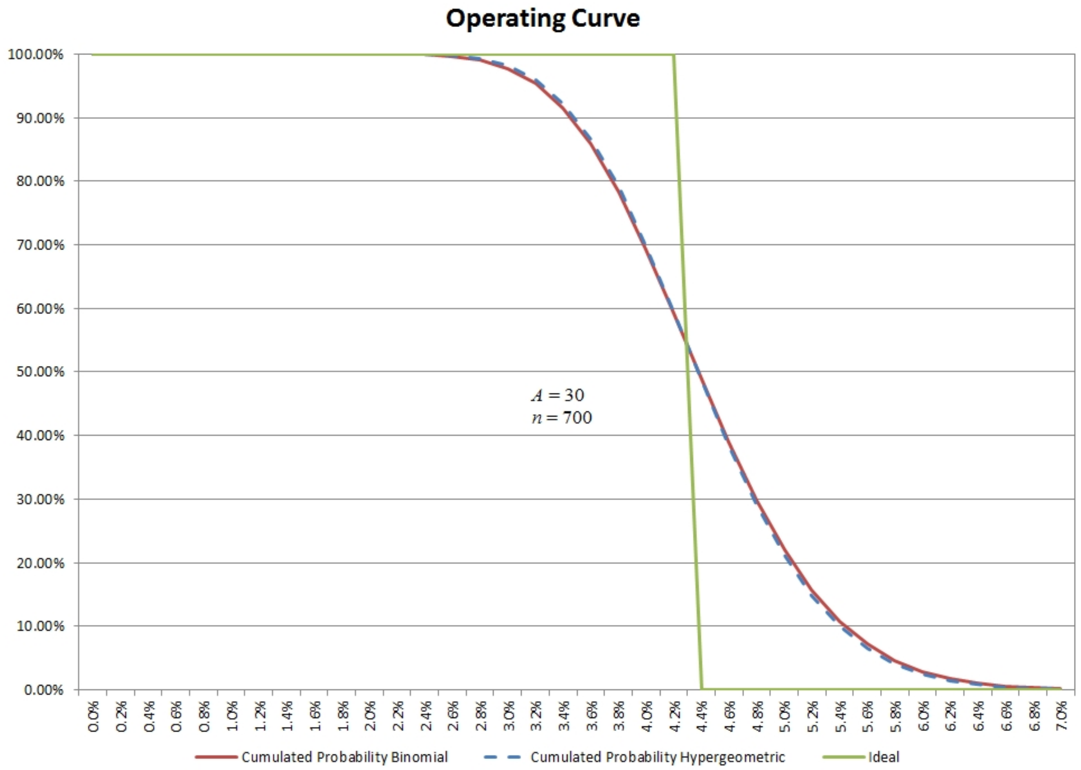

Figure 16.276: Binomial, Hypergeometric and Ideal OC for AQL$=2.5\%$ and $n=200$

Where remember that the values of A and n came from the fact that we seek to establish an approval control acceptance plan by attributes with the cumulative probability (supplier risk) α of 1% that the customer rejects the batch by error with less than 2.5% (p_α) of non-compliant. At his side the customer wishes a cumulative probability (customer risk) β of 10% of accepting by error a batch with more than 5% (p_β) of non-compliant (in fact the requirements are independent of the size N of the batch).

So as we can see, for $A=30$, $n=700$ we have almost 100% probability to accept a batch that has between 0 and almost 2.5% proportion of non-compliant items. After the probability to accept a batch by error decreases as the real proportion of non-compliant items increases (this is quite obvious!).

The reader can see in the Minitab companion book that we get the same binomial OC curve!

An elegant way to represent the concepts of an operating curve without forgetting that in the binomial case:

$$\begin{aligned}1-\alpha &\cong \sum_{k=0}^{A} C_k^n p_\alpha^k (1-p_\alpha)^{n-k}\\ \beta &\cong \sum_{k=0}^{A} C_k^n p_\beta^k (1-p_\beta)^{n-k}\end{aligned} \tag{16.7.705}$$

is as follows:

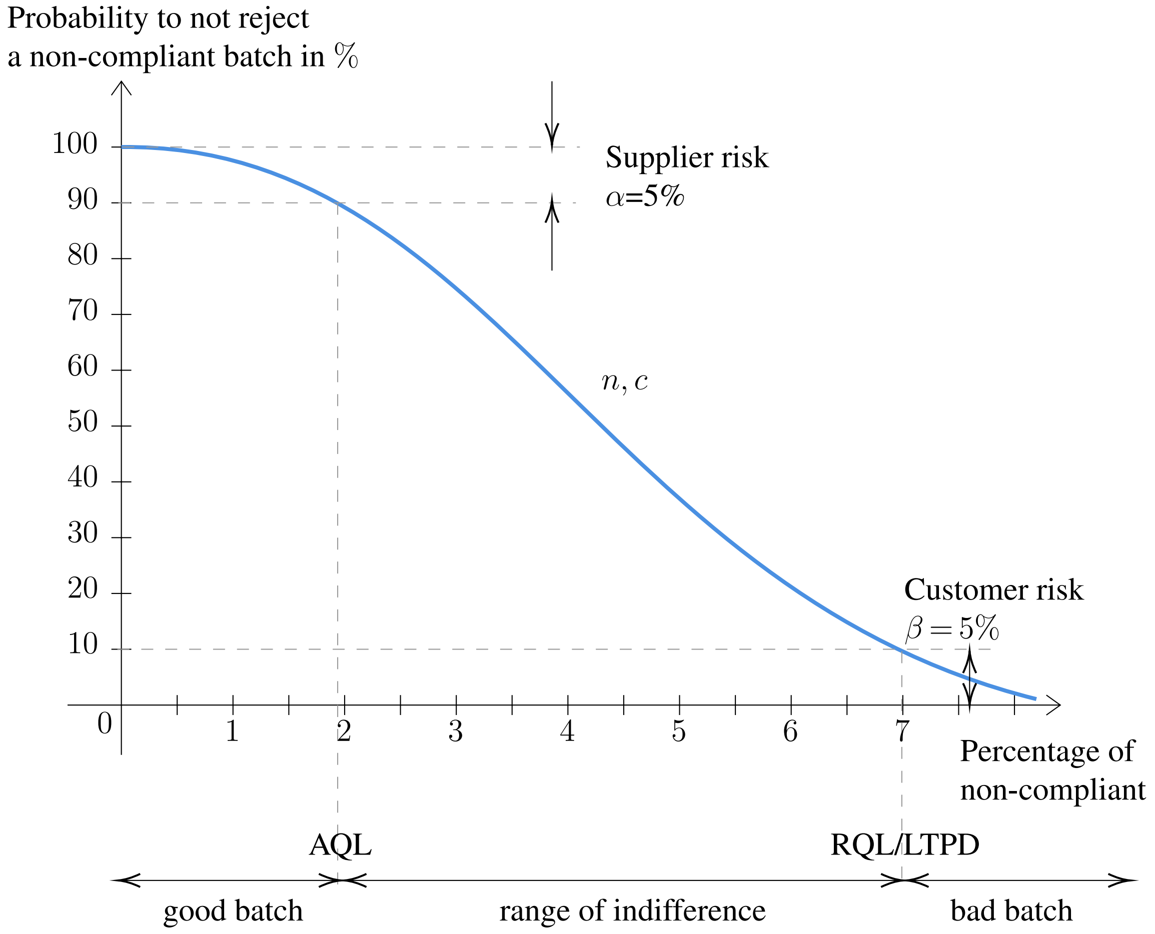

Figure 16.277: **Operating curve summary**

The operating curve shows that the probability of accepting a defective batch decreases - for a constant batch size - when the percentage of defective items in the batch increases: when the quality is good, the probability of accepting the batch by error is high; when the quality is bad, the probability of accepting the batch by error is small.

This type of operating curve based on large sampled batches (dixit using the binomial distribution) is named in the case of using the binomial distribution "operating curve of type B" (OC-B). If obviously the sample size is significant relatively to the size of the batch we will use the hypergeometric and we'll talk then of "operating curve of type A" (OC-A).

16.7.5.5 Average outgoing quality (AOQ)

The batches not accepted by a sampling plan will usually be 100% inspected or screened for nonconforming or defective units. After screening, nonconforming units may be rectified or discarded or replaced by good units, usually taken from accepted lots. Such a program of inspection is known as a "rectifying inspection" or "screening inspection". For those batches accepted by the sampling plan, no screening will be done and the outgoing quality will be the same as that of the incoming quality p.

Since the cumulative probability of accepting by error a bad batch is P_a , the outgoing batches will contain obviously proportion of $P_a \cdot p$ defectives. If only the nonconforming units found in the sample of size n are replaced by good ones, the "average outgoing quality (AOQ)" (its an average proportion!!!) in batches size of N will be given obviously by:

$$\text{AOQ} = \frac{N-n}{N} P_a \cdot p \tag{16.7.706}$$

and for large N we get the approximation:

$$\text{AOQ} \cong P_a \cdot p \tag{16.7.707}$$

So the average outgoing quality is the expected outgoing quality of a lot (of a given incoming quality) after rectifying inspection has been performed!

Using always our companion example with the bottle batch and using always the same spreadsheet software we have (first rows only):

	A	B	C
1	**Effective**	**Cumulated Probability Binomial**	**AOQ**
2	0.00%	100.00%	0.00%
3	0.20%	100.00%	0.19%

21	0.038	=BINOM.DIST(30,700,A21,TRUE)	=(10000-700)/10000*B21*A21
22	0.04	=BINOM.DIST(30,700,A22,TRUE)	=(10000-700)/10000*B22*A22
23	0.042	=BINOM.DIST(30,700,A23,TRUE)	=(10000-700)/10000*B23*A23
24	0.044	=BINOM.DIST(30,700,A24,TRUE)	=(10000-700)/10000*B24*A24
25	0.046	=BINOM.DIST(30,700,A25,TRUE)	=(10000-700)/10000*B25*A25
26	0.048	=BINOM.DIST(30,700,A26,TRUE)	=(10000-700)/10000*B26*A26
27	0.05	=BINOM.DIST(30,700,A27,TRUE)	=(10000-700)/10000*B27*A27
28	0.052	=BINOM.DIST(30,700,A28,TRUE)	=(10000-700)/10000*B28*A28
29	0.054	=BINOM.DIST(30,700,A29,TRUE)	=(10000-700)/10000*B29*A29
30	0.056	=BINOM.DIST(30,700,A30,TRUE)	=(10000-700)/10000*B30*A30
31	0.058	=BINOM.DIST(30,700,A31,TRUE)	=(10000-700)/10000*B31*A31
32	0.06	=BINOM.DIST(30,700,A32,TRUE)	=(10000-700)/10000*B32*A32

and the corresponding chart made by selecting the both last columns:

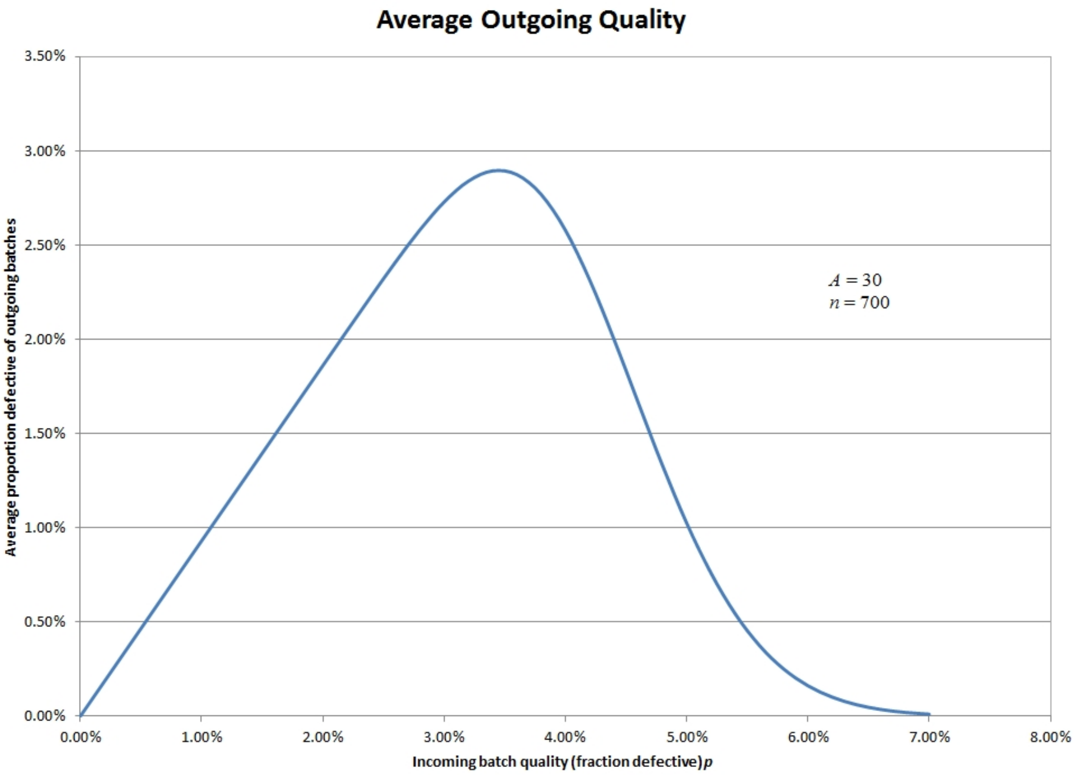

Figure 16.278: **AOQ (Average Outgoing Quality) binomial chart** $A = 30$, $n = 700$

The maximum ordinate of the AOQ curve is known as the "average outgoing quality limit (AOQL)".

So to close this subject we can see below (in the bottom left corner) that Minitab 17.3.1 gives us a result that is not far from our estimation of the Larson's nomograph (yes remember that we get earlier above $A \cong 30$ and $n \cong 700$) and that we also get the same operating curve and average outgoing quality plot:

16.7.6 Quality Control Charts (CC)

A "control chart" (sometimes also referred to as "sequence chart" or "Shewhart chart" or "process-behaviour chart") is a planar empirical representation of the variation of an accurate measurement of a process or a method where the vertical axis represents the quantitative indicator selected and the horizontal axis represents the time or corresponding number of outgoing units (so it is a subfamily of "run charts").

This non-destructive method of quality control that is say to be "on-line" (as the acquisition can be done in real time) permits to highlight special causes of variation and then to optimize the frequency of maintenance operations or recalibration) in the purpose to determine if a manufacturing or business process is in a state of statistical control (or is moving into such a state) and to separate signal from noise!

This technique seems to have been created by the physicist engineer Walter A. Shewhart while working for Bell Labs in the 11920s (holocene calendar) and is since some decades (11991 to be exact) an ISO standard under the name *ISO 8258:1991 - Shewhart control charts*. Moreover, it is also Shewhart who inspired the well known W. Edwards Deming (statistician) in the field of project management and quality (all the masters in the field of advanced project management have a scientific background...).

In the early use of control charts, it is advisable to put control charts on all important measurable product characteristics. The resulting chart generally show quickly what charts are necessary or unnecessary (in reality the quality manager has also to conduct a CoQ - Cost of Quality - analysis). Unnecessary or inappropriate control charts will be removed and other control charts might be added.

The most basic and intuitive planar control chart could looks like this:

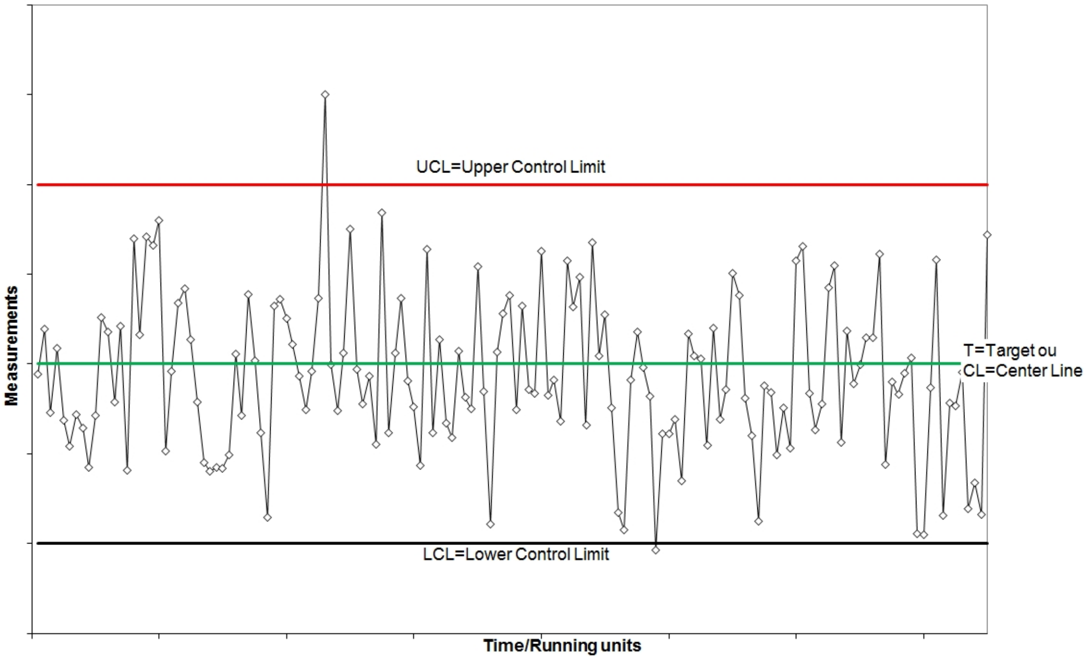

Figure 16.279: **Naive control chart**

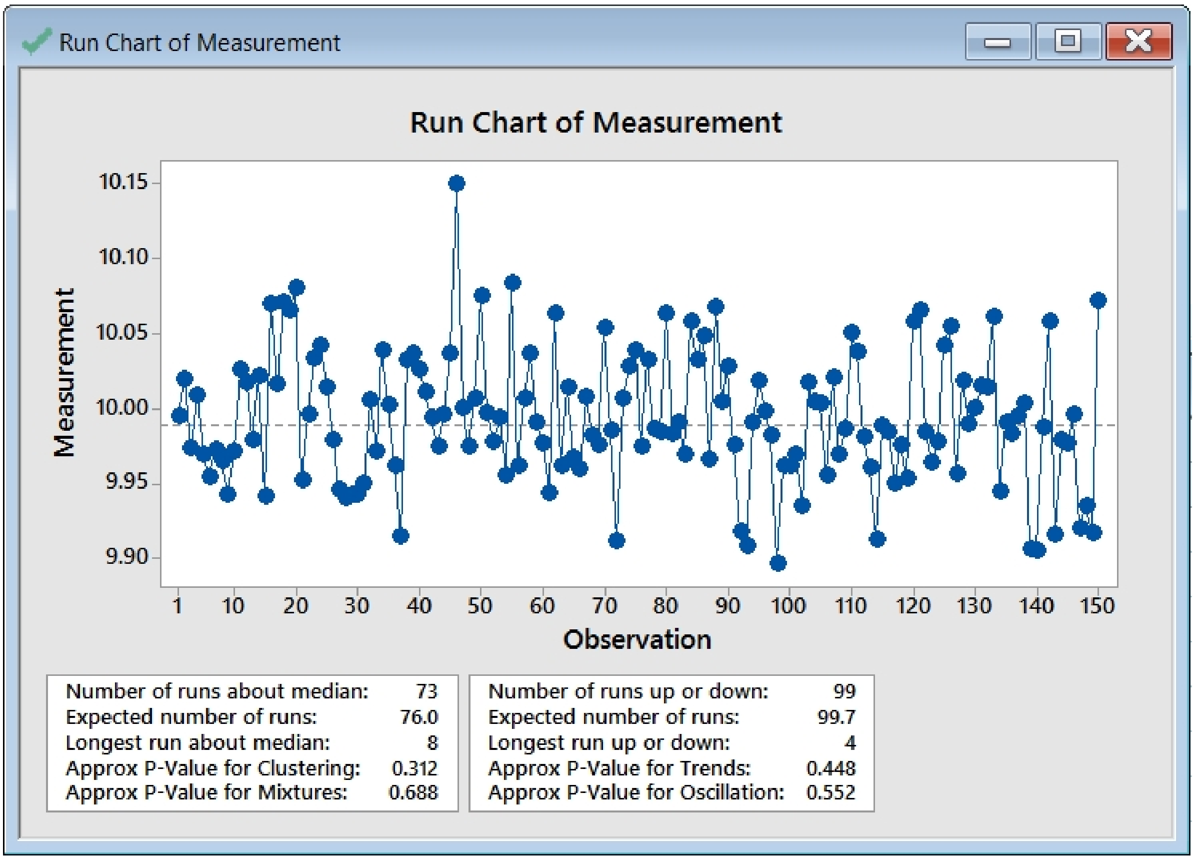
The upper and lower limits can be requested / specified by a customer and therefore we note them, as we already know, USL (Upper Specification Limit) and LSL (Lower Specification Limit), otherwise they are calculated internally and therefore we denote them by "UCL (Upper Control Limit)" and "LCL (Lower Control Limit)". To improve the effectiveness of a control chart, we sometimes add on chart narrower limits named "monitoring limits" (in reality we almost always represent the limits calculated AND requested by the quality control policy on the control chart).

The "Center Line (CL)" is most of time chosen as the arithmetic average of all measurement but it should be better to choose the Median as we already know. The "Target (T)" is the value requested as an ideal by the customer specifications.

The equivalent run chart of the above chart (created with Microsoft® Excel®...) but now made with a professional software like Minitab 17.3.1 gives:



```
Number of runs about median:      73
Expected number of runs:        76.0
Longest run about median:          8
Approx P-Value for Clustering: 0.312
Approx P-Value for Mixtures:   0.688
```

```
Number of runs up or down:         99
Expected number of runs:         99.7
Longest run up or down:             4
Approx P-Value for Trends:      0.448
Approx P-Value for Oscillation: 0.552
```

Figure 16.280: **Run Chart with Minitab 17.1.3**

In practice I highly recommend to represent the center line (CL) and also UCL (Upper Control Limit), LCL (Lower Control Limit) as in reality there is normally always limits and goals that are imposed contractually by the customer but also to represent the target T and USL (Upper Specification Limit), LSL (Lower Specification Limit) on the same control chart when possible!!!

The control chart is therefore a measurement tool for viewing and sometimes anticipating the changes and thus determine when an assignable cause occurs causing a drift of a business process or manufacturing processor a variation of a financial value on stock markets requiring rapid corrective action to reduce the costs of non-quality or losses. Thus, ideally the process will be stopped or corrected at the right time, that is to say before it produces too many non-compliant deliverables / services (outside the tolerance) and therefore to avoid overcontrol (useless re-calibrating because of common variability or application of acceptance plan).

The type of control chart corresponds to the type of characteristic that is the subject of a control. However the economic aspect may be an important factor in the choice of the control chart to implement (time for measurement, destructive or non-destructive procedure and son...). If we look at whether a characteristic complies or not with certain norms, an "attribute control chart" (see further below for the details) will be used, but requires a big sample size. Control on quantitative and almost continuous characteristics requires the use of "measurement control charts" and if the measurement are not independent of "time series control charts". This type of measurement control is more efficient and more precise but also more expensive since it requires the use of measuring instruments that should be checked or re-calibrated regularly. We have also for two dimensional correlated controls the "multivariate control charts".

Another very famous type of control chart is that applied to the residual of regression models and named therefore "residuals control charts" that work for Gaussian, Poisson, or Binomial or even Negative Binomial regression models. Many statistical softwares by defaults when running a regression analysis plot such a residual control chart to assess visually the homoscedasticity and normality (or other) of the residuals!

Remark

The subject of control charts is immensely vast and there is an abundant English literature on the subject. We wish to give here only the fundamental (and therefore only basic control charts!) to show a practical application of the theory or Range Statistics and of Statistics of extreme values outliers developed that we have developed in detail in the section Statistics (see page 1203). To place an order of magnitude, most specialized software offers between 10 and 30 different control charts (Minitab, R, JMP, QI Macros, MATLAB®)!

Before going into the mathematical details notice that the control charts among the most used one are the control charts by measurement of the average $\bar{X}$ in combination with the control charts by range R with Shewhart's limits (when we speak of "Shewhart's limits" we are implicitly referring to the fact that the upper control limit UCL and the lower limit control LCL are empirically calculated at $\pm 3\sigma$ of the arithmetic average of the distribution that the latter is symmetrical or not!). These both control maps are used and interpreted most of time together because both parameters are independent and complementary and simple to understand (even if the majority of employees in companies does not know what is a standard deviation). Indeed, the arithmetic average value can vary without that the range varies and vice versa[35].

Remarks

R1. In the case of a control charts with Shewhart's limits, monitoring limits are traditionally placed at $\pm 2\sigma$ (at the opposite of the control limits that are placed at $\pm 3\sigma$).

R2. In the case of a Normal distribution $\mathcal{N}(\mu,\sigma)$, $\pm\sigma$ corresponds to a 99.73% confidence interval as we have seen earlier in this section and also in the section Statistics. This therefore corresponds to a α of about:

---

[35] Remember the trap of the Anscombe's quartet that we saw in the section Statistics

$$\alpha \cong 100\% - 99.75\% = 0.27\% \tag{16.7.708}$$

Most of the industry therefore takes $\pm 3\sigma$ as limits, but strictly speaking distributions of certain control charts are not symmetrical. We should then take terminals (limits) corresponding to a cumulative probability of $\alpha/2$ which can be calculated quite easily with many distributions (but not all!) just by having available an inexpensive spreadsheet software. The choice of the value α depends on the company's quality policy and has the advantage of being a much more accurate indicator that the Shewhart's limits (the latter being wrong when the distributions are skewed).

R3. Shewhart seems to have proposed that there must be at least 25 samples of 4 individuals for the validity of certain control charts (that we will see further below) to be acceptable.

R4. As we will see it, almost all measurement control charts assume Normal distribution and that the observations are independent (between sub-groups and within subgroups!!). For example (example that will be detailed mathematically further below), for already stable processes as since started a long time ago, we perform several individual observations on several subgroups numbered at a given time frequency (hourly, three times per day ...). On each ordered subgroup k (chronological incrementation), we perform n observations. We report on the control chart the arithmetic average $\bar{X}$ of subgroup according to its chronological number k to be reported on the horizontal axis of the control chart. Because of the central limit theorem (CLT) proved in the section Statistics (see 938), the average values $\bar{X}_k$ of the control chart follows a Normal distribution $\mathcal{N}(\mu, \sigma/\sqrt{n})$ (so symmetrical distribution!) that the observations of the subgroups are Normally distributed or not but at the condition there are independent and identically distributed over time!!! This assumption is valid even for small sample size and a manufacturing process under control, which is common in quality control. Production is said to be "stable" as we know if the tendency and dispersion are statistically constant over time (and considered identically distributed independent variables).

16.7.6.1 WECO's empirical rules

The interpretation of a control chart is not always easy and requires experience and expertise to know if corrective action are required or not. The "Western Electric Rules" were codified by a specially-appointed committee of the manufacturing division of the Western Electric Company and appeared in the first edition of its *Statistical Quality Control Handbook* in 11956 (holocene calendar). Their purpose was to ensure that line workers and engineers interpret control charts in a uniform way (the French health ministry did the same 50 years later ... but with rules that differ a little).

The WECO based at this time on the assumption that the statistical distributions are always symmetrical (same assumption as Shewhart) and has then adopted in the statement of control rules limits that are integer multiples k of the standard deviation. Of course, nothing prevents the quality specialist to adapt these rules with probabilistic limits corresponding to a given confidence interval (the majority of specialized software gives the possibility to select the WECO rules to be applied automatically for the detection of non-conformities).

In the measurement control charts type, among these rules here are those that are applicable in order to identify whether a process has failed and that have been completed over the years by other specialists (we have represent below only some rules into a single control chart for obvious pedagogical reasons):

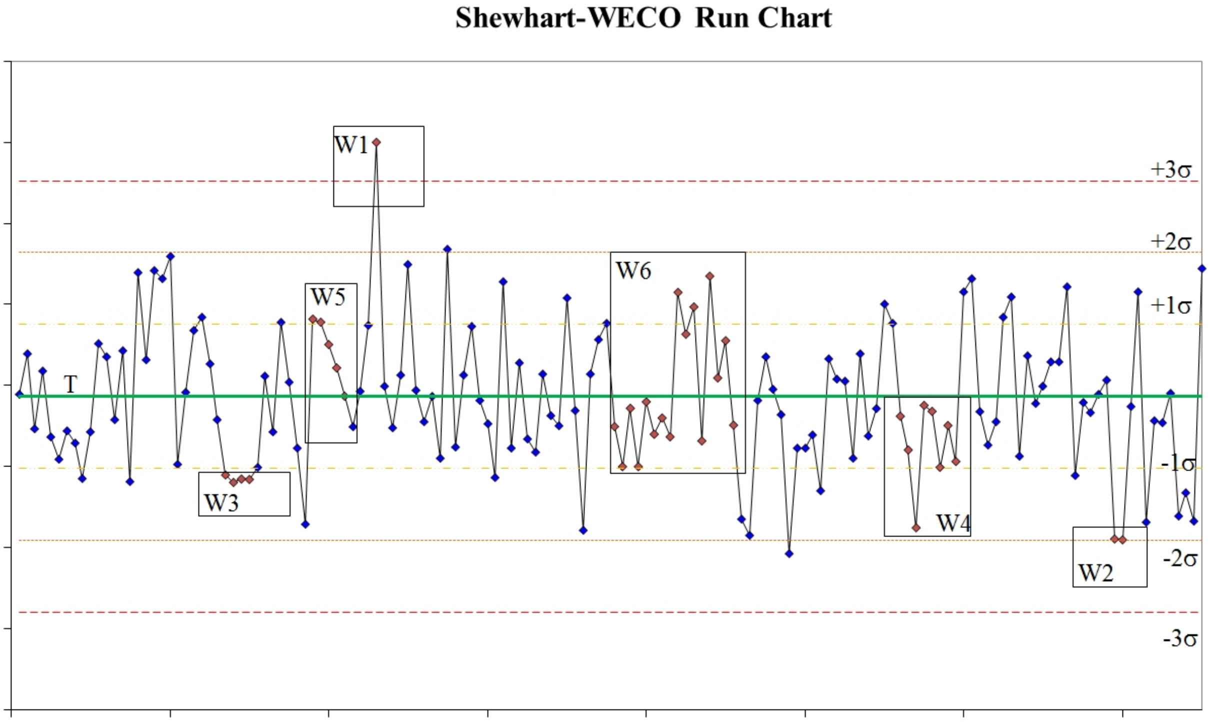


Figure 16.281: **Some WECO rules on a Run Chart**

On the next page you can find some of the empirical "Shewhart-WECO" rules:

W1. A measured point is beyond the USL, LSL specified by the customer or beyond the empirical or probabilistic UCL, LCL corresponding to $\pm 3\sigma$.

W2. Two consecutive measured points are beyond the empirical or probabilistic UCL, LCL corresponding to $\pm 2\sigma$.

W3. Four consecutive measured points are beyond the empirical or probabilistic UCL, LCL corresponding to $\pm 2\sigma$ (in this case named "alert limits").

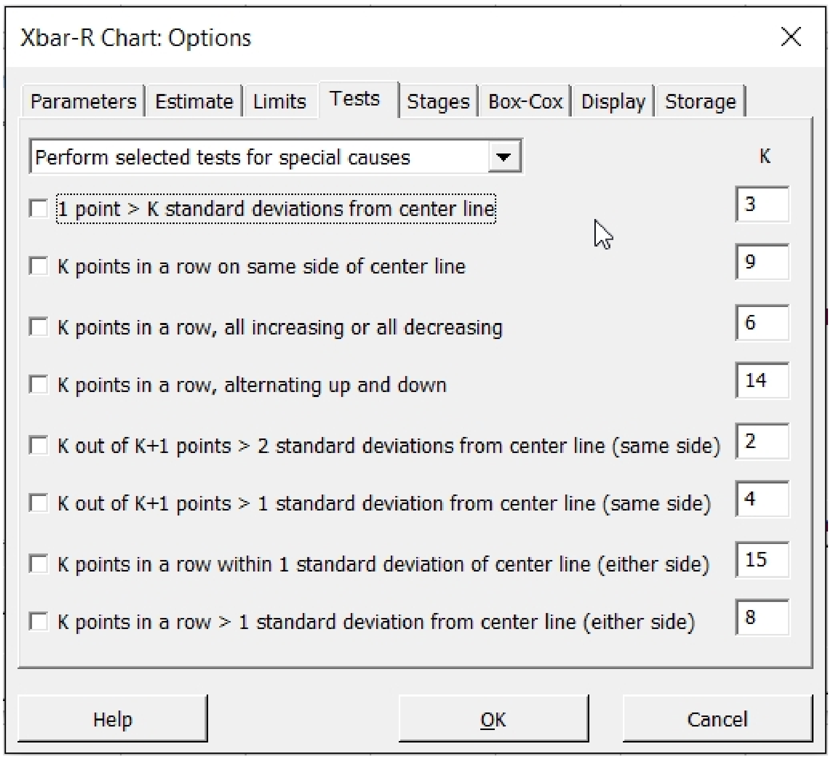
W4. Eight consecutive points fall on the same side of the mean (even if once again the use of the median is more accurate and robust).

W5. Six consecutive points are on an uptrend or downward trend respectively.

W6. Fourteen consecutive points on a systematic up/down alternation trend.

The rules presented above apply to control charts with symmetric control limits. The WECO handbook provides additional guidelines for control charts where the control limits are not symmetrical, as for R charts and p-charts...

As the reader can see below, Minitab includes at least 8 empirical rules (named the "Nelson rules" and first published in the October 11984 (holocene calendar) issue of the Journal of Quality Technology in an article by Lloyd S. Nelson) and that can be furthermore customized:



Perform selected tests for special causes

	K
☐ 1 point > K standard deviations from center line	3
☐ K points in a row on same side of center line	9
☐ K points in a row, all increasing or all decreasing	6
☐ K points in a row, alternating up and down	14
☐ K out of K+1 points > 2 standard deviations from center line (same side)	2
☐ K out of K+1 points > 1 standard deviation from center line (same side)	4
☐ K points in a row within 1 standard deviation of center line (either side)	15
☐ K points in a row > 1 standard deviation from center line (either side)	8

Figure 16.282: **Example of WECO rules implemented in Minitab 17.3.1**

Remark

The reader can also refer to "Westgard Rules" that are a set of rules used for laboratory quality control. They are a copyrighted set of modified Western Electric rules, developed by James Westgard and provided in his books and seminars on quality control.

If the process/method is out of control, corrective actions must be implemented (process review, training, recalibration, code update, etc.). The causes of variation may be obviously random or deterministic. If the causes are only due to chance, then they are named "random causes" (Shewhart) or "common causes" (Deming) and are therefore treated as instantaneous dispersion. Not all changes are due to chance, of course, some are specific and identifiable in a deterministic a certain way. In the latter case, the variations are named "assignable variations" (Shewhart) or "special causes" (Deming) and are assimilated to the overall dispersion (see in the section Statistics the subsection about the propagation of errors at page 1307).

Correct the special causes is obviously most of time much easier than correcting random causes. The primary purpose of control charts is obviously identifying special causes...

OK that's all regarding the customs and traditions of interpretation of measurement points. Now this non-mathematical prelude done, let us see the different types of control charts with a concrete example for each.

16.7.6.2 Sample size and Sampling frequency for Control Charts

The use of control charts pose early two major difficulties:

1. Choosing the family and type of control chart as we have (6 main families, with 25 control charts and including the typical variants to calculate a same control chart, we have a total of almost 60 control charts in reality...!):
    - Variable charts for individuals (continuous data):
        - Levey-Jennings (Pearson standard deviation)
        - Individuals (Pearson standard deviation)
        - I-MR for long runs (Hartley standard deviation)
        - Z-MR for short runs (Hartley standard deviation)
        - Moving Range (Hartley standard deviation)
    - Variable charts for small subgroups (continuous data):
        - Xbar-R (Hartley standard deviation)
        - I-MR-R (Hartley standard deviation)
        - R (Hartley standard deviation)
        - Median-R (Hartley standard deviation)
    - Variable charts for subgroups (continuous data):
        - Xbar-S (Burr standard deviation)
        - I-MR-S (Burr standard deviation)
        - S (Burr standard deviation)

  - Median-S (Burr standard deviation)
- Attribute charts (discrete data):
  - P (binomial proportion)
  - Laney P'/U'
  - NP (binomial np law)
  - C (Poisson counting)
  - U (normalized Poisson)
- Time-weighted charts:
  - Moving Average (prior, central or averaged abscissa)
  - EWMA
  - CUSUM
- Multivariate charts:
  - T-squared
  - Multivariate EWMA
- Rare events charts
  - T (Poisson)
  - G (Negative-Binomial distribution)
- Changepoint Analysis
  - AMOC (At Most One Change) Method
  - PELT (Pruned Exact Linear Time) Method
  - BCP (Bayesian change point) analysis
  - Segmentation Method
  - Tree Method
  - Join-pin regression

2. The choice of the sample size n and of the sampling frequency f_s.

We would here discuss the second point! We must first observe that it is obviously the pace of execution and the quality of operation and also the time it takes to measure the feature (characteristic) that will give us the answer. This quality is appreciated by the average number of corrective interventions observed during a specific period in the past (MTBF typically). The more corrective action there are, the less the quality of the operation of the method / process is good and the higher will be the sampling frequency!

The choice of the sample size is not a problem because as it will result from the statistical calculation of the confidence interval of the statistical indicator that we impose ourselves (see the study of Acceptance Plan earlier above) and therefore of the used distribution law and its properties and also of the assumptions of the chosen the control chart (see below in the text that follows the mathematical description of main control charts).

The challenge is there to determine the sampling frequency. There are for this four main methods and the two first are quite empirical (rule of thumbs):

- Choose a frequency such that the corrective actions T_c are at least four times lower than the sampling frequency (this criterion is independent of the sample size and therefore sometimes not very applicable...):

$$f_s = \frac{T_c}{4} \tag{16.7.709}$$

- We consider T_p as the life of the method / process between each change / modification. We denote as usual n the sample size respecting acceptance plan rules (see previously). We will denote N the number of executions of the method / process (number of produced items) during the period T. So we have a maximum N/n samples that are possible.:

$$f_s = \frac{T_p}{N/n} \tag{16.7.710}$$

- Another method consist to use the MTBF (Mean Time Between Failure) and that as we have proved during our study of reliability techniques is given for recall in the case of the Weibull distribution with three parameters by:

$$f_s = \text{MTBF} = \gamma + \eta\Gamma_{-1}\left(\frac{1+\beta}{\beta}\right) \tag{16.7.711}$$

  or in the case of an exponential law:

$$f_s = \text{MTBF} = \int\limits_0^{+\infty} t\lambda e^{-\lambda t}\mathrm{d}t = \frac{1}{\lambda} \tag{16.7.712}$$

- The last method consist to use a concept we will prove further below and that give a lower bound for the sampling frequency and that is the "average run length" given by:

$$\text{ARL}_0 = \frac{1}{\alpha} \tag{16.7.713}$$

So at a first glance it's not easy to choose a control chart if we are not trained and used to them. So see for example here how the Minitab wizard helps the users to decide what control chart to choose (as you can see the wizard hides the real complexity as most charts are not visible... even if they are available in Minitab menus!):

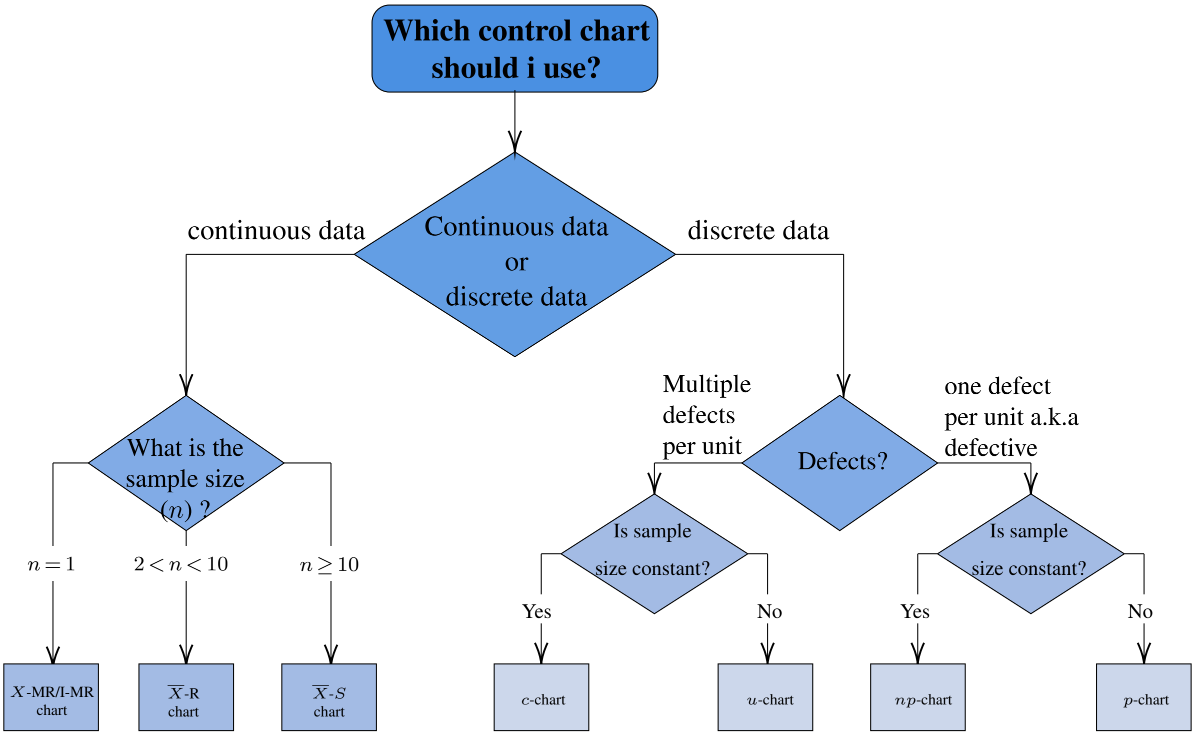
We can find some training centers that provide more complete decision charts but that are sadly a bit misleading (as we will prove it later with the maths). Typically the decision chart below is more complete than the one of Minitab (but simplicity is at the price of exactitude...):



Which control chart should i use?
Continuous data or discrete data

Is sample size constant?
Yes
No
c-chart
u-chart
np-chart
p-chart

Figure 16.284: **iSixSigma control chart wizard**

In all control charts that we will see below, we have presented examples with constant sample size (hence the limits of control charts are always constant with some exceptions that we will also see). Indeed, if the size of the samples change it is that the production rate (or batch size of delivery) has changed or also the overall quality and therefore the manufacturing parameters too. Then we should start a new control chart! It is the same after a re-engineering or changes of the process as shown in the Minitab 15.1.3 screenshot below:

16.7.6.3 Attributes Control Charts (qualitative CC)

To measure qualitative variables (% of defective, % failures, ...), we use attributes p control charts (binomial with proportion), np control charts (binomial with counts), c control charts (Poisson with counts), U control charts (Poisson with percentages) or Laney control charts (two by two range normalized proportions) to monitor the attributes quality control over time.

The attributes by control charts are very easy to study (undergraduate maths only!) use and interpret this is why we teach them always first, but has several disadvantages such as the high asymmetry of distributions, no lower limit for small sample sizes, low efficiency of deterioration detection.

16.7.6.3.1 P Control Charts (binomial proportion CC)

The p control chart (binomial by proportion) is used when it comes to work with ratios, proportions or percentages of compliance or non-compliance of samples.

Good examples of p-type control charts are: product inspection of a production line or receiving batches of a supplier or control malfunction of a number of devices, respect of deadlines, product specifications or also coding line errors (bugs).

Pros:

- This type of control chart is very simple to construct because does not require any advanced statistical knowledge to be calculated.

Cons:

- In reality it's a control chart which control limits may be asymmetric if the practical application are at the limit of acceptable when the theoretical assumptions of construction of this chart are not met.
- Sometimes a difficulty encountered by practitioners of this chart is to determine the batch size and the level of acceptance (A) or rejection (R) equivalent to the USL by taking the decision based on the developments (and norms) of acceptance plans samples seen earlier above.
- This control chart is not suitable for exhaustive sampling since it would then required the use of the hypergeometric law. Unfortunately, as far as we know, there is no analytic relation for the confidence interval of the proportion of a hypergeometric distribution, and therefore is not feasible to build a control chart based on a hypergeometric law.
- A final difficulty is that some employees and board committee are not proficient with the concept of percentages.

The probability law used in this context is the binomial distribution (see section Statistics page 658) where p will represent the proportion in $\%$ of non-compliants and q (which therefore is $1-p$) that proportion in $\%$ of compliants.

We saw in the section Statistics (see page 872) that we were able to write formally, under certain assumptions, the following confidence interval for the real proportion:

$$\hat{p}-Z_{\alpha/2}\sqrt{\frac{\hat{p}(1-\hat{p})}{n}}\leq p\leq\hat{p}+Z_{\alpha/2}\sqrt{\frac{\hat{p}(1-\hat{p})}{n}} \qquad (16.7.714)$$

So we can calculate the probabilities of non-compliant batches by excess or by defect using the fact that p follows under statistical control a Normal distribution of parameters:

$$\mathcal{N}(\mu,\sigma)\cong\mathcal{N}\left(\hat{p},\sqrt{\frac{\hat{p}(1-\hat{p})}{n}}\right) \qquad (16.7.715)$$

In short, we have no choice but to base this control chart on this assumption. Therefore, the first step in creating a p-type control chart is to calculate the proportion of non-compliance, at least its estimator for each batch i:

$$\hat{p}_i=\frac{k_i}{N_i} \tag{16.7.716}$$

where k_i is the number of non-compliant items in the batch of size N_i.

The average proportion of non-conformities, which corresponds to the center line (CL) of the control chart is given by (don't forget that using the median would be better in reality!):

$$\boxed{\bar{\hat{p}}_i=\text{CL}=\frac{\sum\limits_{i=1}^{n}k_i}{\sum\limits_{i=1}^{n}N_i}} \tag{16.7.717}$$

and if the n batches of size N_i are all of equal size N this simplifies obviously to:

$$\bar{\hat{p}}_i=\text{CL}=\frac{\sum\limits_{i=1}^{n}k_i}{nN}=\frac{1}{n}\sum_{i=1}^{n}\frac{k_i}{N}=\frac{1}{n}\sum_{i=1}^{n}\hat{p}_i \tag{16.7.718}$$

Therefore we have:

$$\boxed{\begin{aligned}\text{USL}&=\text{required by customer/board comitee}\\ \text{UCL}_p&=\bar{\hat{p}}+3\sigma_{\bar{\hat{p}}}=\bar{\hat{p}}+3\sqrt{\frac{\bar{\hat{p}}(1-\bar{\hat{p}})}{N_i}}\\ \text{CL}_p&=\bar{\hat{p}}\\ \text{LCL}_p&=\bar{\hat{p}}-3\sigma_{\bar{\hat{p}}}=\bar{\hat{p}}-3\sqrt{\frac{\bar{\hat{p}}(1-\bar{\hat{p}})}{N_i}}\end{aligned}} \tag{16.7.719}$$

and if the batches size are equal we have obviously:

$$\begin{aligned}\text{USL}&=\text{required by customer/board comitee}\\ \text{UCL}_p&=\bar{\hat{p}}+3\sqrt{\frac{\bar{\hat{p}}(1-\bar{\hat{p}})}{N}}\\ \text{CL}_p&=\bar{\hat{p}}\\ \text{LCL}_p&=\bar{\hat{p}}-3\sqrt{\frac{\bar{\hat{p}}(1-\bar{\hat{p}})}{N}}\end{aligned} \tag{16.7.720}$$

According to the study that we made during our study of acceptance plan they can not be any lower limit (LSL) imposed by the customer/board committee or target (T) in this field of application.

So, with the following list where the batches size (special case) are identical (made with Microsoft® Excel® 14.0.7166):

	A	B	C	D	E	F	G	H	I	J
1	Sample Number	Sample size	Non-compliants		Proportion	CL	Sigma	LCL	UCL	USL

where we took as example for limits imposed by the customer/board committee:

$$\text{USL} = 5.00\% \tag{16.7.721}$$

obviously not visible on the chart above as too far away on the y-axes.

This control chart can also be interpreted as any another Shewhart chart using the empirical WECO rules.

16.7.6.3.2 NP Control Charts (binomial counting CC)

The np control chart is obviously similar to the previous p control but it is the number (count) of non-compliant items units than the proportion that is plotted. This chart is easier to interpret as the p control chart since not all employees are able to represent themselves the concept of percentage, but against it is very difficult to compare objectively two points coming from batches that do not have the same size.

Pros:

- This type of control chart is very simple to construct because does not require any advanced statistical knowledge to be calculated. For some employees whose concept of percentage is poorly mastered, it is easier to read a np chart.

Cons:

- In reality it is a control chart which control limits may be asymmetric if the practical application are at the limit of acceptable when the theoretical assumptions of construction of this chart are not met.
- Sometimes a difficulty encountered by practitioners of this chart is to determine the batch size and the level of acceptance (A) or rejection (R) equivalent to the USL by taking the decision based on the developments (and norms) of acceptance plans samples seen earlier above.
- This control chart is not suitable for exhaustive sampling since it would then required the use of the hypergeometric law. Unfortunately, as far as we know, there is no analytic relation for the confidence interval of the proportion of a hypergeometric distribution, and therefore is not feasible to build a control chart based on a hypergeometric law.
- It is very difficult to compare objectively two points coming from batches that do not have the same size

For the values of the control chart, we have still using:

$$\boxed{\bar{\hat{p}}_i = \text{CL} = \frac{\sum_{i=1}^{n} k_i}{\sum_{i=1}^{n} N_i}} \tag{16.7.722}$$

And therefore using the results of the previous control chart it comes immediately in the general case:

$$\boxed{\begin{aligned}\text{USL}&=\text{required by customer/board comitee}\\ \text{UCL}_{np}&=N_i\bar{\hat{p}}+3\sigma_{np}=N_i\bar{\hat{p}}+3\sqrt{\frac{N_i\bar{\hat{p}}N_i(1-\bar{\hat{p}})}{N_i}}=N_i\bar{\hat{p}}+3\sqrt{N_i\bar{\hat{p}}(1-\bar{\hat{p}})}\\ \text{CL}_{np}&=N_i\bar{\hat{p}}\\ \text{LCL}_{np}&=N_i\bar{\hat{p}}-3\sigma_{np}=N_i\bar{\hat{p}}-3\sqrt{\frac{N_i\bar{\hat{p}}N_i(1-\bar{\hat{p}})}{N_i}}=N_i\bar{\hat{p}}-3\sqrt{N_i\bar{\hat{p}}(1-\bar{\hat{p}})}\end{aligned}} \tag{16.7.723}$$

But since it is very difficult (unlike the p control chart) to compare objectively with this control chart two points when the size of the sample is not the same, some specialists required - or recommended - that the batch size is the same such that finally:

$$\begin{aligned}\text{USL}&=\text{required by customer/board comitee}\\ \text{UCL}_{np}&=N\bar{\hat{p}}+3\sqrt{N\bar{\hat{p}}(1-\bar{\hat{p}})}\\ \text{CL}_{np}&=N\bar{\hat{p}}\\ \text{LCL}_{np}&=N\bar{\hat{p}}-3\sqrt{N\bar{\hat{p}}(1-\bar{\hat{p}})}\end{aligned} \tag{16.7.724}$$

According to the study of acceptance plans we know that they can not be any lower limit (LSL) required by the customer / board committee or target (T) in this field of application.

So, with the following list where the batches size (special case) are identical (made with Microsoft® Excel® 14.0.7166):

where we took as example for limits imposed by the customer/board committee:

$$\text{USL} = 5.00\% \cdot N = 5.00\% \cdot 50 = 2.5 \tag{16.7.725}$$

This control chart can also be interpreted as any another Shewhart chart using the empirical WECO rules.

16.7.6.3.3 C Control Charts (Poisson counting CC)

The C control charts are used to look at variation in counting type attributes data. They are used to determine the variation in the number of defects in a constant subgroup size. To use the C chart, the opportunities for defects to occur in the subgroup must be very large, but the number that actually occurs must be small.

Indeed, during our study of statistical laws (or statistical distributions as seen at page 633), we have proved that when the probability p is very small and tends to zero, but that instead the average value $\mu = np$ tends to a fixed value when n approaches infinity, the binomial distribution of mean $\mu = np$ with k trials was therefore given by a Poisson law (see page 686):

$$P(X=k)=\frac{\mu^k}{k!}e^{-\mu} \tag{16.7.726}$$

with:

$$\begin{aligned} \mu &= \mu \\ \sigma &= \sqrt{\mu} \end{aligned} \tag{16.7.727}$$

In practice, some replace the binomial distribution by a Poisson law since $n > 30$ and $np < 5$ or when $n > 50$ and $p < 0.1$... In practice I personally recommend the use of the approximation when $n > 1000$ and $p < 0.01$.

As in practice such situations does not happen very often. Some books and authors say that this control chart is reserved to the count of defects per unit opportunity (see our study of Six Sigma at the beginning of this chapter). Indeed, the fact that each unit can be composed of multiple items this increase "artificially" the n (as 1 unit opportunity can have dozens, hundreds of millions of components) and decrease most of time the probability p such that the assumption of using the Poisson law are respected.

Following the previous rules it comes obviously:

$$\begin{aligned} \text{USL} &= \text{required by customer/board comitee} \\ \text{UCL}_c &= \mu + 3\sqrt{\mu} \\ \text{CL}_c &= \mu \\ \text{LCL}_c &= \mu - 3\sqrt{\mu} \end{aligned} \tag{16.7.728}$$

what is traditionally noted in this field:

$$\boxed{\begin{aligned} \text{USL} &= \text{required by customer/board comitee} \\ \text{UCL}_c &= \bar{c} + 3\sqrt{\bar{c}} \\ \text{CL}_c &= \bar{c} \\ \text{LCL}_c &= \bar{c} - 3\sqrt{\bar{c}} \end{aligned}} \tag{16.7.729}$$

where $\bar{c}$ is simply the average of the count (that's form this word that comes from the "c" in the name of the chart) of nonconformities:

$$\bar{c}=\frac{1}{n}\sum_{i=1}^{n}c_i \tag{16.7.730}$$

According to the study that we made during our study of acceptance plan they can not be any lower limit (LSL) imposed by the customer/board committee or target (T) in this field of application.

Pros:

- This type of control chart is very simple to construct because does not require any advanced statistical knowledge to be calculated.

Cons:

- In reality it's a control chart which control limits may be asymmetric if the practical application are at the limit of acceptable when the theoretical assumptions of construction of this chart are not met.
- Sometimes a difficulty encountered by practitioners of this chart is to determine the batch size and the level of acceptance (A) or rejection (R) equivalent to the USL by taking the decision based on the developments (and norms) of acceptance plans samples seen earlier above.
- This control chart is not suitable for exhaustive sampling since it would then required the use of the binomial or hypergeometric law.

Once again using our spreadsheet software here is an example where the batch sizes are necessarily identical for the reasons mentioned just above (and once again... non-compliant items can not be expressed in $\%$ of the batch size as the Poisson distribution is a discrete law!):

	A	B	C	D	E	F	G	H	I

where we took as example for limits imposed by the customer/board committee:

$$\text{USL} = 2.5 \tag{16.7.731}$$

This control chart can also be interpreted as any another Shewhart chart using the empirical WECO rules.

16.7.6.3.4 U Control Charts (normalized Poisson)

The u control chart is similar to the c control chart except that it has for role to normalize the data to the unit to have a c control chart based on a Poisson distribution but with percentages.

According to the study that we made during our study of acceptance plan they can not be any lower limit (LSL) imposed by the customer/board committee or target (T) in this field of application.

Pros:

- This type of control chart is very simple to construct because does not require any advanced statistical knowledge to be calculated and it is now more easy to compare objectively two points coming from batches that do not have the same size.

Cons:

- In reality its a control chart which control limits may be asymmetric if the practical application are at the limit of acceptable when the theoretical assumptions of construction of this chart are not met.
- Sometimes a difficulty encountered by practitioners of this chart is to determine the batch size and the level of acceptance (A) or rejection (R) equivalent to the USL by taking the decision based on the developments (and norms) of acceptance plans samples seen earlier above.
- This control chart is not suitable for exhaustive sampling since it would then required the use of the binomial or hypergeometric law.
- A final difficulty is that some employees and board committee are not proficient with the concept of percentages.

For this, we use the same working assumptions as those proved during our study of the Poisson distribution:

$$\begin{aligned}\mu &= \mu = Np\\ \sigma &= \sqrt{\mu} = \sqrt{Np}\end{aligned} \tag{16.7.732}$$

This makes that our previous c control chart is then written:

$$\begin{aligned}\text{USL}&=\text{required by customer/board comitee}\\ \text{UCL}_u&=n_i\bar{\hat{p}}+3\sqrt{n_i\bar{\hat{p}}}\\ \text{CL}_u&=n_i\bar{\hat{p}}\\ \text{LCL}_u&=n_i\bar{\hat{p}}-3\sqrt{n_i\bar{\hat{p}}}\end{aligned} \tag{16.7.733}$$

If we divide the random variable $k=n_i\bar{\hat{p}}$ by the batch size (or number of components) we have then by the property of the mean and variance:

$$\begin{aligned}\text{USL}&=\text{required by customer/board comitee}\\ \text{UCL}_u&=\bar{\hat{p}}+3\sqrt{\frac{\bar{\hat{p}}}{n_i}}\\ \text{CL}_u&=\bar{\hat{p}}\\ \text{LCL}_u&=\bar{\hat{p}}-3\sqrt{\frac{\bar{\hat{p}}}{n_i}}\end{aligned} \tag{16.7.734}$$

what is traditionally written:

$$\boxed{\begin{aligned}\text{USL}&=\text{required by customer/board comitee}\\ \text{UCL}_u&=\bar{u}+3\sqrt{\frac{\bar{u}}{n_i}}\\ \text{CL}_u&=\bar{u}\\ \text{LCL}_u&=\bar{u}-3\sqrt{\frac{\bar{u}}{n_i}}\end{aligned}} \tag{16.7.735}$$

with:

$$\boxed{\bar{u}=\text{CL}_u=\frac{\displaystyle\sum_{i=1}^{n}c_i}{\displaystyle\sum_{i=1}^{n}n_i}} \tag{16.7.736}$$

Once again using our spreadsheet software here is an example where the batch sizes are non-necessarily identical this time using the "trick" above (and once again... non-compliant items can now be expressed in % of the batch size!):

where we took as example for limits imposed by the customer/board committee:

$$USL = 0.010 \quad (16.7.737)$$

This control chart can also be interpreted as any another Shewhart chart using the empirical WECO rules.

16.7.6.3.5 Laney's p' and u' control charts

The p and u control charts as we have seen it have a big problem that resides in the fact that the limits use a standard deviation that is proportional to:

$$\sigma_i \propto \sqrt{\frac{1}{N_i}} \tag{16.7.738}$$

which therefore tends to 0 when the N_i are very by (which typically happens in international call centers where its value is often greater than $5,000$ per day) and then the standard deviation becomes so small that we get almost systematically false alarms (therefore the control chart is a little bit much ... too sensitive). Moreover, their standard deviation assumes that the proportion (probability) is constant over time and this is also unrealistic.

It should be noticed that the problem of too much sensitivity almost never appears in the industry since it is often less than a hundred of items!

An alternative proposed by David Laney in 12002 (holocene calendar) is then to consider in a first time the proportions as continuous quantitative values and then of using a control chart taking first the range by paired values of the consecutive proportions:

$$\bar{R}_P = \frac{1}{k-1}\sum_{i=1}^{k} R_i = \frac{1}{k-1}\sum_{i=1}^{k} |p_i - p_{i-1}| \tag{16.7.739}$$

And as (see section Statistics page 1203):

$$\bar{R} = \sigma_p d_2(n) = \sigma_p d_2(2) = \sigma_p \cdot 1.128 \tag{16.7.740}$$

It comes:

$$\sigma_p = \frac{\bar{R}_p}{1.128} \tag{16.7.741}$$

because comparing only the proportion two-by-two, the Hartley constant $d_2(n)$ must be taken with $n = 2$.

We then have the possibility to take:

$$\boxed{\begin{aligned} \text{UCL}_{p(R)} &= \bar{\hat{p}} + 3\sigma_p \cong \bar{\hat{p}} + 2.66\bar{R} \\ \text{CL}_{p(R)} &= \bar{\hat{p}} \\ \text{LCL}_{p(R)} &= \bar{\hat{p}} - 3\sigma_p \cong \bar{\hat{p}} - 2.66\bar{R} \end{aligned}} \tag{16.7.742}$$

Practice shows that this control chart is already much less sensitive, which is a progress but... however it suffers from a big issue!: the upper and lower limits are constant whereas we would like to take into account that the size of the sample varies (or may vary) for each i. Then we have to find another solution!

A track (a little drawn by the hair) then consists first of all in considering that if the N_i are very large and the proportion (probability) is neither too close to 0 nor too close to 1, then each can be approximated By a Normal law and to be centered reduced:

$$Z_i = \frac{\hat{p}_i - \bar{\hat{p}}}{\sigma_{\hat{p}_i}} \cong Z \tag{16.7.743}$$

and therefore:

$$\hat{p}_i = \bar{\hat{p}} + Z\sigma_{\hat{p}_i} \tag{16.7.744}$$

Then if follows that:

$$\text{V}(\hat{p}_i) = \text{V}\left(\bar{\hat{p}} + Z\hat{\sigma}_{\hat{p}_i}\right) = \text{V}\left(\bar{\hat{p}}\right) + \text{V}(Z\hat{\sigma}_{\hat{p}_i}) = \text{V}(Z\hat{\sigma}_{\hat{p}_i}) = hat\sigma^2_{\hat{p}_i}\text{V}(Z) \tag{16.7.745}$$

and therefore the true variance of $\hat{p}_i$ can be thank to:

$$\sigma_{\hat{p}_i} = \hat{\sigma}_{\hat{p}_i}\sigma_Z \tag{16.7.746}$$

Obviously, in the reality the standard deviation of Z will not really be equal to 0. So the idea (questionable ...) is to consider that as now we have a continuous variable we will be able to estimate the true variance of Z thanks to:

$$\bar{R}_Z = \frac{1}{k-1}\sum_{i=1}^{k} R_i = \frac{1}{k-1}\sum_{i=1}^{k} |Z_i - Z_{i-1}| \tag{16.7.747}$$

and:

$$\bar{R}_Z = \sigma_Z d_2(n) = \sigma_Z d_2(2) = \sigma_Z \cdot 1.128 \tag{16.7.748}$$

Therefore:

$$\sigma_Z = \frac{\bar{R}_Z}{1.128} \tag{16.7.749}$$

We then have:

$$\boxed{\begin{aligned}
\text{UCL}_{Z(p)} &= \bar{\hat{p}} + 3\hat{\sigma}_{\hat{p}_i}\sigma_Z = \bar{\hat{p}} + 3\sqrt{\frac{\bar{\hat{p}}_i(1-\bar{\hat{p}}_i)}{N_i}}\frac{\bar{R}_Z}{1.128} \cong \bar{\hat{p}} + 2.66\sqrt{\frac{\bar{\hat{p}}_i(1-\bar{\hat{p}}_i)}{N_i}}\bar{R}_Z \\
\text{CL}_{Z(p)} &= \bar{\hat{p}} \\
\text{LCL}_{Z(p)} &= \bar{\hat{p}} - 3\hat{\sigma}_{\hat{p}_i}\sigma_Z = \bar{\hat{p}} - 3\sqrt{\frac{\bar{\hat{p}}_i(1-\bar{\hat{p}}_i)}{N_i}}\frac{\bar{R}_Z}{1.128} \cong \bar{\hat{p}} - 2.66\sqrt{\frac{\bar{\hat{p}}_i(1-\bar{\hat{p}}_i)}{N_i}}\bar{R}_Z
\end{aligned}} \tag{16.7.750}$$

where if $\text{LCL}_{Z(p)}$ is smaller than zero then we will assume that this limit is zero (as for the previous control charts).

We thus have a control chart which is an attribute-range mixture which according to the return on experience (REX) is less sensitive (less systematic false alerts) and which has variable limits depending on the size of the subgroups.

The same reasoning is applicable with the U control chart (as the Poisson's law can also be approximated by a Normal law, as we have proved it in the section of Statistics at page 937):

$$\boxed{\begin{aligned}\text{UCL}_{Z(u)}&=\bar{u}+3\hat{\sigma}_u\sigma_Z=\bar{u}+2.66\sqrt{\frac{\bar{u}}{N_i}}\bar{R}_Z\\ \text{CL}_{Z(u)}&=\bar{u}\\ \text{LCL}_{Z(u)}&=\bar{u}-3\hat{\sigma}_u\sigma_Z=\bar{u}-2.66\sqrt{\frac{\bar{u}}{N_i}}\bar{R}_Z\end{aligned}} \tag{16.7.751}$$

We notice that if by chance we have for the both set of relations above:

$$\sigma_Z=\frac{\bar{R}_Z}{1.128}=1 \tag{16.7.752}$$

Then we fall back on the standard parameters of a control chart of type p or respectively of type u.

There are however corrections/variants to these two models ... so it is necessary to know well what your software does! It is for this reason that we will not take screenshots of the procedure with Microsoft® Excel® this time and compare it with Minitab (excepted if requested by our readers).

16.7.6.4 Measurement Control Charts (quantitative CC)

Quantitative variables are continuous measurements of the type: weights, lengths, thicknesses, temperature, diameter ...

Unlike autocorrelated control charts and quality (attributes) control charts , quantitative control charts (with measurement) are often - if not always - presented in pairs (or should be!):

- A control chart showing the analysis / evolution of the central statistical trend (often the mean, because it is relatively easy to construct confidence intervals on it).
- A control chart showing the analysis / evolution of the dispersion via the range or the standard deviation.

The controls limits are often taken (for lack of thinking time in business) as the Shewhart or WECO limits and not probabilistic limits.

We also make the distinction between:

- "Individual control charts" (each point on the control chart involve one and only one measurement)
- "Subgroups control charts" (each point on the control chart involve implicitly more than one item)

16.7.6.4.1 Individual measurement control chart with required limits

This is the easiest control chart and most used one by non specialist because it does not require any special knowledge and statistical hypothesis. It consists only to report the measurements and to take corrective actions when it seems necessary by the rule of thumb.

Pros:

- Simple to build because does not require any special knowledge or statistical hypothesis and as all previous control charts, permits the user to check in a timely manner whether a production meets or not the constraints specified by customers.

Cons:

- It may represent temporary random deviations that may make the reader think mistakenly that there is problem in the method / process and will lead to unnecessary corrective actions (false alarms).
- It does not allow to identify if the process / method is under statistical control or not that is to say that as for attribute control charts, it is not possible to make a Capability Six Pack analysis (see page 8708).

For example, let us consider the following list of data still in the same spreadsheet software:

	A	B	C	D	E	F	G	H	I	J	K	L	M
1		→							N°	Measuremen	T	USL	LSL
2	↓	9.9943	10.0196	9.9732	10.0088	9.9685	9.9544		1	9.9943	10.0000	10.1000	9.9000

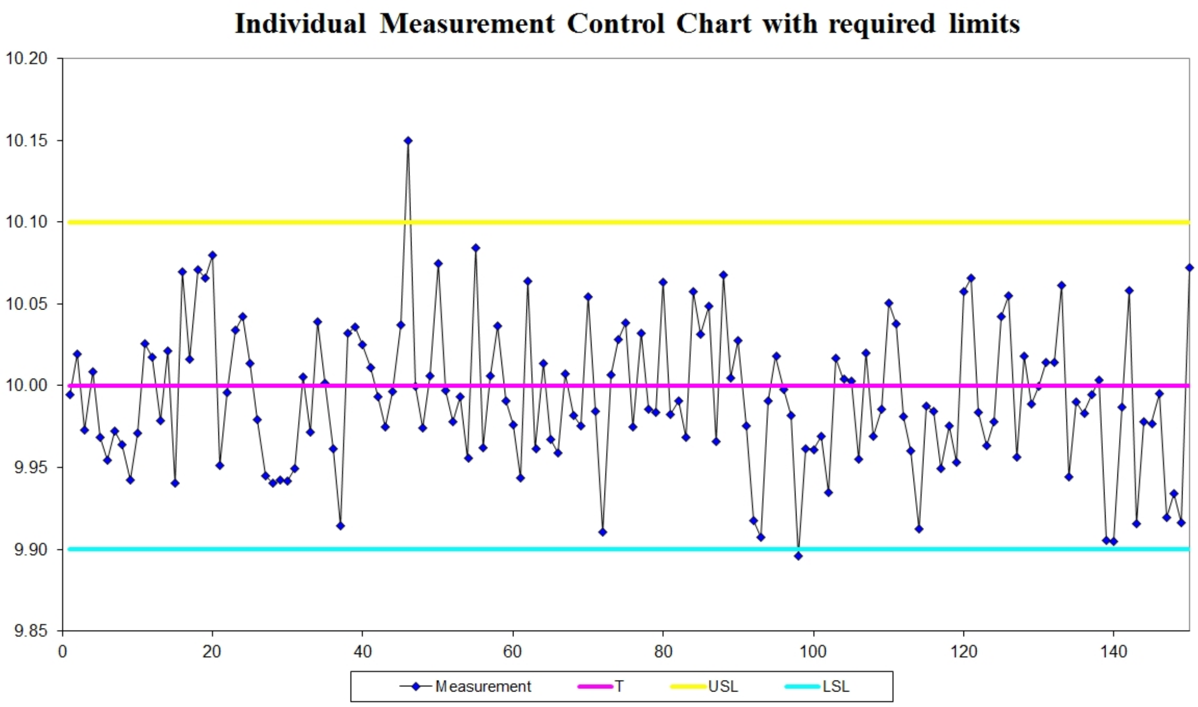
41									40	10.0253	10.0000	10.1000	9.9000
42									41	10.0109	10.0000	10.1000	9.9000
43									42	9.9935	10.0000	10.1000	9.9000
44									43	9.9748	10.0000	10.1000	9.9000
45									44	9.9962	10.0000	10.1000	9.9000
46									45	10.0369	10.0000	10.1000	9.9000
									46	10.1500	10.0000	10.1000	9.9000

where we took empirically (rule of thumb) the limits:

$$\begin{aligned}\text{USL} &= 10+0.1=10.10\\ T &= 10\\ \text{LSL} &= 10-0.1=9.90\end{aligned} \tag{16.7.753}$$

Which gives the following control chart:



While this control chart is the most used in practice (since most people don't have training in S.P.C.), the problem remains that it does not really tell us whether the method or process appears to be stable in time and if the statistical control are in the customer limitations (it shows us only the punctual statistics which is as we know not very robust...!). We will partially remedy with this with the next control chart.

This type of control chart is available in most statistical software but as there is nothing complicated we will not provide here any Minitab (or other...) screenshot.

16.7.6.4.2 Individual measurement control chart with moving limits

When we begin the first observations (measurements), the method or process is rarely stable and there is no way to have fun do manufacture a huge quantity of trial pieces to do a control chart of the average in such conditions and especially if a piece is quite expensive and time consuming!

Pros:

- Highlights the evolution over time of the statistical indicators of positions (average or median) and dispersion and permits to observe the process/methods stabilization during the prototyping phase (often named "Phase I" in the literature).

Cons:

- It may represent temporary random deviations that may make the reader think mistakenly that there is problem in the method / process and will lead to unnecessary corrective actions (false alarms).

- It does not allow to identify statistically if the process / method is under statistical control or not that is to say that as for attribute control charts, it is not possible to make a Capability SixPack analysis.

We stay with a measured control chart to which we add the arithmetic average and the unbiased standard deviation recalculated at each new item. That is, as we don't have enough samples to know the probability distribution and because it is out of question to waste pieces in this purpose and to train people for weeks to statistics, we add to the previous Shewhart control chart the following limits:

$$\boxed{\begin{aligned}\text{USL}&=\text{required by customer/board comitee}\\ \text{UCL}_{\text{ST}}&=\bar{X}_k+3\sigma_{X,k}\\ \text{CL}_{\text{ST}}&=\text{E}(X)=\bar{X}_k\\ T_{\text{ST}}&=\text{target required by customer/board comitee}\\ \text{LCL}_{\text{ST}}&=\bar{X}_k-3\sigma_{X,k}\\ \text{LSL}&=\text{required by customer/board comitee}\end{aligned}} \tag{16.7.754}$$

where CL means "centerline".

Obviously for the estimator of the mean and the standard deviation, we take:

$$\begin{aligned}\text{E}(X)=\bar{X}_k&=\frac{1}{k}\sum_{i=1}^{k}X_i\\ \sigma_{X,k}&=\sqrt{\frac{1}{k-1}\sum_{i=1}^{k}(X_i-\bar{X})^2}\end{aligned} \tag{16.7.755}$$

Once again using our spreadsheet software here is an example where $N=150$ and therefore where k moves from 1 to 150 with the 63 first rows visible:

	A	B	C	D	E	F	G	H	I	J	K	L	M	N	O	P
1		→							N°	**Measurement**	**T**	**CL**	**UCL**	**LCL**	**USL**	**LSL**
2	↓	9.994	10.020	9.973	10.009	9.969	9.954		1	9.9943	10.0000	9.9943	9.9943	9.9943	10.1000	9.9000

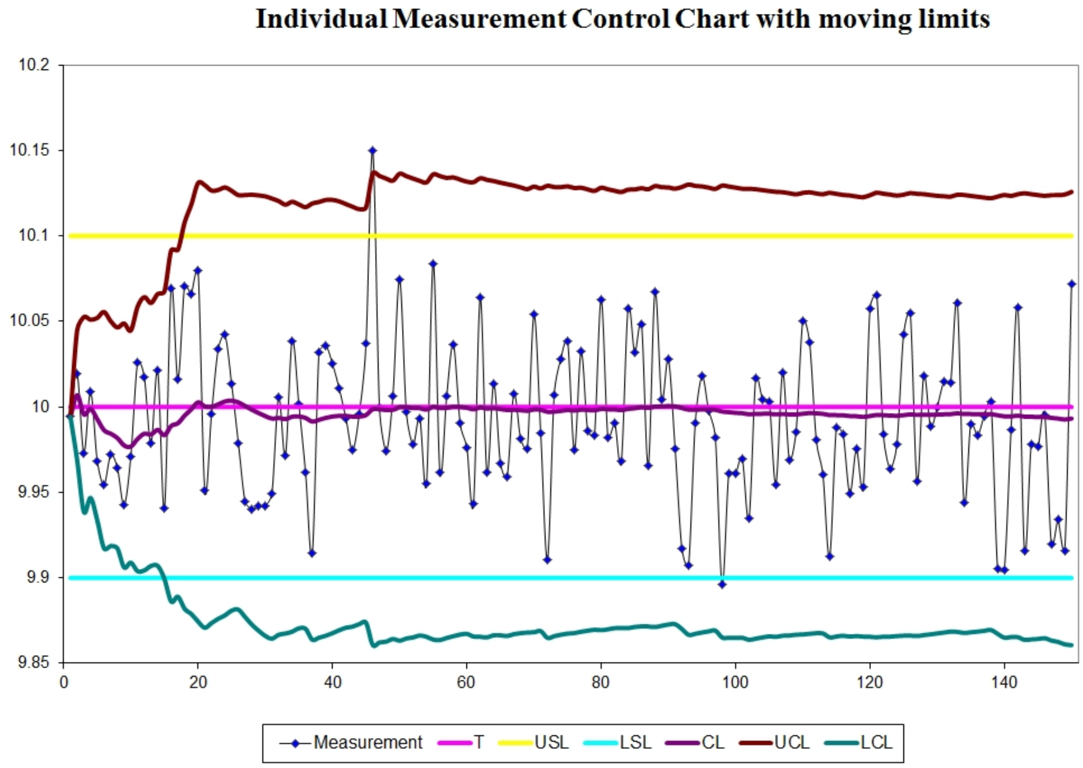
and the corresponding chart still with the same spreadsheet software:



where we took as example for limits imposed by the customer/board committee:

$$\begin{aligned}\text{USL}&=10.10\\T&=10\\\text{LSL}&=9.90\end{aligned}\tag{16.7.756}$$

We see for example the in the above control chart that the CL indicator (so the estimator of the mean) stabilizes close to the target T from the beginning to the end. It's the same for UCL and LCL (because the estimator of the standard deviation stabilizes) by cons following the usage in engineering the results are not good, since the UCL and LCL are beyond the required specifications by the customer! Note that this control chart would according to the WECO rules have only one single point beyond the $\pm 3\sigma$ (we indicate that for comparison reasons with the next control charts).

Remark

On all control charts with no exceptions, the customer specifications (limits) must be indicated in addition to the calculated limits!

This type of control chart is as far as we know not available in statistical softwares. But there is an easy one with the following very common and obvious fixed limits:

$$\begin{aligned}\text{USL}&=\text{required by customer/board comitee}\\ \text{UCL}_{\text{ST}}&=\bar{X}_k+3\sqrt{\frac{1}{N-1}\sum_{i=1}^{N}(X_i-\bar{X})^2}\\ \text{CL}_{\text{ST}}&=\text{E}(X)=\bar{X}\\ T_{\text{ST}}&=\text{target required by customer/board comitee}\\ \text{LCL}_{\text{ST}}&=\bar{X}_k-3\sqrt{\frac{1}{N-1}\sum_{i=1}^{N}(X_i-\bar{X})^2}\\ \text{LSL}&=\text{required by customer/board comitee}\end{aligned} \quad (16.7.757)$$

named a "Levey-Jennings control chart".

With Minitab 15.1.1.0 this gives for people that don't trust simple Microsoft® Excel® calculations (we can also do such a chart with R but the plot quality output is not acceptable in most corporations):

Indice

At this level, we supposed that we are unable to determine the probability distribution of the data (sample problem or statistical skills problems) and therefore unable to calculate the confidence intervals for the mean or the standard deviation!

The next control charts is supposed to remedy to this situation under some assumption!

16.7.6.4.3 Subgroups measurement control chart with standard error

Once the process or method stabilized, we consider that the mean and standard deviation are stabilized and even if the probability distribution that follows a group of k samples is not the same from one day to another, by the central limit theorem, the set of averages follows a Normal distribution as we know of the type:

$$\mathcal{N}=(\overline{X},\sigma_{\overline{X}})=\left(\overline{X},\frac{\sigma_X}{\sqrt{n}}\right) \tag{16.7.758}$$

and written in S.P.C. as (for the reason we will see further below):

$$\mathcal{N}=\left(\overline{\overline{X}},\frac{\sigma_X}{\sqrt{n}}\right) \tag{16.7.759}$$

Therefore it may be more interesting to represent the change in the average over time and not just the single measurement. This also gives us the opportunity to do a capability analysis of our process or method.

Pros:

- Hides (smooth) non-systematic and random variations and often allows to avoid unnecessary corrective actions (false alarms).
- Gives the possibility to associate the control chart with a capability analysis.

Cons:

- This control chart assumes that the samples are identically distributed by the mathematical assumptions it is build on. Moreover, in the framework of fixed Shewhart limits, the distribution law is assumed symmetrical.
- The major issue of this control chart is that the number of individuals per sample must be large enough for the unbiased estimator of the standard deviation is not too far from reality. This is why we do not found this control chart in statistical software (this is why this control chart is replaced with another chart that we will see a little further below).

As companion example let us consider the following example of 25 samples (that we will identify by the variable k) of 6 individuals each (that we will identify by the variable $n_i=n$) taken from a continuous manufacturing process (without machine recalibration or without machine change!):

	A	B	C	D	E	F	G
4		Sample 1	Sample 2	Sample 3	Sample 4	Sample 5	Sample 6
5	Day 1	9.9943	10.0196	9.9732	10.0088	9.9685	9.9544
6	Day 2	9.9721	9.9643	9.9426	9.9712	10.0259	10.0177
7	Day 3	9.9788	10.0213	9.9407	10.0696	10.0161	10.0709
8	Day 4	10.0658	10.08	9.9514	9.9958	10.0338	10.0422
9	Day 5	10.0136	9.9791	9.9449	9.9403	9.9424	9.9421
10	Day 6	9.9495	10.0057	9.9715	10.0388	10.0019	9.9616
11	Day 7	9.9144	10.0321	10.0361	10.0253	10.0109	9.9935
12	Day 8	9.9748	9.9962	10.0369	10.15	9.9996	9.9741
13	Day 9	10.0063	10.0749	9.9971	9.978	9.9934	9.9555
14	Day 10	10.084	9.9619	10.0063	10.0364	9.9907	9.9762
15	Day 11	9.9436	10.0638	9.9617	10.0138	9.9672	9.9591
16	Day 12	10.0074	9.9817	9.9753	10.0541	9.9845	9.9107
17	Day 13	10.0069	10.0282	10.0385	9.9747	10.0323	9.986
18	Day 14	9.9836	10.063	9.9824	9.9909	9.9684	10.0575
19	Day 15	10.0317	10.0485	9.9659	10.0675	10.0047	10.0277
20	Day 16	9.9756	9.9174	9.9076	9.9909	10.018	9.9979
21	Day 17	9.9818	9.8962	9.9614	9.9612	9.9694	9.9349
22	Day 18	10.0168	10.0043	10.0029	9.9549	10.0199	9.9691
23	Day 19	9.9857	10.0503	10.0381	9.9811	9.9603	9.9123
24	Day 20	9.9878	9.9841	9.9496	9.9754	9.9532	10.0576
25	Day 21	10.0657	9.9838	9.9636	9.9779	10.0423	10.0547
26	Day 22	9.9564	10.0184	9.989	9.9999	10.0146	10.0145
27	Day 23	10.0611	9.9443	9.9899	9.9833	9.9947	10.0033
28	Day 24	9.9054	9.9049	9.987	10.058	9.9156	9.9782
29	Day 25	9.9768	9.9954	9.9196	9.9341	9.9162	10.0721

where every day we took a sample of 6 individuals of all manufactured items produced the same day. On the control chart, then we will represent each point as the average of these 6 individuals.

We have proved in the section Statistics (see page 611) that the standard deviation of the mean (standard error) of a series of n independent and identically distributed random variables were if the samples are big enough:

$$\sigma_{\overline{X}}=\frac{\sigma_X}{\sqrt{n}} \tag{16.7.760}$$

and using the finite population correction factor if the sampled population is not infinite (remember that N is the population size):

$$\sigma_{\overline{X}}=\frac{\sigma_X}{\sqrt{n}}\sqrt{\frac{N-n}{N-1}} \tag{16.7.761}$$

We then have the following Shewhart control limit indicators (obviously as we use the average estimators and standard deviation, the greater the number of samples and individuals, the greater the limits are asymptotically accurate but also... known problem... if the samples n_i are too big we will have systematic alarms as we know!):

$$\boxed{\begin{aligned}\text{USL}&=\text{required by customer/board comitee}\\ \text{UCL}_{\text{SE}}&=\overline{\overline{X}}+3\sigma_{\overline{X}}=\overline{\overline{X}}+3\frac{\sigma_X}{\sqrt{n_i}}\\ \text{CL}_{\text{SE}}&=\text{E}(\overline{X})=\overline{\overline{X}}\\ T_{\text{SE}}&=\text{target required by customer/board comitee}\\ \text{LCL}_{\text{SE}}&=\overline{\overline{X}}-3\sigma_{\overline{X}}=\overline{\overline{X}}-3\frac{\sigma_X}{\sqrt{n_i}}\\ \text{LSL}&=\text{required by customer/board comitee}\end{aligned}} \tag{16.7.762}$$

With:

$$\overline{\overline{X}}=\frac{1}{k}\sum_{i=1}^{k}\left(\frac{1}{n_i}\sum_{j=1}^{n_i}X_{i,j}\right) \tag{16.7.763}$$

and if all the n_i are equals:

$$\overline{\overline{X}}=\frac{1}{k}\sum_{i=1}^{k}\left(\frac{1}{n}\sum_{j=1}^{n}X_{i,j}\right)=\frac{1}{nk}\sum_{i=1}^{k}\left(\sum_{j=1}^{n}X_{i,j}\right)=\frac{1}{N}\sum_{i,j}X_{i,j}=\overline{X} \tag{16.7.764}$$

Let us notice that it is the first control chart where we can calculate the probabilistic limits of non-compliance by excess or defect of subgroups by using the fact that $\overline{X}$ follows a Normal distribution of parameters $\mathcal{N}\left(\overline{X},\sigma_X/\sqrt{n}\right)$.

Once again using our spreadsheet software here are the calculations we get in the simple case where all sample still have the same size (calculations based on the previous list of data given just earlier above):

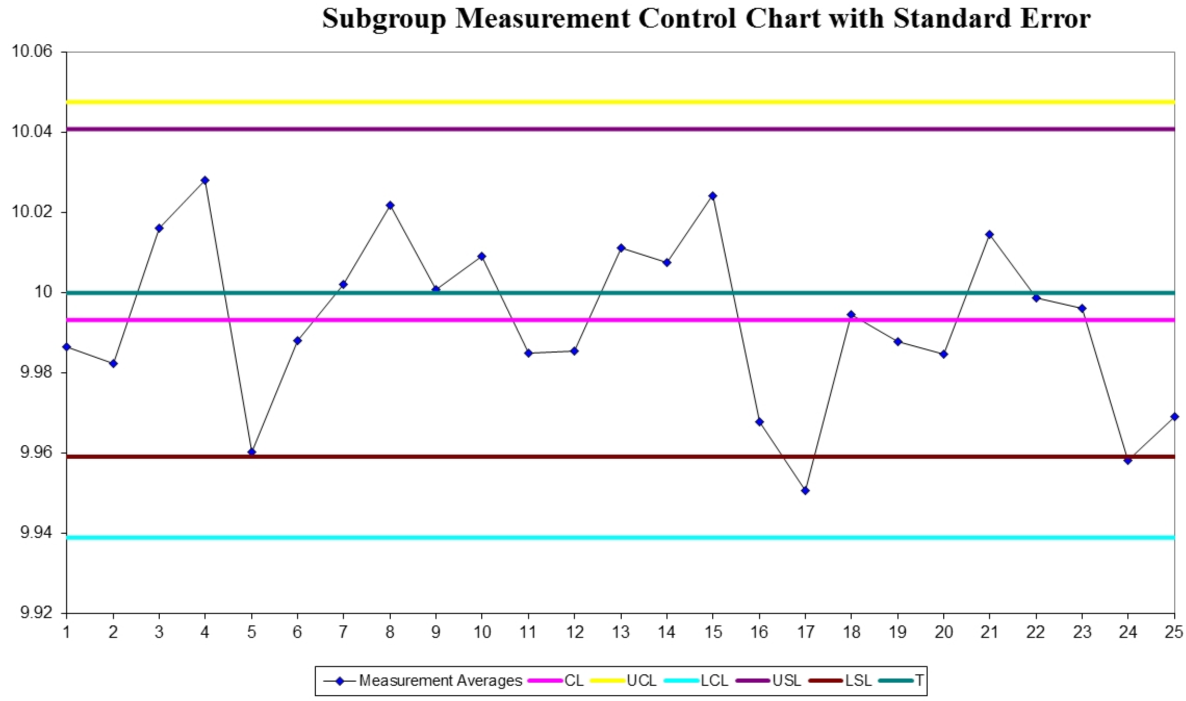
and the corresponding chart still with the same spreadsheet software:



where we took as example for limits imposed by the customer/board committee:

$$\begin{aligned} \text{USL} &= 10+3\frac{0.0\bar{3}}{\sqrt{n}} \cong 10.040 \\ T_{\text{SE}} &= 10 \\ \text{LSL} &= 10-3\frac{0.0\bar{3}}{\sqrt{n}} \cong 9.959 \end{aligned} \tag{16.7.765}$$

Let us notice that this control chart would according to the WECO rules have 6 points beyond the $\pm 3\sigma$ (we indicate that for reasons of comparison with the previous control chart and the next one). It is therefore more sensitive to changes than the control chart. Also notice that the UCL and LCL limits are wider than the imposed USL and LSL.

With the $\pm 3\sigma_X$ limits and according to the hypothesis of Normally distributed data, we have using the symmetry of the Normal distribution and writing as usual Φ the cumulative probability function of the Normal centered reduced distribution (where we suppose $\text{LCL}_{\text{SE}} = \text{UCL}_{\text{SE}} = \sigma_{\overline{X}} = 1$):

$$\begin{aligned}&1-P\left(\text{LCL}_{\text{SE}} \leq \overline{\overline{X}} \leq \text{UCL}_{\text{SE}}\right) = 2P\left(\text{LCL}_{\text{SE}} \leq \overline{\overline{X}}\right) = 2\left(1-P\left(\overline{\overline{X}} \leq \text{UCL}_{\text{SE}}\right)\right)\\&= 2\Phi(-3) = 2(1-\phi(3)) = 2\cdot 0.01350 = 0.0027 \cong \frac{1}{370}\end{aligned} \tag{16.7.766}$$

So we will have statistically 1 point (piece/action) on the control chart on 370 outside the $\pm\sigma_{\overline{X}}$ by unit time/sample measured (so if each point on the map is made by frequency of 1 hour then we have an ARL of 0.0027 [h^{-1}]) only for statistical purposes and that must be therefore considered as false alarms (Type I Error[36]!!!) that the data are centered and reduced or not!!!!

We name the latter number "Average Run Length (ARL)" (some use the French appellation "Average Operational Period (AOP)"). When it is reported to a specific unit of time, then we speak of "Average Time to Signal (ATS)" and write it:

$$\alpha = 1-P\left(\text{LCL}_{\text{SE}} \leq \overline{\overline{X}} \leq \text{UCL}_{\text{SE}}\right) = \frac{1}{\text{ARL}_0} \tag{16.7.767}$$

or more commonly:

$$\boxed{\text{ARL}_0 = \frac{1}{\alpha}} \tag{16.7.768}$$

Obviously, by extension, the addition of the WECO empirical rules add false alarms and it has for immediate effect of reducing the ARL.

As we have already mentioned it at our beginning of the study of control charts, the ARL is important in practice, because it gives the interval sampling size beyond which we must not go! We will ensure in practice (when possible) to take a lower value close to the ARL for large productions but possibly not beyond!

Remark

As we have already mentioned, sometimes several levels of controls are added to the control charts, so we can observe the $\pm 3\sigma_{\overline{X}}$ and simultaneously $\pm 2\sigma_{\overline{X}}$. In the U.S.A factor 2 or 3 seems to be mainly used that the distribution is symmetrical or not ... as in European countries like France and Germany (industrial countries), we use probabilistic limits that have a much better reliability when data are not distributed following a symmetric (as it is the case for well known control charts using the range R that we will see later).

Remember that the problem of this control chart is that σ_X is asymptotically correct only if n_i is big. While in reality it is by far not the case since often this value is less than 10. Therefore we will see below a control chart of the average where the fixed limits are calculated based on the range R and not on σ_x. However, in the section of Statistics (see page 865), we have shown that when the standard deviation is estimated, then we have:

---

[36] Obviously there are also type II errors (no alarm when there should have). But as I've never seen anyone use it in practice for control charts.

$$\overline{X}-\frac{S_X}{\sqrt{n}}T_{\alpha/2}(n-1)\leq\mu\leq\overline{X}+\frac{S_X}{\sqrt{n}}T_{\alpha/2}(n-1) \tag{16.7.769}$$

So we can use the Shewhart control chart with the following probabilistic limits that is more accurate than the previous one:

$$\boxed{\begin{aligned}\text{USL}&=\text{required by customer/board comitee}\\ \text{UCL}_\chi&=\overline{\overline{X}}+T_{\alpha/2}(n_i-1)\frac{S_X}{\sqrt{n_i}}\\ \text{CL}_\chi&=\text{E}(\overline{X})=\overline{\overline{X}}\\ T_{\text{SE}}&=\text{target required by customer/board comitee}\\ \text{LCL}_\chi&=\overline{\overline{X}}-T_{\alpha/2}(n_i-1)\frac{S_X}{\sqrt{n_i}}\\ \text{LSL}&=\text{required by customer/board comitee}\end{aligned}} \tag{16.7.770}$$

Also as part of a process or method under statistical control, it can be interesting to communicate the average control chart (with fixed or probabilistic limits) previously presented with a control chart showing also the evolution of the standard deviation considering a Normal distribution of the random variables. Indeed, remember that the Normal distribution is completely defined by its parameters μ,σ. Hence the reason to have a look on both of them and this is why many S.P.C. softwares plots automatically two control charts at the same time!

16.7.6.4.4 $\overline{S}-S$ Subgroups measurement control chart for standard deviation

Also as part of a process or method under statistical control, it can be interesting to communicate the average control chart (with fixed or probabilistic limits) previously presented with a control chart showing also the evolution of the standard deviation considering a Normal distribution of the random variables. Indeed, remember that the Normal distribution is completely defined by its parameters μ,σ. Hence the reason to have a look on both of them and this is why many S.P.C. softwares plots automatically two control charts at the same time!

Pros:

- Complete well the previous control chart and permits to visualizes if the volatility (standard deviation) of the process stabilizes.
- Represents well the variation within the data of each sampling (instantaneous dispersion).

Cons:

- This control chart must be used only when the prototyping phase is completed (often named "Phase II" in the literature) because it is based on an inescapable strong assumption that the data are Normally distributed.

- The limits of Shewhart controls chart are not adapted in this case because, as we will prove it in details, the variance distribution law is not a symmetrical law while Shewhart limits assume this is the case!

The idea is to represent:

$$\begin{aligned}\text{UCL}_S&=\overline{S}+3\sigma_S\\ \text{CL}_S&=\text{E}(S)=\overline{S}\\ \text{LCL}_S&=\overline{S}-3\sigma_S\end{aligned}\qquad(16.7.771)$$

always with the estimator of mean (k being the number of samples for recall...):

$$\overline{S}=\frac{1}{k}\sum_{i=1}^{k}S_i\qquad(16.7.772)$$

and always with the unbiased maximum likelihood estimator of the standard deviation denoted S_i in the field of quality (at the opposite $\hat{\sigma}$ in the field of pure statistics):

$$S_i=\sqrt{\frac{1}{n_i-1}\sum_{j=1}^{n}(X_j-\overline{X})}\qquad(16.7.773)$$

where n corresponds obviously to the number of individuals for the sample i.

Remark

The mean sample standard deviation $\bar{S}$ above must not be confused with the pooled sample standard deviation used for the $\bar{X}-\tilde{S}$ control charts where:

$$\tilde{S}=\left(\frac{1}{k}\sum_{i=1}^{k}S_i^2\right)^{1/2}$$

where S_i is the i th sample standard deviation defined by:

$$S_i=\left(\frac{1}{n_i-1}\sum_{j=1}^{n}\left(X_{i,j}-\bar{X}_i\right)^2\right)^{1/2}$$

To calculate the mean and the variance of σ_S, we must consider S also as a Normally distributed random variable (it is the strong and essential assumption in this control chart that we had mentioned in the "cons" just before!). We then have proved in the section Statistics (see page 857) that we had:

$$\chi^2(n-1)=\frac{(n-1)S^2}{\sigma^2}\qquad(16.7.774)$$

which we will denote t thereafter as the corresponding random variable.

For the remaining development, we will consider $(n-1)$ and σ as simple constant coefficients of S. So the random variable t is actually implicit function of S as:

$$t=f(S)=\frac{n-1}{\sigma^2}S^2 \tag{16.7.775}$$

We will focus now to the calculation of mean of S. It is then more convenient to take the square root of t such that:

$$\sqrt{t}=\frac{\sqrt{n-1}}{\sigma}S \tag{16.7.776}$$

Therefore it comes:

$$\mathrm{E}(S)=\mu_E=\mathrm{E}\left(\frac{\sigma}{\sqrt{n-1}}\sqrt{t}\right)=\frac{\sigma}{\sqrt{n-1}}\mathrm{E}\left(\sqrt{t}\right)=\int\limits_0^{+\infty}\sqrt{t}f(t)\mathrm{d}t \tag{16.7.777}$$

Let us recall that we proved in the section Statistics (see page 773) that the chi-square law was defined by the following probability density function:

$$P_k(x)=\frac{1}{2^{k/2}\Gamma(k/2)}x^{k/2-1}e^{-x/2}1_{[0,+\infty]} \tag{16.7.778}$$

Therefore it comes:

$$\mathrm{E}(S)=\frac{\sigma}{\sqrt{n-1}}\int\limits_0^{+\infty}\sqrt{t}\frac{t^{\frac{n-1}{2}-1}e^{-t/2}}{2^{\frac{n-1}{2}}\Gamma\left(\dfrac{n-1}{2}\right)}\mathrm{d}t \tag{16.7.779}$$

Let us put for what follows:

$$n-1=k \tag{16.7.780}$$

Then we have:

$$\begin{aligned}\mathrm{E}(S)&=\frac{\sigma}{\sqrt{k}}\int\limits_0^{+\infty}\sqrt{t}\frac{t^{\frac{k}{2}-1}e^{-t/2}}{2^{\frac{k}{2}}\Gamma\left(\dfrac{k}{2}\right)}\mathrm{d}t=\frac{\sigma}{2^{k/2}\Gamma\left(\dfrac{k}{2}\right)\sqrt{k}}\int\limits_0^{+\infty}\sqrt{t}t^{\frac{k}{2}-1}e^{-t/2}\mathrm{d}t\\&=\frac{\sigma}{2^{k/2}\Gamma\left(\dfrac{k}{2}\right)\sqrt{k}}\int\limits_0^{+\infty}t^{\frac{k}{2}-1+\frac{1}{2}}e^{-t/2}\mathrm{d}t=\frac{\sigma}{2^{k/2}\Gamma\left(\dfrac{k}{2}\right)\sqrt{k}}\int\limits_0^{+\infty}t^{\frac{k-1}{2}}e^{-t/2}\mathrm{d}t\\&=\frac{\sigma}{2^{k/2}\Gamma\left(\dfrac{k}{2}\right)\sqrt{k}}\frac{\sqrt{2}\Gamma\left(\dfrac{k+1}{2}\right)}{\sqrt{\left(\dfrac{1}{2}\right)^k}}=\sigma\frac{\sqrt{2}}{2^{k/2}\sqrt{\left(\dfrac{1}{2}\right)^k}\sqrt{k}}\frac{\Gamma\left(\dfrac{k+1}{2}\right)}{\Gamma\left(\dfrac{k}{2}\right)}\\&=\sigma\frac{\sqrt{2}}{\sqrt{k}}\frac{\Gamma\left(\dfrac{k+1}{2}\right)}{\Gamma\left(\dfrac{k}{2}\right)}=\sigma\frac{\sqrt{2}}{\sqrt{n-1}}\frac{\Gamma\left(\dfrac{n}{2}\right)}{\Gamma\left(\dfrac{n-1}{2}\right)}=\sigma\sqrt{\frac{2}{n-1}}\frac{\Gamma\left(\dfrac{n}{2}\right)}{\Gamma\left(\dfrac{n-1}{2}\right)}:=\sigma c_4\end{aligned} \tag{16.7.781}$$

Therefore:

$$\mathrm{E}(S)=\overline{S}=\sigma c_4=\sigma\sqrt{\frac{2}{n-1}}\frac{\Gamma\left(\dfrac{n}{2}\right)}{\Gamma\left(\dfrac{n-1}{2}\right)} \tag{16.7.782}$$

Finally for finish on this point, be aware that it is traditional to denote the "standard deviation unbiasing constants c_4" or "Burr constants" as follows:

$$\boxed{c_4=\sqrt{\frac{2}{n-1}}\frac{\Gamma\left(\dfrac{n}{2}\right)}{\Gamma\left(\dfrac{n-1}{2}\right)}} \tag{16.7.783}$$

and for which we find the values in the tables of various books or softwares. But almost everybody has a spreadsheet software nowadays, these tables are useless as we can obtain their values for examples with spreadsheet software like Microsoft® Excel® 14.0.6123 by writing the following formula:

=SQRT(2/(n_i-1))*EXP(GAMMALN(n_i/2))/EXP(GAMMALN((n_i-1)/2))

or also with:

=SQRT(2/(n_i-1))*GAMMA(n_i/2)/GAMMA((n_i-1)/2)

or in OpenOffice Calc (the formula is there little bit simpler):

=SQRT(2/(n_i-1))*GAMMA(n_i/2)/GAMMA((n_i-1)/2)

Let us now calculate the variance of S using the Huygens relation proved in the section Statistics (see page 593) that is for recall:

$$\mathrm{V}(S)=\mathrm{E}(S^2)-\mathrm{E}(S)^2 \tag{16.7.784}$$

So we can write:

$$\mathrm{V}(S)=\mathrm{E}(S^2)-(c_4\sigma)^2=\mathrm{E}(S^2)-c_4^2\sigma^2 \tag{16.7.785}$$

$$\begin{aligned}\mathrm{E}(S^2)&=\frac{\sigma^2}{k}\int_0^{+\infty}t\frac{t^{\frac{k}{2}-1}e^{-t/2}}{2^{\frac{k}{2}}\Gamma\left(\dfrac{k}{2}\right)}\mathrm{d}t=\frac{\sigma^2}{2^{\frac{k}{2}}\Gamma\left(\dfrac{k}{2}\right)k}\int_0^{+\infty}tt^{\frac{k}{2}-1}e^{-t/2}\mathrm{d}t\\&=\frac{\sigma^2}{2^{\frac{k}{2}}\Gamma\left(\dfrac{k}{2}\right)k}\int_0^{+\infty}t^{\frac{k}{2}}e^{-t/2}\mathrm{d}t=\frac{\sigma^2}{2^{\frac{k}{2}}\Gamma\left(\dfrac{k}{2}\right)k}\frac{\Gamma\left(\dfrac{k}{2}\right)k}{\sqrt{\left(\dfrac{1}{2}\right)^k}}=\sigma^2\end{aligned} \tag{16.7.786}$$

Therefore:

$$\mathrm{V}(S)=\mathrm{E}(S^2)-\mathrm{E}(S)^2=\sigma^2-c_4^2\sigma^2=\sigma^2\left(1-c_4^2\right) \tag{16.7.787}$$

hence:

$$\sigma_S=\sigma\sqrt{1-c_4^2} \tag{16.7.788}$$

This bring us to write now:

$$\begin{aligned}
\text{USL}&=\text{required by customer/board comitee}\\
\text{UCL}_S&=\overline{S}+3\sigma_S=\overline{S}+3\sigma\sqrt{1-c_4^2(n_i)}\\
\text{CL}_S&=\mathrm{E}(S)=\overline{S}=\sigma c_4(n_i)\\
T_{\text{SE}}&=\text{target required by customer/board comitee}\\
\text{LCL}_S&=\overline{S}-3\sigma_S=\overline{S}-3\sigma\sqrt{1-c_4^2(n_i)}\\
\text{LSL}&=\text{required by customer/board comitee}
\end{aligned} \tag{16.7.789}$$

that is to say finally as sometimes written in the literature:

$$\boxed{\begin{aligned}
